Often, but not always, raw fitness is calculated over a set of *fitness cases*. A fitness case corresponds to a representative situation in which the ability of a program to solve a problem can be evaluated. For example, consider the problem of generating an arithmetic expression that approximates the polynomial $x^4 + x^3 + x^2 + x$ over the set of natural numbers smaller than 10. Then, a fitness case is one of those natural numbers. Suppose $x^2 + 1$ is the functionality of a program one needs to evaluate. Then, $2^2 + 1 = 5$ is the value taken by this expression over the fitness case 2. Raw fitness is then defined as the sum over all fitness cases of the distances between the target values expected from a perfect solution and the values actually returned by the individual being evaluated. Formally, the raw fitness, f_R , of an individual i , calculated over a set of N fitness cases, can be defined as

$$f_R(i) = \sum_{j=1}^N |S(i, j) - C(j)|^k \quad (1)$$

where $S(i, j)$ is the value returned by the evaluation of individual i over fitness case j , $C(j)$ is the correct output value associated to fitness case j and k is some natural number (often either $k=1$ or $k=2$).

Fitness cases are typically a small sample of the entire domain space. The choice of how many fitness cases (and which ones) to use is often a crucial one since whether or not an evolved solution will generalize over the entire domain depends on this choice. In practice, the decision is made on the basis of knowledge about the problem and practical performance considerations (the bigger the training set, the longer the time required to evaluate fitnesses). A first theoretical study on the suitable number of fitness cases to be used has been presented in Giacobini et al. (2002).

Standardized fitness is a reformulation of the raw fitness so that lower numerical values are better. When the smaller the raw fitness the better (as in the case in [Eq. 1](#)), then the standardized fitness, f_S , can simply be equal to the raw fitness, that is $f_S = f_R$. It is convenient and desirable to ensure the best value of standardized fitness is equal to zero. When this is not the case, this can be obtained by subtracting or adding a constant to the raw fitness. If, for a particular problem, the bigger the raw fitness the better, the standardized fitness f_S of an individual can be defined as $f_S = f_R^{\max} - f_R$, where f_R is the raw fitness of the individual and f_R^{\max} is the maximum possible value of raw fitness (which is assumed to be known).

2.4 Selection

Each individual belonging to a GP population can undergo three different operations: genetic operators can be applied to that individual, it can be copied into the next generation as it is, or it can be discarded. *Selection* is the operator that decides whether a chance of reproduction is given to an individual. It is a crucial step for GP, as is for all EAs, since the success and pace of evolution often depends on it.

Many selection algorithms have been developed. The most commonly used are *fitness proportionate selection*, *ranking selection*, and *tournament selection*. All of them are based on fitness: individuals with better fitness have higher probability of being chosen for mating. Selection mechanisms used for GP are typically identical to the ones used for GAs and for other EAs. They will not be discussed in detail in this chapter, since they are introduced elsewhere in this book.

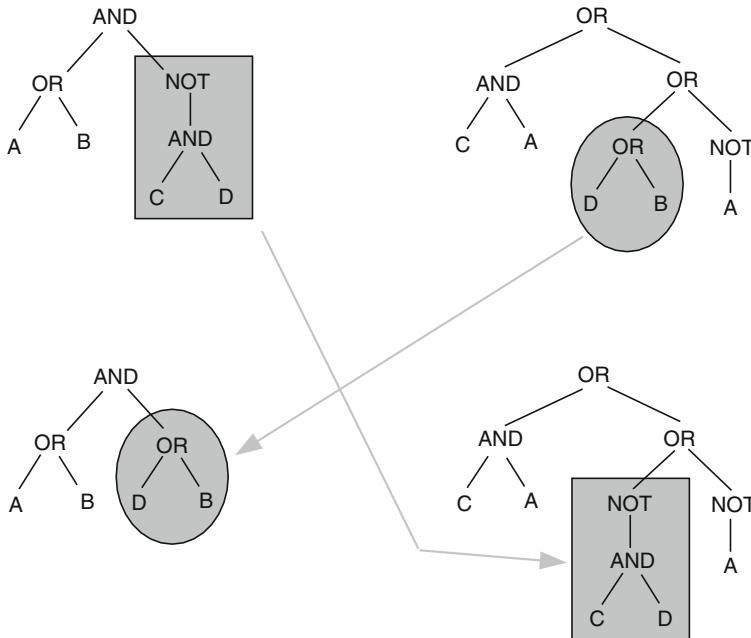

2.5 Crossover

The *crossover* or sexual *recombination* operator creates variation in the population by producing offspring that consist of genetic material taken from the parent. The parents, T_1 and T_2 , are chosen by means of a selection method.

Standard GP crossover (often called *subtree crossover*) (Koza 1992a) begins by independently selecting a random node in each parent – we will call it the *crossover point* for that parent. Usually crossover points are chosen in such a way that internal nodes are picked with a probability of 0.9 and any node (internal node or terminal) with a probability 0.1. The *crossover fragment* for a particular parent is the subtree rooted at the crossover point. An offspring is produced by deleting the crossover fragment of T_1 from T_1 and inserting the crossover fragment of T_2 at the crossover point of T_1 . Some implementations also return a second offspring, which is produced in a symmetric manner. Figure [2](#) shows an example of standard GP crossover. Because entire subtrees are swapped and because of the closure property of the primitive set, crossover always produces syntactically legal programs.

Fig. 2

An example of standard GP crossover. Crossover fragments are indicated by the shaded areas.

It is important to remark that when one of the crossover points is a leaf while the other is the root of a tree the offspring can be much bigger and deeper than the parents. While this may be desirable at early stages of a run, in the presence of the phenomenon of *bloat* – the progressive growth of the code size of individuals in the population generation after generation (more on this in [Sect. 4.4](#)) – some limit may have to be imposed on offspring size. Typically, if the offspring's size or depth is beyond a limit, the offspring is either rejected (and crossover attempted again) or accepted in the population but is given a very low fitness.

Many variants of the standard GP crossover have been proposed in the literature. The most common ones consist in assigning probabilities of being chosen as crossover points to nodes, based on node depth. In particular, it is very common to assign low probabilities to crossover points near the root and the leaves, so as to reduce the occurrence of the phenomenon described above. Another kind of GP crossover is *one-point crossover*, introduced in Poli and Langdon (1997), where the crossover points in the two parents are forced to be at identical positions. This operator was important in the development of a solid GP theory (see [Sect. 4](#)), since it provided a stepping stone that allowed the extension to GP of corresponding GA theory.

2.6 Mutation

Mutation is asexual, that is, it operates on only one parental program.

Standard GP mutation, often called *subtree mutation*, begins by choosing a *mutation point* at random, with uniform probability, within a selected individual. Then, the subtree rooted at the mutation point is removed and a new randomly generated subtree is inserted at that point.

Fig. 3

An example of standard GP mutation.

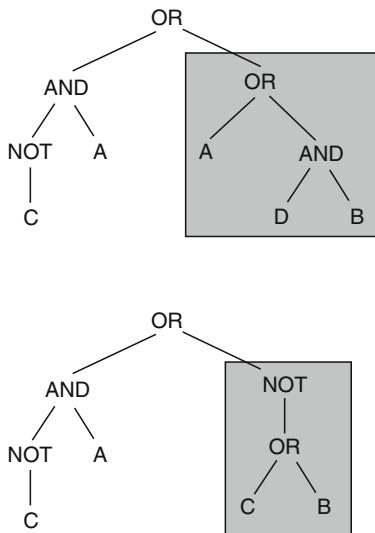

Figure 3 shows an example of standard GP mutation. As it is the case for standard crossover this operation is controlled by a parameter that specifies the maximum depth allowed, thereby limiting the size of the newly created subtree that is to be inserted. Nevertheless, the depth of the generated offspring can be considerably larger than that of the parent.

Many variants of standard GP mutation have been developed. The most commonly used are the ones aimed at limiting the probability of selecting as mutation points the root and/or the leaves of the parent. Another common form of mutation is *point mutation* (Poli and Langdon 1997) that randomly replaces nodes with random primitives of the same arity. Other commonly used variants of GP mutation are *permutation* (or *swap* mutation) that exchanges two arguments of a node and *shrink mutation* that generates a new individual from a parent's subtree. Another form of mutation is *structural mutation* (Vanneschi 2003, 2004). Being consistent with the edit distance measure, this form of mutation is useful in the study of GP problem difficulty (see [Sect. 4.6](#)).

2.7 Other Variants

In GP systems using a *steady state* scheme, the individuals produced by variation operators are immediately inserted into the population without waiting for a full generation to be complete. To keep the population size constant, a corresponding number of individuals need to be removed from the population. The removed individuals are typically the ones with the worst fitness, but versions of GP systems also exist where the removed individuals are randomly selected or where offspring replace their parents. After the new individuals have been inserted into the population, the process is iterated. A GP system using the traditional (non-steady-state) strategy is called *generational*.

Automatically defined functions (ADFs) are perhaps the best-known mechanisms by which GP can evolve and use subroutines inside individuals. In GP with ADFs, each program is represented by a set of trees, one for each ADF, plus one for the main program. Each ADF may have zero, one, two or more variables that play the role of formal parameters. ADFs allow parametrized reuse of code and hierarchical invocation of evolved code. The usefulness of ADFs has been shown by Koza (1994).

In the same vein, Koza defined automatically defined iterations (ADIs), automatically defined loops (ADLs), automatically defined recursions (ADRs), and automatically defined stores (ADSs) (Koza et al. 1999). All these mechanisms may allow a high degree of reusability of code inside GP individuals. However, their use is still not very widespread.

2.8 GP Parameters

The user of a GP has to decide the set of functions \mathcal{F} and the set of terminals \mathcal{T} to be used to represent potential solutions of a given problem and the exact implementation of the genetic operators to be used to evolve programs. This is not all, though. The user must also set some parameters that control evolution.

The most important parameters are population size, stopping criterion, technique used to create the initial population, selection algorithm, crossover type and rate, mutation type and rate, maximum tree depth, steady state vs. generational update, presence or absence of ADFs or other modularity-promoting structures, and presence or absence of elitism (i.e., the guaranteed survival of the best individual(s) found in each generation). The setting of these parameters represents, in general, an important choice for the performance of the GP system, although, based on our experience, we would suggest that population size and anything to do with selection (e.g., elitism, steady state, etc.) are probably the most important ones.

2.9 GP Benchmarks

Koza (1992a) defines a set of problems that can be considered as “typical GP problems,” given that they mimic some important real-life applications and they are simple to define and to apply to GP. For this reason, they have been adopted by the GP research community as a, more or less, agreed-upon set of benchmarks, to be used in experimental studies. They include the following:

- *The Even k Parity Problem*, whose goal is to find a Boolean function of k arguments that returns *true* if an even number of its arguments evaluates to true, and *false* otherwise.
- *The h Multiplexer Problem*, where the goal is to design a Boolean function with h inputs that approximates a multiplexer function.
- *The Symbolic Regression Problem*, that aims at finding a program that matches a given target mathematical function.
- *The Intertwined Spirals problem*, the goal of which is to find a program to classify points in the $x-y$ plane as belonging to one of two spirals.
- *The Artificial Ant on the Santa Fe trail*, whose goal is to find a target navigation strategy for an agent on a limited toroidal grid.

3 Examples of Real-World Applications of GP

Since its early beginnings, GP has produced a cornucopia of results. Based on the experience of numerous researchers over many years, it appears that GP and other evolutionary computation methods have been especially productive in areas having some or all of the following properties:

- The relationships among the relevant variables is unknown or poorly understood.
- Finding the size and shape of the ultimate solution is a major part of the problem.
- Significant amounts of test data are available in computer-readable form.
- There are good simulators to test the performance of tentative solutions to a problem, but poor methods to directly obtain good solutions.
- Conventional mathematical analysis does not, or cannot, provide analytic solutions.
- An approximate solution is acceptable (or is the only result that is ever likely to be obtained).
- Small improvements in performance are routinely measured (or easily measurable) and highly prized.

The literature, which covers more than 5,000 recorded uses of GP, reports an enormous number of applications where GP has been successfully used as an automatic programming tool, a machine learning tool, or an automatic problem-solving engine. It is impossible to list all such applications here. Thus, to give readers an idea of the variety of successful GP applications, below a representative sample is listed (see Poli et al. (2008) for a more detailed analysis):

- *Curve Fitting, Data Modelling, and Symbolic Regression.* A large number of GP applications are in these three fields (see, e.g., Lew et al. 2006 and Keijzer 2004). GP can be used as a stand-alone tool or coupled with one of the numerous existing feature selection methods, or even GP itself can be used to do feature selection (Langdon and Buxton 2004). Furthermore, GP can also be used in cases where more than one output (prediction) is required. In that case, linear GP with multiple output registers, graph-based GP with multiple output nodes, or a GP operating on single trees with primitives on vectors can be used.
- *Image and Signal Processing.* The use of GP to process surveillance data for civilian purposes, such as predicting motorway traffic jams from subsurface traffic speed measurements was suggested in Howard and Roberts (2004); GP found recurrent filters in Esparcia-Alcazar and Sharman (1996); the use of GP to preprocess images, particularly of human faces, to find regions of interest for subsequent analysis was presented in Trujillo and Olague (2006). Classifications of objects and human speech with GP was achieved in Zhang and Smart (2006) and Xie et al. (2006), respectively. A GP system in which the image processing task is split across a swarm of evolving agents and some of its applications have been described in Louchet (2001). Successful GP applications in medical imaging can be found, for instance, in Poli (1996).
- *Financial Trading, Time Series, and Economic Modelling.* Recent papers have looked at the modeling of agents in stock markets (Chen and Liao 2005), evolving trading rules for the S&P 500 (Yu and Chen 2004), and forecasting the Hang Seng index (Chen et al. 1999). Other examples of financial applications of GP include, for example, Jin and Tsang (2006) and Tsang and Jin (2006).

- *Industrial Process Control.* GP is frequently used in industrial process control, although, of course, most industrialists have little time to spend on academic reporting. A notable exception is Dow Chemical, where a group has been very active in publishing results (Castillo et al. 2006; Jordaan et al. 2006). Kordon (2006) describes where industrial GP stands now and how it will progress. Other interesting contributions in related areas are, for instance, Dassau et al. (2006) and Lewin et al. (2006). GP has also been applied in the electrical power industry (Alves da Silva and Abrao 2002).
- *Medicine, Biology, and Bioinformatics.* Among other applications, GP is used in biomedical data mining. Of particular medical interest are very wide data sets, with typically few samples and many inputs per sample. Recent examples include single nuclear polymorphisms (Shah and Kusiak 2004), chest pain (Bojarczuk et al. 2000), and Affymetrix GeneChip microarray data (Langdon and Buxton 2004; Yu et al. 2007).
- *Computational Chemistry.* Computational chemistry is important in the drug industry. However, the interactions between chemicals that might be used as drugs are beyond exact calculation. Therefore, there is great interest in approximate models that attempt to predict either favorable or adverse interactions between proto-drugs and biochemical molecules. These models can be applied very cheaply in advance of the manufacturing of chemicals, to decide which of the myriad of chemicals is worth further study. Examples of GP approaches include Barrett and Langdon (2006), Hasan et al. (2006), and Archetti et al. (2007).
- *Entertainment, Computer Games, and Art.* Work on GP in games includes, among others, (Azaria and Sipper 2005; Langdon and Poli 2005). The use of GP in computer art is reported for instance in Jacob (2000, 2001). Many recent techniques are described in Machado and Romero (2008).
- *Compression.* GP has been used to perform lossy compression of images (Koza 1992b; Nordin and Banzhaf 1996) and to identify iterated functions system, which are used in the domain of fractal compression (Lutton et al. 1995). GP was also used to evolve wavelet compression algorithms (Klappenecker and May 1995) and nonlinear predictors for images (Fukunaga and Stechert 1998). Recently, a GP system called *GP-ZIP* has been proposed that can do for lossless data compression (Kattan and Poli 2008).
- *Human-Competitive Results.* Getting machines to produce competitive results is the very reason for the existence of the fields of AI and machine learning. Koza et al. (1999) proposed that an automatically created result should be considered “human-competitive” if it satisfies at least one of eight precise criteria. These include patentability, beating humans in regulated competitions, producing publishable results, etc. Over the years, dozens of GP results have passed the human-competitiveness test (see Trujillo and Olague 2006 and Hauptman and Sipper 2007).

4 GP Theory

As discussed in [Sect. 3](#), GP has been remarkably successful as a problem-solving and engineering tool. One might wonder how this is possible, given that GP is a nondeterministic algorithm, and, as a result, its behavior varies from run to run. Why can GP solve problems and how? What goes wrong when it cannot? What are the reasons for certain undesirable behaviors, such as bloat? Below a summary of current research will be given.

4.1 Schema Theories

If we could visualize the search performed by GP, we would often find that initially the population looks like a cloud of randomly scattered points, but that, generation after generation, this cloud changes shape and moves in the search space. Because GP is a stochastic search technique, in different runs we would observe different trajectories. If we could see regularities, these might provide us with a deep understanding of how the algorithm is searching the program space for the solutions, and perhaps help us see why GP is successful in finding solutions in certain runs and unsuccessful in others. Unfortunately, it is normally impossible to exactly visualize the program search space due to its high dimensionality and complexity, making this approach nonviable.

An alternative approach to better understanding the dynamics of GP is to study mathematical models of evolutionary search. Exact mathematical models of GP are probabilistic descriptions of the operations of selection, reproduction, crossover, and mutation. They explicitly represent how these operations determine which areas of the program space will be sampled by GP, and with what probability. There are a number of cases where this approach has been very successful in illuminating some of the fundamental processes and biases in GP systems.

Schema theories are among the oldest and the best-known models of evolutionary algorithms (Holland 1975). These theories are based on the idea of partitioning the search space into subsets, called *schemata*. They are concerned with modelling and explaining the dynamics of the distribution of the population over the schemata. Modern GA schema theory (Stephens and Waelbroeck 1999) provides exact information about the distribution of the population at the next generation in terms of quantities measured at the current generation, without having to actually run the algorithm.

The theory of schemata in GP has had a difficult childhood. However, recently, the first exact GP schema theories have become available (Poli 2001), which give exact formulations for the expected number of individuals sampling a schema at the next generation. Initially, these exact theories were only applicable to GP with one-point crossover (see  Sect. 2.5). However, more recently, they have been extended to other types of crossover including most crossovers that swap subtrees (Poli and McPhee 2003a,b).

Other models of evolutionary algorithms include models based on Markov chain theory. These models are discussed in the next section.

4.2 Markov Chains

Markov chains are important in the theoretical analysis of evolutionary algorithms operating on discrete search spaces (e.g., Davis and Principe 1993). Since such algorithms are stochastic but Markovian (e.g., in GAs and GP the population at the next generation typically depends only on the population at the current generation), all one needs to do to study their behavior is to compute with which probability an algorithm in any particular state (e.g., with a particular population composition) will move any other state (e.g., another population composition) at the next generation. These probabilities are stored in a stochastic matrix M , which therefore describes with which probability the algorithm will exhibit all possible behaviors over one generation. By taking powers of the matrix M and multiplying it by the initial probability distribution over states determined by the initialization algorithm, it is then possible to study

the behavior of the algorithm over any number of generations. It is, for example, possible to compute the probability of solving a problem within n generations, the first hitting time, the average and best fitness after n generations, etc.

Markov models have been applied to GP (Poli and McPhee 2003; Mitanskiy and Rowe 2006), but so far they have not been developed as fully as the schema theory model.

4.3 Search Spaces

The models presented in the previous two sections treat the fitness function as a black box. That is, there is no representation of the fact that in GP, unlike in other evolutionary techniques, the fitness function involves the execution of computer programs on a variety of inputs. In other words, schema theories and Markov chains do not tell how fitness is distributed in the search space.

The theoretical characterization of the space of computer programs explored by GP from the point of view of fitness distributions aims at answering this very question (Langdon and Poli 2002). The main result in this area is the discovery that the distribution of functionality of non Turing-complete programs approaches a limit as program length increases. That is, although the number of programs of a particular length grows exponentially with length, beyond a certain threshold, the fraction of programs implementing any particular functionality is effectively constant. This happens in a variety of systems and can be proven mathematically for LISP expressions (without side effects) and machine code programs without loops (e.g., see Langdon and Poli 2002). Recently, Poli and Langdon (2006) started extending these results to Turing complete machine code programs. A mathematical analysis of the halting process based on a Markov chain model of program execution and halting was performed, which derived a scaling law for the *halting probability* for programs as their length is varied.

4.4 Bloat

Very often, the average size (number of nodes) of the programs in a GP population, after a certain number of generations in which it is largely static, starts growing at a rapid pace. Typically, the increase in program size is not accompanied by any corresponding increase in fitness. This phenomenon is known as *bloat*. Its origin has been the focus of intense research for over a decade. Bloat is not only interesting from a scientific point of view: it also has significant practical deleterious effects, slowing down the evaluation of individuals, and often consuming large computational resources. There are several theories of bloat.

For instance, the *replication accuracy theory* (McPhee and Miller 1995) states that the success of a GP individual depends on its ability to have offspring that are functionally similar to the parent: as a consequence, GP evolves toward (bloated) representations that increase replication accuracy.

The nodes in a GP tree can be categorized into two classes: *inactive code* (code that is not executed or has no effect) and *active code* (all code that is not inactive). The *removal bias theory* (Soule and Foster 1998b) observes that inactive code in a GP tree tends to be low in the tree, residing in smaller-than-average-size subtrees. Crossover events excising inactive subtrees produce offspring with the same fitness as their parents. On average the inserted subtree is bigger than the excised one, so such offspring are bigger than average while retaining the fitness of their parent, leading ultimately to growth in the average program size.

The *nature of program search spaces theory* (Langdon et al. 1999) relies on the result mentioned above that above a certain size, the distribution of fitnesses does not vary with size. Since there are more long programs, the number of long programs of a given fitness is greater than the number of short programs of the same fitness. Over time GP samples longer and longer programs simply because there are more of them.

In Poli and McPhee (2003), a *size evolution equation* for GP was developed, which provided an exact formalization of the dynamics of average program size. The original equation was derived from the exact schema theory for GP. This equation can be rewritten in terms of the expected change in average program size as

$$E[\Delta\mu(t)] = \sum_{\ell} \ell \times (p(\ell, t) - \Phi(\ell, t)) \quad (2)$$

where $\Phi(\ell, t)$ is the proportion of programs of size ℓ in the current generation and $p(\ell, t)$ is their selection probability. This equation does not directly explain bloat, but it constrains what can and cannot happen size-wise in GP populations. So, any explanation for bloat (including the theories above) has to agree with it.

The newest, and hopefully conclusive, explanation for bloat has been recently formalized in the so-called *crossover bias theory* (Dignum and Poli 2007; Poli et al. 2007), which is based on [Eq. 2](#). On average, each application of subtree crossover removes as much genetic material as it inserts; consequently crossover on its own does not produce growth or shrinkage. While the *mean* program size is unaffected, however, *higher moments* of the distribution are. In particular, crossover pushes the population toward a particular distribution of program sizes, known as a *Lagrange distribution of the second kind*, where small programs have a much higher frequency than longer ones. For example, crossover generates a very high proportion of single-node individuals. In virtually all problems of practical interest, however, very small programs have no chance of solving the problem. As a result, programs of above average size have a selective advantage over programs of below average size, and the mean program size increases. Because crossover will continue to create small programs, the increase in average size will continue generation by generation.

Numerous empirical techniques have been proposed to control bloat (Soule and Foster 1998; Langdon et al. 1999). These include the use of size and depth limits, the use of genetic operators with an inbuilt anti-bloat bias, the use of multi-objective selection techniques to jointly optimize fitness and minimize program size. Among these are the famous parsimony pressure method (Koza 1992b; Zhang and Mühlenbein 1995) and a recent improvement of if, the covariant parsimony pressure method (Poli and McPhee 2008). The reader is referred to Poli et al. (2008), Chap. 11 for a survey.

4.5 Is GP Guaranteed to Find Solutions to Problems?

While often Markov transition matrices describing evolutionary algorithms are very large and difficult to manage numerically, it is sometimes possible to establish certain properties of such matrices theoretically. An important property in relation to the ability of an algorithm to reach all possible solutions to a problem (given enough time) is the property of *ergodicity*. What it means in practice is that there exist some $k \in \mathbb{N}$ such that all elements of M^k are nonzero. In this case, $\lim_{k \rightarrow \infty} M^k$ is a particular matrix where all elements are nonzero. This means that irrespective of the starting state, the probability of reaching a solution to a problem

(e.g., the global optimum of a function, if one is using EAs for function optimization) is nonzero. As a result, given enough generations, the algorithm is guaranteed to find a solution.

In the context of EAs acting on traditional fixed-length representations, this has led to proving that EAs with nonzero mutation rates are global optimizers with guaranteed convergence (Rudolph 1994). While these results have been extended to more general search spaces (Rudolph 1996) and, as we discussed in [Sect. 4.2](#), Markov chain models of some forms of GP have been recently derived (e.g., see Poli et al. (2004)), the calculations involved in setting up and studying these models are of considerable mathematical complexity. Furthermore, extending the work to infinite search spaces (which is required to model the traditional form of GP where operators can create trees of potentially any size over a number of generations) presents even bigger challenges. So, it is fair to say that at the present time there is no formal mathematical proof that a GP system can always find solutions.

Despite these formal obstacles, it is actually surprisingly easy to find good reasons in support of the conjecture that, with minor modifications, the traditional form of GP is guaranteed to visit a solution to a problem, given enough generations. In fact, if one uses mutation and the mutation operator is such that, albeit with a very low probability, any point in the search space can be generated by mutating any other point, then it is clear that sooner or later the algorithm will visit a solution to the problem. It is then clear that in order to ensure that GP has a guaranteed asymptotic ability to solve all problems, all we need to do is to add to the mix of operators already present in a GP system some form of mutation that has a nonzero probability of generating any tree in the search space. One such mutation operator is the subtree mutation operator described in [Sect. 2.6](#).

4.6 Problem Difficulty in GP

What problems are solvable via GP? Is it possible to measure the difficulty of a problem for GP? In classical algorithms, we have a well-developed complexity theory that allows us to classify problems into complexity classes such that problems in the same class have roughly the same complexity, that is, they consume (asymptotically) the same amount of computational resources, usually time. Although, properly speaking, GP is a randomized heuristic and not an algorithm, it would be nice if we were able to somehow classify problems according to some measure of *difficulty*.

Difficulty studies have been pioneered in the related but simpler field of GAs, by Goldberg and coworkers (e.g., see Goldberg 1989 and Horn and Goldberg 1995). Their approach consisted in constructing functions that should *a priori* be easy or hard for GAs to solve. These approach has been followed by many others (e.g., Mitchell et al. 1992 and Forrest and Mitchell 1993) and have been at least partly successful in the sense that they have been the source of many ideas as to what makes a problem easy or difficult for GAs. One concept that underlies many measures of difficulty is the notion of *fitness landscapes*.

The metaphor of a fitness landscape (Stadler 2002), although not without faults, has been a fruitful one in several fields and is attractive due to its intuitiveness and simplicity. Probably, the simplest definition of fitness landscape in EAs is a plot where the points in the abscissas represent the different individual genotypes in a search space and the ordinates represent the fitness of each of these individuals (Langdon and Poli 2002). If genotypes can be visualized in two dimensions, the plot can be seen as a three-dimensional “map,” which may contain peaks

and valleys. The task of finding the best solution to the problem is equivalent to finding the highest peak (for maximization problems).

One early example of the application of the concept of fitness landscapes to GP is represented by the work of Kinnear (1994), where GP difficulty was related to the shape of the fitness landscape and analyzed through the use of the fitness *auto-correlation function*. Langdon and Poli (2002) took an experimental view of GP fitness landscapes in several works summarized in their book. After selecting important and typical classes of GP problems, they study fitness landscapes either exhaustively, whenever possible, or by randomly sampling the program space when enumeration becomes unfeasible. Their work highlights several important characteristics of GP spaces, such as density and size of solutions and their distribution. This is useful work. Even if the authors' goals were not establishing problem difficulty, it certainly has a bearing on it. More recently, Langdon (2003) has extended his studies for convergence rates in GP for simple machine models (which are amenable to quantitative analysis by Markov chain techniques) to convergence of program fitness landscapes for the same machine models using genetic operators and search strategies to traverse the space. This approach is rigorous because the models are simple enough to be mathematically treatable. The ideas are thus welcome, although their extension to standard GP might prove difficult.

The work of Nikolaev and Slavov (1998) represents the first effort to apply a difficulty measure called *fitness distance correlation* (FDC) (first studied by Jones (1995) for GAs) to GP, with the aim of determining which mutation operator, among a few that they propose, "sees" a smoother landscape on a given problem. Pros and cons of FDC as a general difficulty measure in GP were investigated in Vanneschi (2004), and Tomassini et al. (2005). Those contributions claimed the reliability of FDC and pointed out, as one of its major drawbacks, its lack of predictiveness of FDC (the genotype of the global optima must be known beforehand to calculate it).

In order to overcome this limitation, a new hardness measure, called *negative slope coefficient* (NSC) has been recently presented and its usefulness for GP investigated in Vanneschi et al. (2004, 2006). Results indicated that, although NSC may still need improving and is not without faults, it is a suitable hardness indicator for many well-known GP benchmarks, for some hand-tailored theoretical GP problems and also for some real-life applications (Vanneschi 2007).

Even though interesting, these results still fail to take into account many typical characteristics of GP. For instance, the NSC definition only includes (various kinds of) mutation, but it does not take crossover into account. A similarity/dissimilarity measure related to standard subtree crossover has been presented in Gustafson and Vanneschi (2005, 2008) and Vanneschi et al. (2006). This could be used in the future to build new measures of problem difficulty.

4.7 Does No-Free-Lunch Apply to GP?

Informally speaking, the no-free-lunch (NFL) theory originally proposed by Wolpert and Macready (1997) states that, when evaluated over all possible problems, all algorithms are equally good or bad irrespective of our evaluation criteria.

In the last decade there have been a variety of results which have refined and specialized NFL (see Whitley and Watson 2005). One such result states that if one selects a set of fitness functions that are *closed under permutation*, the expected performance of any search algorithm over that set of problems is constant, that is, it does not depend on the algorithm we choose (Schumacher et al. 2001). What does it mean for a set of functions to be

closed under permutation? A fitness function is an assignment of fitness values to the elements of the search space. A permutation of a fitness function is simply a rearrangement or reshuffling of the fitness values originally allocated to the objects in the search space. A set of problems/fitness functions is closed under permutation, if, for every function in the set, all possible shuffles of that function are also in the set.

The result is valid for any performance measure. Furthermore, Schumacher et al. (2001) showed that it is also the case that two arbitrary algorithms will have identical performance over a set of functions only if that set of functions is closed under permutation.

Among the many extension of NFL to a variety of domains, Woodward and Neil (2003) have made some progress in assessing the applicability of NFL to the search spaces explored by GP. In particular, they argued that there is a free lunch in a search space whenever there is a nonuniform many-to-one genotype–phenotype mapping, and that the mapping from syntax to functionality in GP is one such mapping. The reason why NFL would not normally be applicable to search in program spaces is that there are many more programs than functionalities and that not all functionalities are equally likely. So, interpreting syntax trees as genotypes and functionalities as phenotypes, the GP genotype–phenotype mapping is many-to-one and nonuniform, which invalidates NFL.

Beyond this interesting counterexample, to show that in general not all functionalities are equally likely in program search spaces, Woodward and Neil (2003) referred to the results on the limiting distribution of functionality reviewed above and to the universal distribution (Kirchherr et al. 1997) (informally this states that there are many more programs with a simple functionality than programs with a complex one). The latter result, however, applies to Turing complete languages, that is, to programs with memory and loops. So, Woodward and Neil proof applies only to Turing-complete GP, which is essentially a rarity.

In very recent work (Poli et al. 2009) it has been possible to extend these results to the case of standard GP problems and systems and to ascertain that a many-to-one genotype–phenotype mapping is not the only condition under which NFL breaks down when searching program spaces. The theory is particularly easy to understand because it is based on geometry. It is briefly reviewed in the rest of this section.

As seen above, the fitness of a program p in GP is often the result of evaluating the behavior of p in a number of fitness cases and adding up the results (Poli et al. 2008). That is

$$f(p) = \sum_{i=1}^n g(p(x_i), t(x_i)) \quad (3)$$

where f is the fitness function, $\{x_i\}$ is a set of fitness cases of cardinality n , and g is a function that evaluates the degree of similarity of its arguments. Almost invariably, the function g respects the axioms of a metric, the most common form of g being $g(a, b) = |a - b|^k$ for $k=1$ or $k=2$.

One can consider a finite space of programs $\Omega = \{p_i\}_{i=1}^r$, such as, for example, the space of all possible programs with at most a certain size or depth. A fitness function f over Ω can be represented as a vector $\mathbf{f} = (f_1, \dots, f_r)$ where $f_i = f(p_i)$. Using this vector representation for fitness functions, we can write \bullet Eq. 3 as

$$\mathbf{f} = \left(\sum_{i=1}^n g(p_1(x_i), t(x_i)), \dots, \sum_{i=1}^n g(p_r(x_i), t(x_i)) \right) \quad (4)$$

As we can see from \bullet Eq. 4, if n and the set of fitness cases $\{x_i\}$ are fixed a priori, then a fitness function is fully determined by the value of the vector of target behaviors, $\mathbf{t} = (t_1, t_2, \dots, t_n)$,

where $t_i = t(x_i)$ is fixed. If we focus on the most frequent type of program induction application in GP, symbolic regression, we typically have that the components t_i are scalars representing the desired output for each fitness case.

The function g is a distance (on \mathbb{R}). Because the sum of distances is also a distance, we can define the following distance function:

$$d(\mathbf{u}, \mathbf{v}) = \sum_{i=1}^n g(\mathbf{u}_i, \mathbf{v}_i) \quad (5)$$

where $\mathbf{u}, \mathbf{v} \in \mathbb{R}^n$. With this in hand, we can see that the fitness associated to a program p can be interpreted as the distance between the vector \mathbf{t} and the vector $\mathbf{p} = (p(x_1), p(x_2), \dots, p(x_n))$. That is

$$f(\mathbf{p}) = d(\mathbf{p}, \mathbf{t}) \quad (6)$$

Note that whenever we represent programs using their behavior vector we are essentially focusing on the phenotype-to-fitness mapping, thereby complementing the analysis of Woodward and Neil (2003) summarized above.

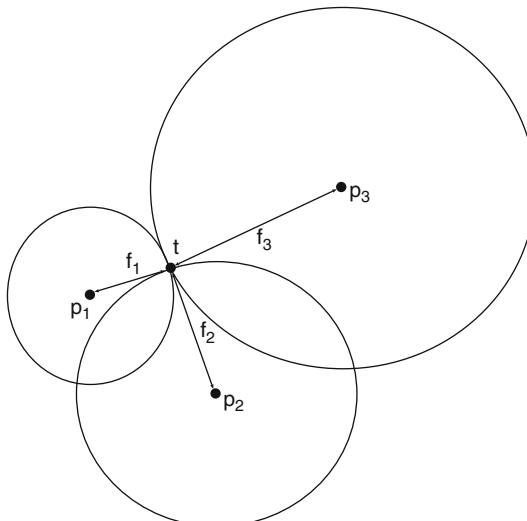

Using distances, [Fig. 4](#) can be rewritten more concisely as

$$\mathbf{f} = (d(\mathbf{p}_1, \mathbf{t}), d(\mathbf{p}_2, \mathbf{t}), \dots, d(\mathbf{p}_r, \mathbf{t})) \quad (7)$$

Note that if we know the fitness f of a program p , we know that the target behavior \mathbf{t} that generated that fitness must be on the surface of a sphere centered on \mathbf{p} (the vector representation of p) and of radius f . So, for every valid symbolic regression fitness function, the target behavior is at the intersection of the spheres centered on the behavior of each program in the search space (see [Fig. 4](#)).

Fig. 4

If g measures the squared difference between two numbers, a valid fitness function requires the spheres centered on each program behavior and with radius given by their corresponding fitness to meet in one point: the target vector \mathbf{t} .

With this geometric representation of symbolic regression problems in hand, it is not difficult to find out under which conditions NFL does or does not hold for GP. In particular, Poli et al. (2009) showed that:

Theorem 1 (NFL for GP). Let $\mathcal{F} = \{\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_m\}$ be a set of fitness functions of the form in [Eq. 7](#) and let $\mathcal{T} = \{\mathbf{t}_1, \mathbf{t}_2, \dots, \mathbf{t}_m\}$ be the set of target vectors associated to the functions in \mathcal{F} , with \mathbf{t}_i being the vector generating \mathbf{f}_i for all i . The set \mathcal{F} is closed under permutation (and NFL applies to it) if and only if for all target vectors $\mathbf{t} \in \mathcal{T}$ and for all permutations σ of $(1, 2, \dots, r)$ there exists a target vector $\tilde{\mathbf{t}} \in \mathcal{T}$ such that:

$$\sum_{i=1}^n g(p_{\sigma(j)}(x_i), t_i) = \sum_{i=1}^n g(p_j(x_i), \tilde{t}_i) \quad (8)$$

or, equivalently,

$$d(\mathbf{p}_{\sigma(j)}, \mathbf{t}) = d(\mathbf{p}_j, \tilde{\mathbf{t}}) \quad (9)$$

for all $j = 1, 2, \dots, r$.

⦿ [Equation 9](#) is a mathematical statement of the geometric requirements for $\tilde{\mathbf{t}}$ to exist. Namely, the target vector $\mathbf{t} \in \mathcal{T}$ associated to a function $\mathbf{f} \in \mathcal{F}$ must be at the intersection of the spheres centered on programs $\mathbf{p}_1, \mathbf{p}_2, \dots, \mathbf{p}_r$ and having radii f_1, f_2, \dots, f_r , respectively. Permuting the elements of \mathbf{f} via a permutation σ to obtain a new fitness function corresponds to shuffling the radii of the spheres centered on $\mathbf{p}_1, \mathbf{p}_2, \dots, \mathbf{p}_r$. Note these centers remain fixed since they represent the behavior of the programs in the search space. After the shuffling, some spheres may have had their radius decreased, some increased, and some unchanged. If any radius has changed, then \mathbf{t} can no longer be the intersection of the spheres. However, we must be able to find a new intersection $\tilde{\mathbf{t}} \in \mathcal{T}$ or else the new fitness function we have generated is not a symbolic regression fitness function and therefore cannot be a member of \mathcal{F} , which would imply that the set is not closed under permutation.

We should also note that Theorem 1 focuses on the set of program behaviors. So, it tells us something about the nature of the phenotype-to-fitness function. It really states under which conditions there can be an NFL for a searcher exploring program behaviors with no resampling. If a search algorithm instead explores the space of syntactic structures representing programs, in the presence of symmetries (such as those highlighted by Woodward and Neil), then the searcher will produce resampling of program behaviors even if it never resampled the same syntactic structure. So, in the presence of a set of behaviors for which NFL holds, this would unavoidably give the “syntactic” searcher lower average performance than an algorithm that never resampled behaviors.

This theorem is useful since, by designing fitness functions that break its assumptions, we can find conditions where there is a free lunch for GP. It turns out that such conditions are really easy to satisfy. In particular, it is easy to see that if two programs have identical behavior, they must have identical fitness or there cannot be any intersection between the spheres centered around them. Formally:

Theorem 2 Consider a search space which includes at least two programs p_1 and p_2 such that $p_1(x) = p_2(x)$ for all x in the training set. Let a set of symbolic regression problems \mathcal{F} contain a fitness function f induced by a target vector \mathbf{t} such that there exists a third program p_3 in the

search space with fitness $f(p_3) \neq f(p_1) = f(p_2)$. Then \mathcal{F} cannot be closed under permutation and NFL does not hold.

Note that this result is valid for search in the space of syntactic structures representing programs. As one can see, a many-to-one mapping is not required for a free lunch to be available.

Continuing with our geometric investigation of NFL, it is clear that a necessary condition for the existence of a target vector \mathbf{t} , which induces a particular fitness function, is that the triangular inequality be verified. More precisely:

Lemma 1 *If a target vector \mathbf{t} induces a symbolic regression fitness function \mathbf{f} , then for every pair of program behaviors \mathbf{p}_1 and \mathbf{p}_2 the distance $d(\mathbf{p}_1, \mathbf{p}_2)$ between \mathbf{p}_1 and \mathbf{p}_2 (based on the same metric used to measure fitnesses) must not be greater than $f_1 + f_2$.*

From this result, we can see that another common situation where there is incompatibility between an assignment of fitness to programs and the fitness representing a symbolic regression problem is the case in which two programs have different behaviors (and so are represented by two distinct points in the \mathbb{R}^n), but the sum of their fitnesses is smaller than their distance. This leads to the following result:

Theorem 3 *Given a set of symbolic regression functions \mathcal{F} , if there exists any function $\mathbf{f} \in \mathcal{F}$ and any four program behaviors $\mathbf{p}_1, \mathbf{p}_2, \mathbf{p}_3, \mathbf{p}_4$ in a search space such that $d(\mathbf{p}_1, \mathbf{p}_2) > f_3 + f_4$ then the set is not closed under permutation and NFL does not apply.*

So, it is extremely easy to find realistic situations in which a set of symbolic regression problems is provably not closed under permutation. This implies that, in general, we can expect that there is a free lunch for techniques that sample the space of computer programs for the purpose of fitting data sets. This is particularly important since it implies that, for GP, unlike other areas of natural computing, it is worthwhile to try to come up with new and more powerful algorithms.

5 Open Issues

Despite the successful application of GP to a number of challenging real-world problem domains and the recent theoretical advancements in explaining the behavior and dynamics of GP, there remains a number of significant open issues. These must be addressed for GP to become an even more effective and reliable problem-solving method.

The following are some of the important open issues:

- Despite some preliminary studies trying to remove this limit, at present, GP is fundamentally a “static” process, in the sense that many of its characteristics are fixed once and for all before executing it. For instance, the population size, the language used to code individuals (\mathcal{F} and \mathcal{T} sets), the genetic operators used to explore the search space and the fitness function(s) used are all static.
- Directly related to the previous point, until now GP has been mainly used for static optimization problems. No solid explorations, neither theoretical nor applicative, exist of dynamic optimization problems, where for instance the target function (and thus the fitness value of the candidate solutions) change over time.

- While a large body of literature and well-established results exist concerning the issue of generalization for many non-evolutionary machine-learning strategies, this issue in GP has not received the attention it deserves. Only recently, a few papers dealing with the problem of generalization have appeared. Nonetheless, generalization is one of the most important performance evaluation criteria for artificial learning systems and its foundations for GP still have to be deeply understood and applied.
- Although some constructs for handling modularity in GP have been defined (some of them, like ADFs, have been discussed in [Sect. 2.7](#)) and widely used, still some questions remain unanswered. Can these constructs help in solving substantially more complex problems? Can we achieve modularity, hierarchy, and reuse in a more controlled and principled manner? Can we provide insights and metrics on how to achieve this?

In the rest of this section, some of these grand challenges and open issues will be expanded upon. It is hoped that this chapter will help focus future research in order to deepen our understanding of the method to allow the development of more powerful problem-solving algorithms.

5.1 Dynamic and/or Self-Adapting GP Frameworks

Although the difficulty measures discussed in [Sect. 4.6](#) are useful to statically calculate the hardness of a given problem for GP starting from its high-level specifications, they have not been applied to dynamically improve the search as yet. Indeed, a dynamic modification “on the fly” (i.e., during the evolutionary process) of the fitness function, the population size, the genetic operators, or representation used, driven by one or more hardness measures represents one of the most challenging open issues in GP, as in many other fields of evolutionary computation. One of the major difficulties in the realization of such a dynamic and self-adapting GP environment is probably represented by the fact that both FDC and NSC have always been calculated, until now, using a large sample of the search space and not the evolving population that is typically much smaller. Furthermore, the lack of diversity in populations after some generations may seriously compromise the reliability of these indicators. Nevertheless, this issue remains a challenge and a first attempt in this direction has recently been presented in Wedge and Kell ([2008](#)).

Models using dynamically sized populations, although not based on the values of difficulty indicators, have been presented, among others, in Rochat et al. ([2005](#)), Tomassini et al. ([2004](#)), and Vanneschi ([2004](#)), where the authors show that fixed-size populations may cause some difficulties to GP. They try to overcome these difficulties by removing or adding new individuals to the population in a dynamic way during evolution. In particular, individuals are removed as long as the best or average population’s fitness keeps improving, while new individuals (either randomly generated ones or mutations of the best ones in the population) are added when fitness stagnates. The authors show a set of experimental results that confirm the benefits of the presented methods, at least for the studied problems. These results suggest that fixed-size population unnaturally limits the GP behavior and that, according to what happens in nature, the evolution has a benefit when populations are left free to shrink or increase in size dynamically, according to a set of events. Some of the most relevant and macroscopic of these events are so called *plagues* that usually cause a violent decrease in natural population sizes. Plagues have been successfully applied to GP in Fernandez et al. ([2003a,b](#)) and Fernandez and Martin ([2004](#)). These contributions go in the

same direction as the previous ones: fixed-size populations limit and damage the behavior of GP while the use of dynamically sized populations is often beneficial. Furthermore, the models presented in the above quoted references have been successfully used by Silva (2008) to study and control bloat.

5.2 GP for Dynamic Optimization

Dynamic environments abound and offer particular challenges for all optimization and problem-solving methods. A well-known strategy for survival in dynamic environments is to adopt a population-based approach (Dempsey 2007). This allows a diversity of potential solutions to be maintained, which increases the likelihood that a sufficiently good solution exists at any point in time to ensure the survival of the population in the long term. Dynamic environments can exhibit changes in many different ways including the frequency and degree/size of change. The types of changes might range from relatively small smooth transitions to substantial perturbations in all aspects of the domain (Dempsey 2007).

Given the power of the biological process of evolution to adapt to ever, changing environments, it is surprising that the number of studies applying and explicitly studying their artificial counterpart of GP in dynamic environments have been minimal (Dempsey 2007). Despite the existence of a recent special issue in the GP journal on dynamic environments (Yang et al. 2006), none of the four articles actually dealt with GP directly (e.g., Wang and Wineberg (2006)). While some applications in dynamic environments have been undertaken in the past two years (e.g., Wagner et al. 2007, Hansen et al. 2007, Jakobović and Budin 2006, and Kibria and Li 2006), there has been little analysis of the behavior of GP in these environments. The two main examples have examined bloat (Langdon and Poli 1998) and constant generation (Dempsey 2007).

This seems to hint that we are missing the boat by focusing on static problems where there is a single fixed target. Recent experiments in evolutionary biology simulations suggest that EC/evolution could work efficiently “because” of dynamic environments as opposed to “despite” them (Kashtan et al. 2007).

5.3 Generalization in GP

Generalization is one of the most important performance-evaluation criteria for artificial learning systems. Many results exist concerning the issue of generalization in machine learning, like, for instance, support vector machines (see for instance Smola and Scholkopf 1999). However, this issue in GP has not received the attention it deserves and only recently a few papers dealing with the problem of generalization have appeared (Eiben and Jelasity 2002; Kushchu 2002). A detailed survey of the main contributions on generalization in GP has been done by Kushchu (2002). Another important contribution to the field of generalization in GP is due to the work of Banzhaf and coworkers. In particular, in Francone et al. (1996) they introduce a GP system called *Compiling GP* and they compared its generalization ability with that of other machine-learning paradigms. Furthermore, in Banzhaf et al. (1996) they show the positive effect of an extensive use of the mutation operator on generalization in GP using sparse data sets. In 2006, Da Costa and Landry (2006) have proposed a new GP model called *Relaxed GP*, showing its generalization ability. In 2006, Gagné et al. (2006) have investigated two methods to improve generalization in GP-based learning: (1) the selection

of the best-of-run individuals using a three-data-sets methodology, and (2) the application of parsimony pressure to reduce the complexity of the solutions.

A common design principle among ML researchers is the so called *minimum description length principle* (see for instance Rissanen 1978), which states that the best model is the one that minimizes the amount of information needed to encode it. In this perspective, preference for simpler solutions and over-fitting avoidance seem to be closely related. It is more likely that a complex solution incorporates specific information from the training set, thus over-fitting it, compared to a simpler solution. But, as mentioned in Domingos (1999), this argumentation should be taken with care as too much emphasis on minimizing complexity can prevent the discovery of more complex yet more accurate solutions. Finally, in Vanneschi et al. (2007), authors hint that GP generalization ability (or more precisely, *extrapolation* ability) can be improved by performing a multi-optimization on the training set. A related idea has been used in Gagné et al. (2006) in the domain of binary classification, where a two-objective sort is performed in order to extract a set of nondominated individuals. However, different objectives in the realm of regression problems are used in Vanneschi et al. (2007).

Despite the above mentioned studies, the issue of generalization remains an open one in GP, since no theoretical approach has ever been presented to tackle this problem until now.

5.4 Modularity in GP

The use of modules may be very important to improve GP expressiveness, code reusability, and performance. The best-known of these methods is Koza's ADFs, which is introduced in ➤ Sect. 2.7. The first step toward a theoretically motivated study of ADFs is probably represented by Rosca (1995), where an algorithm for the automatic discovery of building blocks in GP called *Adaptive Representation Through Learning* was presented. In the same year, Spector (1995) introduced techniques to evolve collections of automatically defined macros and showed how they can be used to produce new control structures during the evolution of programs and Seront (1995) extended the concept of code reuse in GP to the concept of generalization, showing how programs (or “concepts,” using Seront’s terminology) synthesized by GP to solve a problem can be reused to solve other ones. Altenberg offers a critical analysis of modularity in evolution in Altenberg (2009), stating that the evolutionary advantages that have been attributed to modularity do not derive from modularity *per se*. Rather, they require that there be an “alignment” between the spaces of phenotypic variation, and the selection gradients that are available to the organism. Modularity in the genotype–phenotype map may make such an alignment more readily attained, but it is not sufficient; the appropriate phenotype–fitness map in conjunction with the genotype–phenotype map is also necessary for evolvability. This contribution is interesting and stimulating, but its applicability to GP remains an open question.

In Jonyer and Himes (2006) the concept of ADFs is extended by using graph-based data mining to identify common aspects of highly fit individuals and modularizing them by creating functions out of the subprograms identified. In Hemberg et al. (2007) the authors state that the ability of GP to scale to problems of increasing difficulty operates on the premise that it is possible to capture regularities that exist in a problem environment by decomposition of the problem into a hierarchy of modules.

Although the use of modularity in GP has helped solve some problems and provide new data/control abstractions, for instance in the form of ADFs, still some issues remain open.

For instance: Has it solved really substantially more complex problems and does it hold the promise to do so in the near future? Are ADFs necessary/sufficient as a formalism to help solve grand-challenge problems, that is to provide scalability? And even more ambitiously: Can we achieve modularity, hierarchy, and reuse in a more controlled and principled manner? Can we provide insights and metrics on how to achieve this? Is it possible to routinely evolve algorithms? How to achieve iteration and/or recursion in a controlled and principled manner? What is the best way to handle the generation and maintenance of constants?

A first attempt to answer this last question is represented by Vanneschi et al. (2006) and Cagnoni et al. (2005) where the authors present a new coevolutionary environment where a GA dynamically evolves constants for GP. Although interesting, this contribution, as many others aimed at improving GP modularity, is mainly empirical, that is, it shows the benefits of the presented method(s) by means of a set of experimental results on some test functions. In order to be able to get a deeper insight of the real usefulness of modularity and code-reuse in GP, more theoretical studies are needed.

6 Conclusions

GP is a systematic method for getting computers to automatically solve a problem starting from its high-level specifications. It extends the model of genetic algorithms to the space of computer programs. In its almost 30 years of existence, it has been successfully applied to a number of challenging real-world problem domains. Furthermore, solid theory exists explaining its behavior and dynamics.

After a general introduction to the mechanics of GP, this chapter has discussed some examples of real-world applications of GP. In general, GP is particularly suitable for applications of curve fitting, data modeling, or symbolic regression, typically characterized by a large amount of data and where little is known about the relationships among the relevant features. Over the years, dozens of GP results have passed the human-competitiveness test, defined by Koza by establishing eight precise criteria, including patentability, beating humans in regulated competitions, producing publishable results, etc. Fields where GP have been successfully applied in the last few years include: image and signal processing; financial trading, time series, and economic modeling; industrial process control; medicine, biology and bioinformatics; computational chemistry; entertainment and computer games; arts; and compression.

Subsequently, we presented some of the most relevant GP theoretical results, including schema theories and Markov chains-based models. We discussed recent studies of the distribution of fitness in GP search spaces and of the distribution of programs' length. We presented various theories explaining the phenomenon of bloat, including the recently introduced crossover bias theory, which is based on a precise equation of the programs' size evolution, and that, hopefully, will give a conclusive explanation of this phenomenon. We gave arguments in support of the conjecture that GP is a global optimizer, that is, it is guaranteed to find a globally optimal solution, given enough time. Furthermore, we presented the most important results obtained in the field of GP problem difficulty, including a discussion of fitness distance correlation and negative slope coefficient, two of the most effective measures of problem difficulty for GP, and the recently introduced subtree crossover similarity/dissimilarity measure, that should help in defining new and hopefully more powerful

difficulty measures. Finally, we summarized results on the existence of a “free lunch” for GP under some weak (and, in practice, often satisfied) conditions.

In the last part of this chapter, hot topics and open issues of GP have been discussed, including the development of a self-adapting framework to dynamically modify the GP configuration (population size, representation, genetic operators, etc.) during the evolution; the study of the usefulness of GP for dynamic optimization problems; the study and better understanding of the concept of generalization and its implications for GP; and the definition of more powerful and self-adaptive methods of using modularity in GP.

Although our chapter could not exhaustively cover the immensity of the field, it is hoped that this chapter will attract newcomers to the field of GP as well as help focus future research, leading to a wider application and deeper understanding of GP as a problem-solving strategy.

Abstract

This chapter considers local progress and the dynamical systems approach. The approach can be used for a quantitative analysis of the behavior of evolutionary algorithms with respect to the question of convergence and the working mechanism of these algorithms. Results obtained so far for evolution strategies on various fitness functions are described and discussed before presenting drawbacks and limitations of the approach. Furthermore, a comparison with other analysis methods is given.

1 Introduction: Evolutionary Algorithms as Dynamical Systems

Evolutionary algorithms can be studied in various ways – theoretically and experimentally. This section gives an overview of an analysis approach that models the algorithms as dynamical systems. As in physics and engineering sciences, the time evolution of the systems is due to the forces acting on the systems. Thus, the forces, also referred to as local progress measures, are the basis to understand how evolutionary algorithms function.

The text is divided as follows: first, a short introduction to evolution strategies, the evolutionary algorithm to which the approach was mainly applied, is given. Afterward, a description of how the dynamics of evolution strategies can be transformed into a deterministic dynamical system is given. In the next step, the local progress measures are defined before some results are discussed. The following overview starts with a description of several commonly used fitness functions. Afterward, the dynamical systems and local progress approach is explained in more detail using a simple example. The next section lists the results obtained for undisturbed and uncertain environments. The approach presented has certain drawbacks and limitations. The remaining section is devoted to these aspects, setting the approach used in relation to other theoretical approaches.

1.1 Evolution Strategies

An *evolution strategy* (ES) is a specific evolutionary algorithm (EA) invented in 1963 by Bäck, Rechenberg, and Schwefel. The population-based search heuristic moves through the search space by means of variation, that is, mutation and recombination, and selection. A population consists of several individuals. Each individual represents a candidate solution coded in the object parameters.

The performance of an ES strongly depends on the choice of a so-called strategy parameter, the *mutation strength* also referred to as the *step size*, which controls the spread of the population due to mutation. During an optimization run, the mutation strength must be adapted continuously to allow the ES to travel with sufficient speed. To this end, several methods have been developed – for example, Rechenberg's well-known 1 / 5th-rule (Rechenberg 1973), self-adaptation (Rechenberg 1973; Schwefel 1977), or the cumulative step-size adaptation (CSA) and covariance matrix adaptation (CMA) of Ostermeier, Gawelczyk, and Hansen, for example Ostermeier et al. (1995) and Hansen and Ostermeier (2001).

         $\mathcal{P}_\lambda^{(g)} := \{(y_l, \sigma_l, F_l)\}$ ;
        CASE “,”-SELECTION:  $\mathcal{P}_\mu^{(g+1)} :=$  SELECT( $\mathcal{P}_\lambda^{(g)}$ );
        CASE “+”-SELECTION:  $\mathcal{P}_\mu^{(g+1)} :=$  SELECT( $\mathcal{P}_\mu^{(g)}, \mathcal{P}_\lambda^{(g)}$ );
        g:=g+1;
    UNTIL stop;
END

```

Following Beyer (2001b, p. 8), Fig. 1 illustrates the basic algorithm of a multi-parent $(\mu/\rho + \lambda)$ -ES with σ -self-adaptation (σ SA). In a self-adaptive ES, the tuning of the mutation strength is left to the evolution strategy itself. Similar to the object parameters, the strategy parameters are subject to variation. If an offspring is selected, it also has a chance to bequeath its strategy parameters to the offspring generation. That is, self-adaptation assumes a statistic or probabilistic connection between strategy parameters and “good” fitness values.

As Fig. 1 shows, a $(\mu/\rho + \lambda)$ -ES maintains a population $\mathcal{P}_\mu^{(g)}$ of μ candidate solutions at generation g – with the strategy parameters used in their creation. Based on that parent population, λ offspring are created via variation.

Offspring are created as follows: For each offspring, ρ of the μ parents are chosen for recombination leading to the set \mathcal{P}_ρ . The selection of the parents may be deterministic or probabilistic (see, e.g., Beyer and Schwefel 2002; Eiben and Smith 2003).

First, the strategy parameters are changed. The strategy parameters of the chosen ρ parents are recombinated and the result is mutated afterward. The change of the object parameters occurs in the next step. Again, the parameters are first recombinated and then mutated. The newly created strategy parameter σ_l is used in the mutation process. Afterward, the fitness of the offspring is determined.

After the offspring population of λ individuals has been created, the μ best individuals with respect to their fitness values are chosen as the next parental population $\mathcal{P}_\mu^{(g+1)}$. Two selection schemes are generally distinguished: “comma” and “plus”-selection. In the case of “comma”-selection, only the offspring population is considered for selection, that is, only individuals of the offspring population have a chance to be selected into the next parent population. The old parent population is completely discarded.

In the case of “plus”-selection, members of the old parent population and the offspring population may be selected into the succeeding parent population.

There are two types of recombination that are mainly used in practice: intermediate and dominant multi-parent recombination denoted by $(\mu/\mu_B, \lambda)$ and $(\mu/\mu_D, \lambda)$, respectively. Using intermediate recombination for both the object parameters and the mutation strengths, the offspring are generated in the following manner:

1. Compute the mean, $\langle \sigma \rangle = \frac{1}{\mu} \sum_{m=1}^{\mu} \sigma_m$, of the mutation strengths σ_m of the parent population.
2. Compute the centroid, $\langle \mathbf{y} \rangle = \frac{1}{\mu} \sum_{m=1}^{\mu} \mathbf{y}_m$, of the object vectors \mathbf{y}_m of the μ parents.
3. For all offspring $l \in \{1, \dots, \lambda\}$:
 - a. Derive the new mutation strength by mutating the mean $\langle \sigma \rangle$ according to $\sigma_l = \langle \sigma \rangle \zeta$ where ζ is a random variable, which should fulfill $E[\zeta] \approx 1$ (see Beyer and Schwefel (2002) for a discussion of this and further requirements). Typical choices of ζ 's distribution include the log-normal distribution, the normal distribution, or a two-point distribution (Bäck 1997).
 - b. Generate the object vector \mathbf{y}_l according to $y_i = \langle y_i \rangle + \sigma_l \mathcal{N}(0, 1)$ where y_i is the vector's i th component and $\mathcal{N}(0, 1)$ stands for a standard normally distributed random variable.

Dominant recombination works differently. For each offspring, the recombination vector is created component-wise by randomly choosing one parent for each position and copying the value.

A nonrecombinant multi-parent strategy is denoted as a (μ, λ) -ES or a $(\mu + \lambda)$ -ES. Offspring are generated by choosing one of the parents at random and adding a mutation vector.

After the offspring or the candidate solutions have been created, the μ best solutions (“plus”: offspring and parents, “comma”: offspring) are chosen, according to their fitness, and become the succeeding parent population.

Self-adaptive strategies also retain the strategy parameters for each selected individual. The strategy parameters can be seen as an additional part of an individual's genome – neutral with respect to the fitness but influencing the evolutionary progress. The mutation is usually realized by using the log-normal operator with *learning parameter* τ . The learning parameter τ is a parameter of the log-normal distribution. Similar to the standard deviation of the normal distribution, it controls the spread of the distribution (see [Table 1](#)). Larger values result in a larger spread whereas smaller values lead to a shrink toward an area including one.

Table 1

Common mutation operators for self-adaptive evolution strategies. The parameter τ appearing in the log-normal operator is usually called the *learning parameter*. The random variable U for the two-point distribution is uniformly distributed in the interval $(0, 1]$. The second row for the two-point mutation gives an alternative definition, producing the same random process when using $\alpha = \ln(1 + \beta)$

Operator	Mutation	Random variable
Log-normal	$\sigma' := \zeta \sigma$	$\zeta = e^{\tau \mathcal{N}(0, 1)}$
Meta-EP	$\sigma' := \zeta \sigma$	$\zeta = 1 + \tau \mathcal{N}(0, 1)$
Two-point	$\sigma' := \begin{cases} \sigma(1 + \beta) & \text{if } U(0, 1] \leq 1/2 \\ \sigma/(1 + \beta) & \text{if } U(0, 1] > 1/2 \end{cases}$	
Two-point	$\sigma' := \zeta \sigma$	$\zeta = e^{\alpha \operatorname{sign}(\mathcal{N}(0, 1))}$

Note, however, that the log-normal distribution is restricted to positive values and is not symmetric. Furthermore, the learning parameter controls the spread but *is not* a central moment of the distribution, that is, τ^2 is not the variance. Further alternatives are given in [Table 1](#).

Self-adaptation uses only one kind of information from the evolutionary search: the ranking of the fitness values. In contrast, the cumulative step-size adaptation (CSA) and the standard version of covariance matrix adaptation (CMA) use a so-called *evolution path*, which sums up the actually realized search steps. Therefore, these algorithms do not only use information from the fitness ranking but also related search space information. In the following, the basic CSA-algorithm is described for $(\mu/\mu_b, \lambda)$ -ES:

$$\forall l = 1 \dots \lambda : \mathbf{w}_l^{(g)} := \overrightarrow{\mathcal{N}}_l(0, 1) \quad (1)$$

$$\mathbf{x}^{(g)} := \sigma^{(g)} \mathbf{z}^{(g)} := \frac{\sigma^{(g)}}{\mu} \sum_{m=1}^{\mu} \mathbf{w}_{m;\lambda} \quad (2)$$

$$\mathbf{y}^{(g+1)} := \mathbf{y}^{(g)} + \mathbf{x}^{(g)} \quad (3)$$

$$\mathbf{s}^{(g+1)} := (1 - c)\mathbf{s}^{(g)} + \sqrt{\mu c(2 - c)} \mathbf{z}^{(g)} \quad (4)$$

$$\sigma^{(g+1)} := \sigma^{(g)} \exp\left(\frac{\|\mathbf{s}^{(g+1)}\| - \overline{\chi_N}}{D\overline{\chi_N}}\right) \quad (5)$$

with $\overrightarrow{\mathcal{N}}_l(0, 1)$ as a random vector with standard normally distributed components and D as the dampening constant (Beyer and Arnold [2003b](#)). The mechanism of cumulative step size adaptation is based on the assumption that the step size is adapted optimally when consecutive search steps are uncorrelated or perpendicular: If the mutation strength is too small, the ES takes several steps into the same or similar direction. These steps could be substituted by a single larger step. The control rule should therefore increase the mutation strength and with it the step size. If otherwise the mutation strength is too large, the ES has to retrace its movements – consecutive steps may be antiparallel. In this case, the mutation strength must be decreased.

The *evolutionary path* or *accumulated progress vector* ([Eq. 4](#)) and its length can be used to ascertain which situation is occurring at present. Let one neglect for a moment the influence of selection and assume that selection is purely random. In this case, the consecutive steps are normally distributed. Their weighted sum is therefore also normally distributed, and its length follows a χ -distribution with N degrees of freedom. This explains the appearance of the mean $\overline{\chi_N}$ of the χ_N -distribution in [Eq. 5](#).

Selection changes the situation: If the mutation strength is too large, the ES has to retrace, and antiparallel movements may occur resulting in a path length smaller than the ideal case $\overline{\chi_N}$. The CSA decreases the step size according to [Eq. 5](#). If the mutation strength is too small, the algorithm takes several steps into roughly the same direction, which results in a path length longer than that in the uncorrelated case. The CSA then increases the mutation strength.

Theoretical analyses of ESs performed so far have been devoted mainly to the isotropic mutation case that needs to consider a single mutation parameter – the mutation strength σ – only. The adaptation of arbitrary Gaussian mutation distributions is state-of-the-art in algorithm design, known as the covariance matrix adaptation-ES. This ES uses the concept of the evolutionary path and adapts additionally the full covariance matrix. Detailed descriptions of the CMA and CSA can be found in Hansen and Ostermeier ([1996, 1997, 2001](#)) and Hansen ([2006](#)). Theoretical performance analysis of the CMA-ES is, however, still in its infancy.

Table 2

Types of ESs considered. Note a $(\mu/\mu, \lambda)$ -ES and a (μ, λ) -ES always include the $(1, \lambda)$ -ES as a special case. The groups for the $(1, \lambda)$ -ES only list publications solely devoted to this ES

Table 2 gives an overview of the ES variants analyzed up to now using the progress rate and dynamical system approaches. The analysis of the CSA-ES used a slightly different version of the CSA than previously presented. Instead of Eq. 5, the mutation strength update rule reads

$$\sigma^{(g+1)} = \sigma^{(g)} e^{\frac{\|s^{(g)}\|^2 - N}{2DN}} \quad (6)$$

See, e.g., Arnold (2002a) for a discussion and usual settings of the parameters c and D .

1.2 A Short Introduction to Dynamical Systems

The dynamical systems approach uses concepts that stem from the theory of dynamical systems. This section gives a short introduction to this area. To obtain more information, the reader is referred, for example, to Wiggins (1990) and Braun (1998). The term *dynamical* already points to one of the main characteristics of these systems: they change in time. But how does the system change? Are there any points where the system comes to rest? These are some of the questions that the theory of dynamical systems addresses.

The section starts with some illustrative examples. Afterward, the concept of equilibrium solutions, the rest points of a system, is addressed. The section closes with a short introduction to the stability of equilibrium points.

1.2.1 What Are Dynamical Systems?

First of all, the term *dynamical system* has to be explained. Dynamical systems can be approached in two ways. On the one hand, on an abstract level, a dynamical system is just a difference or differential equation, the properties of which shall be studied. On the other hand, this formal mathematical description generally appears as the result of a modeling process in the analysis of a time-dependent process, for example, the course of a chemical reaction, the spread of a forest fire, the growth of a population, the spreading of an epidemic disease, or the run of an evolutionary algorithm.

A modeling process aims at formalizing and quantifying the important characteristics of the system, for instance, the interactions between entities. If the modeler is interested in how the system evolves in time, the result is a dynamic system. Thus, a dynamical system is a model of a time-dependent system or process expressed in a formal mathematical way.

In general, several classes of dynamical systems can be distinguished. Dynamical systems can be grouped by the nature of the change, that is, whether the changes are deterministic or stochastic. This section considers deterministic systems. For a rigorous introduction to the field of random dynamical systems, the reader is referred to Arnold (2002b).

Dynamical systems can further be classified into discrete time and continuous time dynamical systems. In the first case, the change of the variable, $y \in \mathbb{R}$, occurs at discrete time steps, leading to an *iterated map* or *difference equation*

$$y(t+1) = f(y(t)) \quad (7)$$

with $f: \mathbb{R}^N \rightarrow \mathbb{R}^N$ and starting point $y(0) = y_0$. In this and the following sections, it is assumed that the time always starts at $t_0 = 0$.

A dynamical system in continuous time leads to a *differential equation*

$$\frac{d}{dt}y(t) = g(y(t)) \quad (8)$$

with $g: \mathbb{R}^N \rightarrow \mathbb{R}^N$ and starting point $y(0) = y_0$. The behavior of the system (7) or (8), respectively, depends on (a) the properties of f and g and (b) to some lesser extent on the initial value y_0 .

In the following, some examples of dynamic systems are discussed. Let one consider the situation that a saver opens a bank account with a starting capital y_0 . The bank offers an interest rate of $p\%$ per annum. How does the capital increase?

The problem can be described by

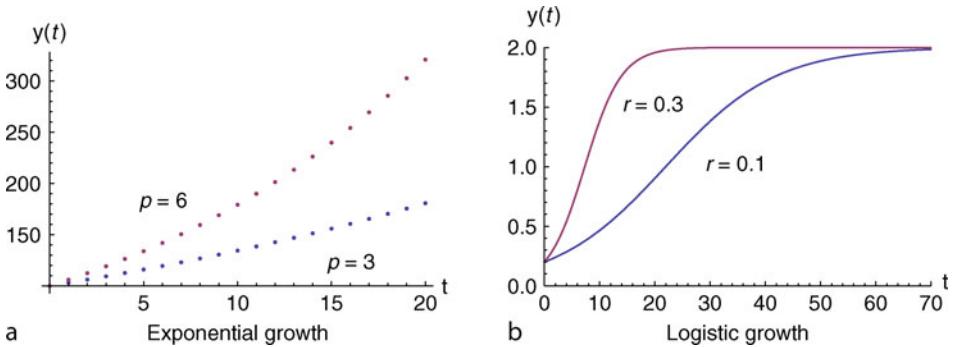

$$y(t+1) = y(t) \left(1 + \frac{p}{100}\right) \quad (9)$$

with the time, t , in discrete years. It is easy to see by performing a few iterations of Eq. 9 starting with $y(0) = y_0$ that the solution of Eq. 9 can be given in closed form as

$$y(t) = y_0 \left(1 + \frac{p}{100}\right)^t \quad (10)$$

Fig. 2

Examples for dynamical systems: (a) shows [Eq. 10](#), a time-discrete exponential growth, with initial value $y_0 = 100$ and two choices for the interest rate. (b) shows [Eq. 13](#) with carrying capacity $C = 2$ and initial value $y_0 = 0.2$.

The capital grows exponentially, see [Fig. 2a](#). The exact value at time t depends on the initial value, whereas the general behavior – the exponential growth – is a result of the form of the change. The form of [Eq. 10](#) follows from the fact that [Eq. 9](#) is a simple linear difference equation.

Let one now consider the growth of a population of bacteria in a petri dish. In experiments, it was found that a bacteria population first experiences an exponential growth which slows down in further progress. The decrease of the growth can be attributed among others to intra-species competition over increasingly scarce resources. Usually, an environment or a habitat (the petri dish) allows a maximal population density, the so-called carrying capacity C . (The population density is determined as (number of individuals)/(size of habitat).) The process can be described by a continuous model

$$\frac{d}{dt}y(t) = ry(t)\left(1 - \frac{y(t)}{C}\right) \quad (11)$$

with r standing for the exponential growth rate. Again, it is possible to obtain a solution in closed form. The calculations require partial fraction decomposition

$$\frac{\frac{d}{dt}y(t)}{ry(t)\left(1 - \frac{y(t)}{C}\right)} = \frac{d}{dt}y(t) \left(\frac{A}{ry(t)} + \frac{B}{\left(1 - \frac{y(t)}{C}\right)} \right) = 1 \quad (12)$$

with A and B to be determined and some knowledge in the area of differential equations. Finally,

$$y(t) = \frac{Cy_0 e^{rt}}{C - y_0 + y_0 e^{rt}} \quad (13)$$

is obtained. [Figure 2b](#) shows two examples of a logistic growth which differ in the size of the parameter r . The larger r is, the faster the carrying capacity is reached. Let one consider a third example. This time, consider the interaction between a predator population and a prey

population. Lotka and Volterra (see, e.g., Hofbauer and Sigmund 2002) used the following difference equation to describe the species' interactions

$$\begin{aligned}\frac{d}{dt}x(t) &= ax(t) - bx(t)y(t) \\ \frac{d}{dt}y(t) &= -cy(t) + dx(t)y(t)\end{aligned}\tag{14}$$

with $x(t)$ denoting the density of the prey population and $y(t)$ the density of the predator. Lotka and Volterra assumed that in the absence of the predator the prey population would grow exponentially, whereas the predator would die out without any prey. In the absence of the prey, the predator decreases exponentially. The parameters a and c determine the growth rate of the prey and the loss rate of the predator. It is assumed that the population growth of the predator depends on its preying and therefore on its meeting the prey. The loss of the prey due to predation is also proportional to the meeting of predator and prey. The constants b and d regulate the respective loss and gain. The Lotka–Volterra predator–prey model is one of the earliest and simplest models in population biology. However, although it is extremely simple, there are no general analytical solutions of [Eq. 14](#) which express x and y as time-dependent functions.

In the next case, the growth of a population, that is, the logistic growth, is reconsidered (Hofbauer and Sigmund 2002). For instance, in the case of insect populations with non-overlapping generations, the growth should be modeled with a difference equation instead of a differential equation leading to

$$y(t+1) = Ry(t) \left(1 - \frac{y(t)}{K}\right)\tag{15}$$

In contrast to the continuous model [\(13\)](#), a general analytical solution to [Eq. 15](#) that depends on the time cannot be obtained.

There are many more examples where it is not possible to obtain a closed analytical solution for a differential or difference equation. The question that remains is what should be done in this case. One solution that comes to mind is to perform simulations or computer experiments, to let the system evolve inside the computer and to draw statistically sound conclusions from the observations. This established method may have some drawbacks, though. What if the behavior of the system depends strongly on the size of some parameters or the initial values, and the simulations did not consider these? Or what if the time horizon of the simulation is not sufficiently long for the system to show the interesting behavior? The study of equilibrium solutions provides another way to obtain more information about a system.

1.2.2 Rest Points: Equilibrium Solutions

Equilibrium solutions are solutions of [Eqs. 8](#) or [7](#) that are the rest points of the system, that is, points where no more changes of the system occur. In other words, an equilibrium solution is a solution \mathbf{y}_{eq} of the discrete system [\(7\)](#) that does not change in time, that is,

$$\mathbf{y}(t+1) = \mathbf{y}(t) = \mathbf{y}_{\text{eq}} \Rightarrow f(\mathbf{y}_q) = \mathbf{y}_q\tag{16}$$

or a solution \mathbf{y}_{eq} of the continuous system [\(8\)](#)

$$\frac{d}{dt}\mathbf{y}(t) = g(\mathbf{y}(t)) = 0 \Rightarrow g(\mathbf{y}(t)) = g(\mathbf{y}_{\text{eq}}) = 0\tag{17}$$

There are many synonyms for equilibrium solutions – including the terms rest point, singularity, fix point, fixed point, stationary point (also solution or state), or steady state (Wiggins 1990, p. 6).

In the examples, the equilibrium solutions can be determined straightforwardly. In the case of the time-discrete exponential growth, [\(Eq. 9\)](#)

$$y(t+1) = y(t) \left(1 + \frac{p}{100}\right) \quad (18)$$

requiring $y(t+1) = y(t)$ leads only to one equilibrium solution, $y_{\text{eq}} = 0$: Only zero capital is not changed by interest yield.

In the case of the time-continuous logistic growth [\(Eq. 11\)](#), one requires $d/(dt)y(t) = 0$ for no change, leading to

$$0 = ry(t) \left(1 - \frac{y(t)}{C}\right) \quad (19)$$

with two solutions $y_{\text{eq}1} = 0$ and $y_{\text{eq}2} = C$, the zero population and the carrying capacity. Again, this immediately makes sense. A population with zero individuals cannot grow and if the maximal allowed capacity is reached, a further increase is not possible.

In the case of the Lotka–Volterra model [\(Eq. 14\)](#), the system only “rests” as a whole, if the predator equation and the prey equation have equilibrium solutions. Therefore, one has to set $d/(dt)x(t) = 0$ and $d/(dt)y(t) = 0$, leading to

$$0 = ax(t) - bx(t)y(t) = x(t)(a - by(t)) \quad (20)$$

$$0 = -cy(t) + dx(t)y(t) = y(t)(-c + dx(t)) \quad (21)$$

One solution, $x_{\text{eq}} = y_{\text{eq}} = 0$, follows immediately. If $x_{\text{eq}} \neq 0$, $a - by(t) = 0$ has to hold. Therefore, $y_{\text{eq}} = a/b$. For $a \neq 0$, $y_{\text{eq}} \neq 0$. In order to have $d/(dt)y(t) = 0$, $-c + dx = 0$ has to be fulfilled. This leads to the pair $x_{\text{eq}} = c/d$ and $y_{\text{eq}} = a/b$. Thus, the Lotka–Volterra model has two pairs of equilibrium solutions. The first one, $x_{\text{eq}} = y_{\text{eq}} = 0$ corresponds to an extinction of both populations, whereas the second corresponds to a coexistence of predator and prey.

Let one reconsider the time-discrete logistic growth model [\(Eq. 15\)](#)

$$y(t+1) = Ry(t) \left(1 - \frac{y(t)}{K}\right) \quad (22)$$

The demand $y(t+1) = y(t)$ leads to the first solution $y_{\text{eq}1} = 0$ and

$$\begin{aligned} 1 &= R \left(1 - \frac{y}{K}\right) \Rightarrow \frac{K}{R} = K - y \\ &\Rightarrow y_{\text{eq}} = K \left(\frac{R-1}{R}\right) \end{aligned} \quad (23)$$

if $R \geq 1$. The second solution starts in zero for $R = 1$ and increases afterward – approaching K for $R \rightarrow \infty$.

Note the difference of the equilibrium solutions between the time-discrete and the time-continuous logistic growth. As the examples showed, there is more than one equilibrium solution in some cases. This immediately raises the question of how the system behaves:

- Are these points ever attained by the system?
- What happens if the system is in one of these fix points and a disturbance occurs. Does it return?

In other words, one has to address the question of the stability of the equilibrium solutions.

1.2.3 On the Stability of Equilibrium Solutions

This section provides a very short introduction to the analysis of the stability of equilibrium solutions. The concept of a local stability, that is, the behavior of solutions that start close to one of the equilibrium solutions, is considered.

First of all, the term “stability” has to be defined. An equilibrium solution is *stable*, if solutions of the system which start close to it remain close for all times. This form of stability is also called *Liapunov stability*. An equilibrium solution is called *asymptotically stable*, if solutions of the dynamical system which start close to the equilibrium solution approach the equilibrium solution (Wiggins 1990, p. 6).

The concept is illustrated by the simple linear system $y(t+1) = ay(t)$, $a \in \mathbb{R}$. The only equilibrium solution is $y_{\text{eq}} = 0$. The size of a decides the behavior of solutions starting close to the equilibrium. Consider a solution $y(t)$ of the linear system which starts close to $y_{\text{eq}} = 0$, for example, $y(t) = 0 + u(t)$ with $y(0) = u(0)$, $|u(0)|$ “small.” Due to the form of the equation, the “new system” leads to $u(t) = a^t u(0)$.

If $|a| < 1$, the system is (asymptotically) stable, since $u(t)$ converges to zero. For $|a| > 1$ it is unstable; the disturbance explodes as the system moves toward infinity. The case of $|a| = 1$ is a special one: The system leaves the equilibrium solution, and does neither return nor does it go toward infinity. It remains at the distance which was given by $|u(0)|$ and may show oscillating behavior depending on the sign of a . This is not a case of asymptotical stability but only of (Liapunov) stability.

Let one consider now the discrete time logistic growth model (❷ 15)

$$y(t+1) = Ry(t) \left(1 - \frac{y(t)}{K}\right) \quad (24)$$

with equilibrium solutions $y_{\text{eq}1} = 0$ and $y_{\text{eq}2} = K(1 - 1/R)$ for $R \geq 1$. In contrast to the previous example, the system is nonlinear. How can stability criteria be derived in this case? In general, one has a system with a nonlinear function $f: \mathbb{R} \rightarrow \mathbb{R}$

$$y(t+1) = f(y(t)) \quad (25)$$

Let $y(t)$ be a solution which starts close to the equilibrium solution y_{eq} , $y(t) = y_{\text{eq}} + u(t)$ with $|u(0) - y_{\text{eq}}| \leq \delta$, $\delta > 0$. How can information be gained on how $y(t)$ behaves? Considering solutions close to the equilibrium solution allows us to apply a Taylor series expansion for the function f around y_{eq}

$$\begin{aligned} y(t+1) &= f(y_{\text{eq}}) + \frac{d}{dy}f(y)|_{y=y_{\text{eq}}} u + \mathcal{O}(|u|^2) \\ y(t+1) - y_{\text{eq}} &= \frac{d}{dy}f(y)|_{y=y_{\text{eq}}} u(t) + \mathcal{O}(|u|^2) \\ u(t+1) &= \frac{d}{dy}f(y)|_{y=y_{\text{eq}}} u(t) + \mathcal{O}(|u|^2) \end{aligned} \quad (26)$$

Neglecting the quadratic and higher terms, it depends on the first derivative of f at the equilibrium solution whether the equilibrium solution is asymptotically stable or not. If

$|d/(dy)f(y_{eq})| < 1$, then y_{eq} is asymptotically stable. If $|d/(dy)f(y_{eq})| > 1$, then y_{eq} is unstable. (This can be proven formally, see, e.g., Wiggins (1990).) If $|d/(dy)f(y_{eq})| = 1$, the equilibrium solution is called *non-hyperbolic* and no information can be gained by using the approach presented. The opposite is a *hyperbolic* equilibrium solution. In this example of a nonlinear one-dimensional system, the equilibrium solution is called hyperbolic if the absolute value of the derivative of the function at the solution is not equal to one. In these cases, the linearization of the system via Taylor series expansion suffices completely for the analysis. If the point is non-hyperbolic, other methods have to be applied. A discussion of alternative ways to proceed can be found for instance in Wiggins (1990).

In the case of the discrete logistic growth [Eq. 15](#), the nonlinear function, f , reads

$$f(y) = Ry \left(1 - \frac{y}{K}\right) \text{ with} \quad (27)$$

$$\frac{d}{dy}f(y) = R \left(1 - 2 \frac{y}{K}\right) \quad (28)$$

The equilibrium solutions are $y_{eq1} = 0$ and $y_{eq2} = K(R - 1)/R$ for $R \geq 1$. It follows immediately that the first solution, $y_{eq1} = 0$, is stable for $R < 1$ and unstable for $R > 1$. In the case of the second solution,

$$\begin{aligned} \frac{d}{dy}f(y_{eq2}) &= R \left(1 - \frac{2y_{eq2}}{K}\right) \\ &= R \left(1 - \frac{2K}{K} \left(\frac{R-1}{R}\right)\right) \\ &= R \left(1 - 2 \left(\frac{R-1}{R}\right)\right) \\ &= R - 2R + 2 = 2 - R \end{aligned} \quad (29)$$

follows. Since stability requires $|d/(dy)f(y_{eq2})| < 1$, one proceeds with determining the zero point of $2 - R$ as $R_0 = 2$. Considering first $R \leq 2$, $2 - R < 1 \Rightarrow 1 < R$ has to hold in order that y_{eq2} is stable. The second equilibrium solution is stable for $R \in (1, 2]$. For $R > 2$, $R - 2 < 1 \Rightarrow R < 3$ must be fulfilled. In short, the second equilibrium point is stable for $R \in (1, 3)$. For all larger growth parameters, both equilibrium solutions are unstable. Note, though, that this system shows a very interesting behavior – exhibiting periodic solutions and moving toward a chaotic regime. Readers interested in a more thorough discussion of the behavior of the general logistic map are referred, for example, to Hofbauer and Sigmund ([2002](#)).

Let one now consider the N -dimensional linear system

$$\mathbf{y}(t+1) = \mathbf{A}\mathbf{y}(t) \quad (30)$$

with $\mathbf{y}(t) \in \mathbb{R}^N$, $\mathbf{A} \in \mathbb{R}^{N \times N}$, and initial value $\mathbf{y}(0)$. The only equilibrium solution is $\mathbf{y}_{eq} = \mathbf{0}$. To analyze the stability, consider a solution, $\mathbf{y}(t)$, starting close to \mathbf{y}_{eq} with $\mathbf{y}(t) = \mathbf{y}_{eq} + \mathbf{u}(t)$, $\|\mathbf{u}(0) - \mathbf{y}_{eq}\| \leq \delta$, $\delta > 0$ and system

$$\mathbf{u}(t+1) = \mathbf{A}\mathbf{u}(t) \quad (31)$$

The solution is given by

$$\mathbf{u}(t) = \mathbf{A}^t \mathbf{y}(0) = \mathbf{A}^t \mathbf{u}(0) \quad (32)$$

Although the system is now in closed form, the behavior of the system is not easy to discern. One way to simplify the analysis is to switch to an alternative coordinate system. Let one

consider the eigenvalues λ_i and eigenvectors \mathbf{v}_i of the quadratic matrix \mathbf{A} (to simplify the discussions, one assumes that \mathbf{A} is diagonalizable) and recall that $\mathbf{Av}_i = \lambda_i \mathbf{v}_i$. Setting $\mathbf{M} := (\mathbf{v}_1, \dots, \mathbf{v}_N)$ and $\Lambda := (\lambda_1 \mathbf{e}_1, \dots, \lambda_N \mathbf{e}_N)$, with \mathbf{e}_i denoting the i th unit vector, it follows that

$$\mathbf{AM} = \mathbf{M}\Lambda \Rightarrow \mathbf{M}^{-1}\mathbf{AM} = \Lambda \quad (33)$$

Setting $\mathbf{z}(t) := \mathbf{M}^{-1}\mathbf{u}(t)$, [Eq. 31](#) changes to

$$\mathbf{z}(t+1) = \Lambda \mathbf{z}(t) \quad (34)$$

with the solution

$$\mathbf{z}(t) = \Lambda^t \mathbf{z}(0) \quad (35)$$

or

$$\mathbf{u}(t) = \mathbf{M}\Lambda^t \mathbf{M}^{-1}\mathbf{u}(0) \quad (36)$$

respectively. The eigenvalues of \mathbf{A} determine the behavior. If $\max |\lambda_i| < 1$, then the system converges to zero: The equilibrium solution is stable. If $\max |\lambda_i| > 1$, the system diverges to infinity and the equilibrium solution is unstable. In both cases, equilibrium solution is hyperbolic. If $\max |\lambda_i| \leq 1$ and $|\lambda_i| = 1$ for at least one eigenvalue, the respective component of \mathbf{z} remains at the initial value. In this case, the system is stable. Note, this only holds for diagonalizable matrices.

As in the one-dimensional case, the findings for the linear system can be transferred to the nonlinear system. Again, a Taylor series expansion around the equilibrium solution can be used. The equivalent to the first derivative in the one-dimensional case is the Jacobian matrix or Jacobian for functions $f: \mathbb{R}^N \rightarrow \mathbb{R}^M$: It gives the partial derivatives of the function components.

Concerning the question of stability, the Jacobian is decisive, or more correctly, its eigenvalues λ_i . If $\max |\lambda_i| < 1$ holds, then the equilibrium solution is asymptotically stable. If $|\lambda_i| > 1$ holds for at least one eigenvalue, then the solution is not stable.

Generally, in the case of time-discrete dynamic systems, an equilibrium solution is called *hyperbolic* if no eigenvalue λ_i of the Jacobian has an absolute value (modulus) equal to one, that is, $|\lambda_i| \neq 1$ for all eigenvalues. If $\max |\lambda_i| < 1$ and $|\lambda_i| = 1$ for at least one eigenvalue, then the equilibrium solution is non-hyperbolic and other methods than the one presented have to be applied.

Note, that the discussion has been limited, in this section, to the stability of the equilibrium solutions of maps or difference equations, respectively. The stability of equilibrium solutions of differential equations has not been considered. However, the discussions can be transferred with minor changes. This becomes clear when considering the simple linear system

$$\frac{d}{dt}y(t) = ay(t) \quad (37)$$

with $a \in \mathbb{R}$. The only equilibrium solution is $y_{\text{eq}} = 0$. Consider a solution $y(t)$ of [Eq. 37](#) that starts close to $y_{\text{eq}} = 0$, that is, $y(t) = y_{\text{eq}} + u(t)$ with $|u(0)| \leq \delta$, $\delta > 0$. Then

$$\begin{aligned} \frac{d}{dt}y(t) &= \frac{d}{dt}u(t) = ay(t) = a(y_{\text{eq}} + u(t)) = au(t) \\ &\Rightarrow \frac{\frac{d}{dt}u(t)}{u(t)} = a \end{aligned} \quad (38)$$

holds, leading to

$$\begin{aligned}
 \frac{\frac{d}{dt}u(t)}{u(t)} &= a \\
 \Rightarrow \frac{d}{dt}\ln(u(t)) &= a \\
 \Rightarrow \ln\left(\frac{u(t)}{u(0)}\right) &= at \\
 \Rightarrow u(t) &= u(0)e^{at}
 \end{aligned} \tag{39}$$

Again, the constant a is decisive for the question of stability. For $a < 0$, the system (39) goes to zero: The equilibrium solution is asymptotically stable. For $a > 0$, the system diverges and the system is not stable. For $a = 0$, the solution remains at the starting point. Again, this is a case of Liapunov stability not of asymptotical stability. As in the case of maps, these findings can be transferred to the nonlinear case using Taylor series expansion and to the N -dimensional case via the eigenvalues of the Jacobian.

1.3 From Stochastic Processes to Dynamical Systems

The run of an evolutionary algorithm is a dynamical movement of the population in the search space. Due to random influences, for example mutation, the movement of an EA is stochastic. In other words, the algorithm induces a stochastic process which can be analyzed in several ways. The process itself takes place in a high-dimensional state space (dimensionality $\geq N$, N – search space dimension). However, it is often preferable to consider derived or aggregated quantities with respect to the task of the analysis: that is, whether the ES converges, how fast the optimizer is approached, how EA parameters influence the behavior, and whether the step-size adaptation mechanism works adequately.

The state of an evolution strategy can be characterized by so-called state variables: variables which characterize the important and interesting features and the system behavior completely. Common variables include the fitness values, the distance to the optimizer, $\hat{\mathbf{y}}$, (depending on the fitness model), and, if the effects of step-size adaptation mechanism shall be considered, the mutation strength.

The task is to model and to analyze the evolution of these state variables over time. In the following, the sphere model (71) is used for further explanations. Since the sphere model consists of functions of the form $f(\mathbf{y}) = g(\|\mathbf{y} - \hat{\mathbf{y}}\|) = g(R)$, the state variables are chosen as the distance to the optimizer $R^{(g)} := \|\mathbf{y}^{(g)} - \hat{\mathbf{y}}\|$ and the mutation strength $\sigma^{(g)}$ at generation g . The dynamics of an ES generate the stochastic process

$$\begin{pmatrix} R^{(g)} \\ \sigma^{(g)} \end{pmatrix} \rightarrow \begin{pmatrix} R^{(g+1)} \\ \sigma^{(g+1)} \end{pmatrix} \tag{40}$$

Till now, no closed solution for the transition kernels could be derived in general. The only exception is a (1, 2)-ES using the two-point rule for the mutation of the mutation strength (see Beyer 1996b or Beyer 2001b, p. 287).

Another way to proceed is to transform the stochastic process into a deterministic dynamical system in a first approximation (mean value dynamics) and into a Gaussian

random process in a second approximation. This is done via a step-by-step approach introduced in Beyer (1996b).

The approach introduces the *evolution equations*: stochastic difference equations or iterated maps, respectively, used to describe the change of the state variables during one generation.

The change of the random variables can be divided into two parts: The first denotes the expected change. The second part covers the random fluctuations and is denoted by ε_R or ε_σ . In their most general form, the evolution equations read

$$R^{(g+1)} = R^{(g)} - E[R^{(g)} - R^{(g+1)} | R^{(g)}, \sigma^{(g)}] + \varepsilon_R(R^{(g)}, \sigma^{(g)}) \quad (41)$$

$$\sigma^{(g+1)} = \sigma^{(g)} \left(1 + E \left[\frac{\sigma^{(g+1)} - \sigma^{(g)}}{\sigma^{(g)}} | R^{(g)}, \sigma^{(g)} \right] \right) + \varepsilon_\sigma(R^{(g)}, \sigma^{(g)}) \quad (42)$$

in the case of self-adaptation. The case of CSA is described below. In \blacktriangleright Eq. 41, a well-known *progress measure* appears: the *progress rate* φ_R . The progress rate measures the expected change of the distance in one generation

$$\varphi_R(\sigma^{(g)}, R^{(g)}) := E[R^{(g)} - R^{(g+1)} | \sigma^{(g)}, R^{(g)}] \quad (43)$$

In the case of the evolution of the mutation strength, a different progress measure is used when self-adaptation is considered. Note, since the mutation of the mutation strength is generally realized by a multiplication with a random variable, \blacktriangleright Eq. 42 gives the relative change. The progress measure is called the (first-order) *self-adaptation response* (SAR) ψ . The SAR gives the expected relative change of the mutation strength in one generation

$$\psi(\sigma^{(g)}, R^{(g)}) := E \left[\frac{\sigma^{(g+1)} - \sigma^{(g)}}{\sigma^{(g)}} | \sigma^{(g)}, R^{(g)} \right]. \quad (44)$$

This progress measure is not used in analyses of CSA-evolution strategies. In CSA, the change of the mutation strength is derandomized. The stochastic influences stem from the mutation of the object parameters and enter the progress vector $\mathbf{z}^{(g)}$ \blacktriangleright Eq. 2. Analyses of the CSA usually consider the evolution of the length of the evolutionary path $\|\mathbf{s}^{(g)}\|$, \blacktriangleright Eq. 4, and the mutation strength \blacktriangleright Eq. 6

$$\|\mathbf{s}^{(g+1)}\|^2 = (1 - c)^2 \|\mathbf{s}^{(g)}\|^2 + 2(1 - c) \sqrt{2\mu(2 - c)} (\mathbf{s}^{(g)})^T \mathbf{z}^{(g)} + \mu c(2 - c) \|\mathbf{z}^{(g)}\|^2 \quad (45)$$

$$\sigma^{(g+1)} = \sigma^{(g)} e^{\frac{\|\mathbf{s}^{(g+1)}\|^2 - N}{2DN}} \quad (46)$$

The fluctuation terms in \blacktriangleright Eqs. 41 and \blacktriangleright 42 present a problem: Their distribution is not known and must be approximated using a reference density. Common approaches comprise an expansion into a Gram–Charlier or Edgeworth series (see, e.g., Kolossa 2006). The reference distribution is usually (but not necessarily) chosen to be the normal distribution. In order to expand an unknown distribution at all, it must be possible to determine some of its moments or cumulants. If this is the case, the approach continues by standardizing the fluctuation terms using the mean and the standard deviations. Clearly, the conditional mean of ε_σ and ε_R is zero. Therefore, only the standard deviation remains to be determined.

The main points of the derivation are explained considering the case of ε_R . The case of the mutation strength is analogous. Let D_φ denote the standard deviation. Therefore, the standardized random part ε'_R is related to ε_R by $\varepsilon_R = D_\varphi \varepsilon'_R$. The standard deviation can

be derived via \blacktriangleright Eq. 41 since its square equals the second conditional moment of ε_R (note $E[\varepsilon_R] = 0$)

$$\begin{aligned} D_\varphi^2(\sigma^{(g)}, R^{(g)}) &= E\left[\varepsilon_R^2 | \sigma^{(g)}, R^{(g)}\right] = E\left[\left(R^{(g+1)} - R^{(g)} + \varphi_R(\sigma^{(g)}, R^{(g)})\right)^2 | \sigma^{(g)}, R^{(g)}\right] \\ &= E\left[\left(R^{(g+1)} - R^{(g)}\right)^2 | \sigma^{(g)}, R^{(g)}\right] - \varphi_R^2(\sigma^{(g)}, R^{(g)}) \end{aligned} \quad (47)$$

The distribution of ε_R is expanded into an Edgeworth series. For the analysis, the expansion is cut off after the first term (cf. Beyer (2001b, p. 265)). That is to say, it is supposed that the deviations from the normal distribution are negligible in the analysis scenario the equations will be applied to. The random variable ε_R reads

$$\varepsilon_R = D_\varphi(\sigma^{(g)}, R^{(g)}) \mathcal{N}(0, 1) + \dots \quad (48)$$

The expectation $E[(R^{(g+1)} - R^{(g)})^2 | \sigma^{(g)}, R^{(g)}]$ appearing in \blacktriangleright Eq. 47 is called the *second-order progress rate*

$$\varphi_R^{(2)}(\sigma^{(g)}, R^{(g)}) := E\left[\left(R^{(g+1)} - R^{(g)}\right)^2 | \sigma^{(g)}, R^{(g)}\right] \quad (49)$$

The random variable ε_σ is obtained similarly. As in the case of the distance, a first-order approach (i.e., the first term of the series expansion) is used

$$\varepsilon_\sigma = D_\psi(\sigma^{(g)}, R^{(g)}) \mathcal{N}(0, 1) + \dots \quad (50)$$

The derivation of the standard deviation is exactly the same. One has

$$\begin{aligned} D_\psi^2(\sigma^{(g)}, R^{(g)}) &= E\left[\varepsilon_\sigma^2 | \sigma^{(g)}, R^{(g)}\right] = E\left[\left(\sigma^{(g+1)} - \sigma^{(g)} - \sigma^{(g)}\psi(\sigma^{(g)}, R^{(g)})\right)^2 | \sigma^{(g)}, R^{(g)}\right] \\ &= (\sigma^{(g)})^2 E\left[\left(\frac{\sigma^{(g+1)} - \sigma^{(g)}}{\sigma^{(g)}}\right)^2 | \sigma^{(g)}, R^{(g)}\right] - (\sigma^{(g)})^2 \psi^2(\sigma^{(g)}, R^{(g)}) \end{aligned} \quad (51)$$

(cf. \blacktriangleright Eq. 42). Again, this introduces a new measure, the *second-order SAR*

$$\psi^{(2)}(\sigma^{(g)}, R^{(g)}) := E\left[\left(\frac{\sigma^{(g+1)} - \sigma^{(g)}}{\sigma^{(g)}}\right)^2 | \sigma^{(g)}, R^{(g)}\right] \quad (52)$$

Using the results obtained so far, the evolution equations can be rewritten as

$$R^{(g+1)} = R^{(g)} - \varphi_R(\sigma^{(g)}, R^{(g)}) + D_\varphi(\sigma^{(g)}, R^{(g)}) \mathcal{N}(0, 1) + \dots \quad (53)$$

$$\begin{aligned} \sigma^{(g+1)} &= \sigma^{(g)} \left(1 + \psi(\sigma^{(g)}, R^{(g)})\right) + D_\psi(\sigma^{(g)}, R^{(g)}) \mathcal{N}(0, 1) + \dots \\ &= \sigma^{(g)} \left(1 + \psi(\sigma^{(g)}, R^{(g)}) + D'_\psi(\sigma^{(g)}, R^{(g)}) \mathcal{N}(0, 1) + \dots\right) \end{aligned} \quad (54)$$

with $D'_\psi = D_\psi / \sigma^{(g)}$.

1.3.1 The Deterministic Evolution Equations

In most analyses, the fluctuation parts are neglected with the exception of Beyer (1996b). The evolution equations without perturbation parts are generally termed *deterministic evolution*

equations (Beyer 2001b). This approach serves well to extract the general characteristics of self-adaptive evolution strategies. The deterministic evolution equations read

$$R^{(g+1)} = R^{(g)} - E[R^{(g)} - R^{(g+1)} | \sigma^{(g)}, R^{(g)}] \quad (55)$$

$$\sigma^{(g+1)} = \sigma^{(g)} \left(1 + E \left[\frac{\sigma^{(g+1)} - \sigma^{(g)}}{\sigma^{(g)}} | \sigma^{(g)}, R^{(g)} \right] \right) \quad (56)$$

for σ SA. In the case of the CSA, \textcircled{O} Eq. 56 is replaced by the system \textcircled{O} 45), \textcircled{O} 46). Analyses can usually be conducted only in the case that the evolution approaches a time-invariant distribution or a stationary (steady) state. In the deterministic approach, this is characterized by $R^{(g+1)} = R^{(g)}$, $\|\mathbf{s}^{(g+1)}\|^2 = \|\mathbf{s}^{(g)}\|^2$ and $\sigma^{(g+1)} = \sigma^{(g)}$. Note, demanding stationarity of the $R^{(g)}$ -evolution equals a complete standstill of the ES. Often more interesting is the evolution equation of the normalized mutation strength $\sigma^{*(g)} := \sigma^{(g)} N / R^{(g)}$

$$\sigma^{*(g+1)} = \sigma^{*(g)} \left(\frac{1 + \psi(\sigma^{*(g)}, R^{(g)})}{1 - \frac{\varphi_R^*(\sigma^{*(g)}, R^{(g)})}{N}} \right) \quad (\sigma\text{SA}) \quad (57)$$

$$\sigma^{*(g+1)} = \sigma^{*(g)} \frac{R^{(g)}}{R^{(g+1)}} e^{\frac{\|\mathbf{s}^{(g+1)}\|^2 - N}{2DN}} \quad (\text{CSA}) \quad (58)$$

with $\varphi_R^* := \varphi_R N / R^{(g)}$ and $\sigma^{*(g+1)} = \sigma^{(g+1)} N / R^{(g+1)}$ since it admits a stationary state without requiring a stationary state of the $R^{(g)}$ -evolution. In the case of the CSA, $\|\mathbf{s}^{(g+1)}\|^2 = \|\mathbf{s}^{(g)}\|^2$ is additionally demanded.

The assumption of the existence of a stationary state is motivated by the observation that it is optimal in many cases for the mutation strength to scale with the distance to the optimizer. Optimal in this case refers to a local progress measure, that is, to a maximal expected gain during one generation.

1.3.2 Including the Fluctuations

Considering the perturbation parts complicates the analysis. \textcircled{O} Equations 53 and \textcircled{O} 54 describe a Markov process or a Gaussian random field, the transition densities p_{tr} of which have to be determined. The variables $R^{(g+1)}$, $R^{(g)}$, $\sigma^{(g+1)}$, and $\sigma^{(g)}$ are all random variables. Assuming decomposability of the joint density of σ and R , the density of the distance R at generation g is denoted with $p(R^{(g)})$ and the density of the mutation strength with $p(\sigma^{(g)})$. As pointed out in Beyer (2001b, p. 313), it generally suffices to concentrate on some of the moments, generally the expected values, and not to determine the complete distribution

$$\begin{aligned} \overline{R^{(g+1)}} &= \int_0^\infty R^{(g+1)} p(R^{(g+1)}) dR^{(g+1)} \\ &= \int_0^\infty \int_0^\infty (R^{(g)} - \varphi_R(R^{(g)}, \sigma^{(g)})) p(\sigma^{(g)}) p(R^{(g)}) dR^{(g)} d\sigma^{(g)} \end{aligned} \quad (59)$$

$$\begin{aligned} \overline{\sigma^{(g+1)}} &= \int_0^\infty \sigma^{(g+1)} p(\sigma^{(g+1)}) d\sigma^{(g+1)} \\ &= \int_0^\infty \int_0^\infty \sigma^{(g)} ((1 + \psi(\sigma^{(g)}, R^{(g)})) p(\sigma^{(g)}) p(R^{(g)}) d\sigma^{(g)} dR^{(g)}) \end{aligned} \quad (60)$$

As can be inferred from [Eqs. 59](#) and [60](#), the transition densities are not needed if only the expected values are to be determined.

An equilibrium or a time-invariant limit distribution of a stochastic process is then characterized by a convergence to an equilibrium distribution, that is, $\lim_{g \rightarrow \infty} p(\sigma^{(g+1)}) = \lim_{g \rightarrow \infty} p(\sigma^{(g)}) = p_\infty(\sigma)$. Note, only the normalized mutation strength converges toward an equilibrium as long as the ES progresses still. If a stationary state is reached, the invariant density solves the eigenvalue equation

$$cp_\infty(\sigma) = \int_0^\infty p_{\text{tr}}(\sigma|\sigma)p_\infty(\sigma) d\sigma \quad (61)$$

with $c = 1$ and p_{tr} the transition density. In general, the equilibrium distribution p_∞ is unknown. As pointed out in Beyer ([2001b](#), p. 318), it is possible to determine p_∞ numerically or even analytically. The results, however, tend to be quite complicated and do not allow a further analytical treatment. Instead of trying to obtain the distribution itself, the expected value is obtained by analyzing the mean value dynamics of the system. Unfortunately, the form of the evolution equations hinders a direct determination of the expectation since in general lower order moments depend on higher order moments leading to a nonending recursion.

1.4 Local Progress Measures

This section briefly describes some local progress measures. Local refers to the concept of time: They describe the (expected) changes for two consecutive generations.

1.4.1 Quality Gain

The *quality gain* is a local performance measure or local progress measure in fitness space. Instead of the expected change in distance to the objective, it gives the expected change of the fitness from one parent population to the next. It depends on the state $\mathcal{P}^{(g)}$ of the evolution strategy at generation g

$$\overline{\Delta Q(\mathbf{y}^{(g)})} := E[F(\mathbf{y}^{(g+1)})_p - F(\mathbf{y}^{(g)})_p | \mathcal{P}^{(g)}] \quad (62)$$

When considering the $(\mu/\mu, \lambda)$ -ES, the fitness of the parent populations is usually defined as the fitness of the centroid, that is, $F(\mathbf{y}^{(g)})_p := F(\langle \mathbf{y}^{(g)} \rangle)$ with $\langle \mathbf{y}^{(g)} \rangle := (1/\mu) \sum_{m=1}^{\mu} \mathbf{y}_m^{(g)}$. Another possible definition for an ES with μ parents is for instance the average fitness $F(\mathbf{y}^{(g)})_p := \langle F(\mathbf{y}^{(g)}) \rangle := (1/\mu) \sum_{m=1}^{\mu} F(\mathbf{y}_m^{(g)})$. The definitions are not equivalent except for $\mu = 1$.

The parental population at $g + 1$ consists of the μ best candidate solutions with respect to their fitness – or with respect to the fitness change to a constant reference point. In the case of “plus”-strategies, the new parental population can contain old parental individuals of generation g . In the case of “comma”-strategies, the populations are disjunct and the determination of [Eq. 62](#) is usually simpler. The expectations can be calculated by obtaining the distribution of the offspring conditional to the state at g and using order statistics (Arnold et al. ([1992](#))). An important quantity is the *local quality change* or *local fitness change* induced by a mutation

$$Q_y(\mathbf{z}) = F(\mathbf{y} + \mathbf{z}) - F(\mathbf{y}) \quad (63)$$

being usually the starting point for the determination of the quality gain and the progress rate.

1.4.2 Progress Rate

The *progress rate* is a local performance measure in parameter space. Progress rates measure the expected change of the distance to the optimizer or other reference points $\hat{\mathbf{y}}$

$$\varphi := E[\|\mathbf{y}_P^{(g)} - \hat{\mathbf{y}}\| - \|\mathbf{y}_P^{(g+1)} - \hat{\mathbf{y}}\| | \mathcal{P}^{(g)}] \quad (64)$$

This is not mandatory, however. On functions with no finite optimizer, for instance linear or ridge functions, the progress rate measures the speed (i.e., the rate of change) in a predefined direction. When considering ridge functions, for example, a progress rate can be defined to measure the expected difference of the axial component for two consecutive generations.

Like the quality gain, the progress rate considers the parent population. Again, there are several possibilities for a definition. On the one hand, it is possible to define the progress rate as the expected change of the distance of two parental centroids

$$\varphi := E[\langle \|\mathbf{y}^{(g)}\| - \hat{\mathbf{y}} \rangle - \langle \|\mathbf{y}^{(g+1)}\| - \hat{\mathbf{y}} \rangle | \mathcal{P}^{(g)}] \quad (65)$$

Alternatively,

$$\varphi := E[\langle \|\mathbf{y}^{(g)} - \hat{\mathbf{y}}\| \rangle - \langle \|\mathbf{y}^{(g+1)} - \hat{\mathbf{y}}\| \rangle | \mathcal{P}^{(g)}] \quad (66)$$

with $\langle \|\mathbf{y}^{(g)} - \hat{\mathbf{y}}\| \rangle := (1/\mu) \sum_{m=1}^{\mu} \|\mathbf{y}_m^{(g)} - \hat{\mathbf{y}}\|$ is also possible. As in the case of the quality gain, both definitions are not interchangeable except for $\mu = 1$. The determination of the progress rate requires either the determination of the distribution of the distances of the m th best individuals, $m = 1, \dots, \mu$, or the determination of the distribution of the distance of the centroid of the μ best individuals. For “plus”-strategies, the best individuals are taken from the offspring and parent population. Again, “comma”-strategies lead to disjunct populations and are easier to analyze. It should be noted that the m th best candidate solution means the solution with m th best fitness, not distance. It is therefore necessary to derive the distribution of the distance connected to the m th best fitness. Unless there is a straightforward relationship of distance and fitness, this task may not be solvable.

The progress rate is often used to derive the efficiency of an ES. The *serial efficiency* is defined as

$$\eta := \frac{\max_{\sigma} \varphi(\sigma)}{\lambda} \quad (67)$$

that is, the maximal progress per offspring or fitness evaluation. The measure can be used to compare different strategies assuming an optimally working step-size adaptation mechanism.

1.4.3 Self-Adaptation Response (SAR)

Self-Adaptation refers to a specific way to adapt control parameters of evolutionary algorithms. In short, if parameters are changed dynamically and according to feedback from the evolutionary process, the control rule is *adaptive*, and it is *self-adaptive* if the control is left to the EA itself. The *self-adaptation response (SAR)* is the expectation of the one-generational change of the mutation strength $\sigma_P^{(g)}$ of the parent population

$$\psi(\sigma_P^{(g)}, \mathcal{P}^{(g)}) := E\left[\frac{\sigma_P^{(g+1)} - \sigma_P^{(g)}}{\sigma_P^{(g)}} | \mathcal{P}^{(g)}\right] \quad (68)$$

given the state of the algorithm at generation g . The relative change is considered because the mutation of the mutation strength is usually realized by a multiplication with a random number.

The SAR is not used in analyses of CSA-evolution strategies. However, the *logarithmic adaptation response*

$$\Delta_\sigma := \ln\left(\frac{\sigma^{(g+1)}}{\sigma^{(g)}}\right) \quad (69)$$

is often considered. While it is not a progress measure per se, the measure is similar to the integrand in [Eq. 68](#) for $\sigma^{(g+1)} \approx \sigma^{(g)}$, since the logarithm has the series expansion $\ln(x) = \sum_{k=1}^{\infty} (1/k)(x-1)^k(-1)^{k-1}$ for $x \neq 0$. For $x \approx 1$, $\ln(x) \approx x - 1$ and $\ln(\sigma^{(g+1)} / \sigma^{(g)}) \approx (\sigma^{(g+1)} - \sigma^{(g)}) / \sigma^{(g)}$.

2 Results from the Local Progress and Dynamical Systems Approach

This section presents results obtained using the local progress and dynamical systems approach. Firstly, some fitness functions that were used in the analyses are introduced. Secondly, the $(\mu/\mu_b, \lambda)$ -ES is used on the sphere to explain how to derive a local progress measure, the quality gain, in detail. Afterward, the case of undisturbed fitness environments is considered. In practical optimization tasks, exact function values or exact information on the position in the search space often cannot be obtained. Therefore, noise is an important factor that has to be taken into account. The results for noisy and robust optimization are presented in the remaining part of this section.

2.1 Fitness Environments Considered

This section gives a short overview of test functions considered in the analysis.

2.1.1 Linear Functions

Linear functions are given by

$$F_{lf}(\mathbf{y}) = \mathbf{c}^T \mathbf{y} \quad (70)$$

with $\mathbf{c} \in \mathbb{R}^N$. The task is usually maximization. Since the “optimum” lies in infinity, the ES has to increase the fitness perpetually. Linear functions can be used to analyze, for instance, the effectiveness of the step-size adaptation mechanism.

2.1.2 Sphere Model

The sphere model is given by

$$F_{sphere}(\mathbf{y}) = g(\|\hat{\mathbf{y}} - \mathbf{y}\|) =: g(R) \quad (71)$$

with $\hat{\mathbf{y}}$ the optimal state and g either a strictly monotonically increasing or strictly monotonically decreasing function of $\|\hat{\mathbf{y}} - \mathbf{y}\|$. The simplest form of the sphere is

$$F_{\text{sphere}}(\mathbf{y}) = \beta \|\hat{\mathbf{y}} - \mathbf{y}\|^{\alpha} =: \beta R^{\alpha} \quad (72)$$

The sphere model is a simple test function, generally modeling more general functions in the vicinity of the optimizer. It is used to gain deeper insights into the working mechanisms of the evolutionary algorithm, its convergence speed and its scaling behavior with respect to the search space dimensionality N .

2.1.3 General Quadratic Functions

An extension of the sphere model is the function class of general quadratic functions

$$F_{\text{GQF}}(\mathbf{y}) = \mathbf{b}^T \mathbf{y} - \mathbf{y}^T \mathbf{Q} \mathbf{y} \quad (73)$$

with \mathbf{Q} a symmetric, positive definite $\mathbb{R}^{N \times N}$ matrix and \mathbf{b} an N -dimensional vector with $b_i \in \mathbb{R}$. The sphere (❷ Eq. 72) with $\alpha = 2$ and $\hat{\mathbf{y}} = \mathbf{0}$ is therefore a special case of general quadratic functions with $\mathbf{b} = \mathbf{0}$ and $\mathbf{Q} = \beta \mathbf{I}$.

2.1.4 Biquadratic Functions

Biquadratic functions are defined by

$$F_{\text{BQF}}(\mathbf{y}) = \sum_{i=1}^n a_i y_i - c_i y_i^4 \quad (74)$$

with $a_i \in \mathbb{R}$ and $c_i \in \mathbb{R}$.

2.1.5 Ridge Functions

The general ridge function, with axis direction \mathbf{v} and parameters α and d determining the shape of the ridge, is given by

$$F_{\text{gR}}(\mathbf{y}) := \mathbf{v}^T \mathbf{y} - d \left(\sqrt{(\mathbf{v}^T \mathbf{y} - \mathbf{y})^T (\mathbf{v}^T \mathbf{y} - \mathbf{y})} \right)^{\alpha} \quad (75)$$

with $d > 0$ and $\alpha > 0$. The vector $\mathbf{v} \in \mathbb{R}^N$ with $\|\mathbf{v}\| = 1$ is called the ridge direction. Usually, a rotated version of ❷ Eq. 75 is considered

$$F_{\text{ridge}}(\mathbf{y}) = y_1 - d \left(\sum_{i=2}^N y_i^2 \right)^{\frac{\alpha}{2}} \quad (76)$$

In this model, the ridge axis aligns with the coordinate axis $y_1 \mathbf{e}_1$ (Beyer 2001a). Ridge functions consist of two parts: a linear gain part and a nonlinear loss part. The loss part in ❷ Eq. 76 resembles an $(N - 1)$ -dimensional sphere. The $(N - 1)$ -terms which make up the sphere component of the ridge can be interpreted as an $(N - 1)$ -dimensional distance to the axis $y_1 \mathbf{e}_1$. Two parameters appear in ❷ Eq. 76: the weighting constant $d > 0$ and the parameter $\alpha > 0$. The latter determines the topology of the fitness landscape. Ridge functions with $\alpha = 1$ are

called *sharp ridges*, with $\alpha = 2$ *parabolic ridges*, and with $\alpha = 3$ *cubic ridges*. The constant d weights the influence of the embedded sphere. In general, if $d \rightarrow 0$, the problem degenerates to the hyperplane $F(\mathbf{y}) = y_1$, whereas for increasing d , the isofitness lines appear more and more parallel to the axis and the problem approaches a sphere model with $F(\mathbf{y}) = -d(\sum_{i=2}^N y_i^2)^{\alpha/2}$.

Ridge functions do not have a finite optimum and therefore may be considered an “ill-posed” problem for ES (Arnold and Beyer 2008): Since the “optimum” lies in infinity, the fitness of the ES must be steadily increased. Improvement is possible in many ways. Generally, there are two viewpoints that may be taken (Beyer 2001a). The first viewpoint states (Oyman 1999, p. 32) the “object variable for the optimum [...]” reads

$$\hat{y}_1 \rightarrow \infty, \forall i \neq 1: \hat{y}_i = 0.$$

This viewpoint derives its justification from seeing ridge functions as the limit of

$$F_c(\mathbf{y}) = y_1 - cy_1^2 - d\left(\sum_{i=2}^N y_i^2\right)^{\alpha/2} \quad (77)$$

for $c \rightarrow 0$ (cf. Oyman 1999 and Beyer 2001a). For every finite c , F_c has an optimal point at $(1/(2c), 0, \dots, 0)^T$. If c decreases, the position on the axis moves toward infinity.

Evolution strategies use local information. They sample the search space randomly and select the μ best offspring, that is, the candidate solutions with the μ highest fitness values. This is the foundation of the second viewpoint which takes a more process-oriented view: The ridge does not have a finite optimum. The algorithm is required to increase the fitness perpetually. This does not necessarily mean that it has to find the ridge. Although the highest fitness value is on the axis for every finite interval, the situation changes if an unbounded search space is considered. Actually, it is not even necessary to require a finite distance to the ridge. Since the search space is infinite, there are infinitely many points in arbitrary distance to the ridge with exactly the same fitness as a position on the axis. As a result, the ES may diverge from the axis – as long as it increases the linear component faster than the loss components, it still increases the overall fitness.

2.2 Example: The $(\mu/\mu_l, \lambda)$ -Evolution Strategy on the Sphere

The determination of the quality gain of the $(\mu/\mu_l, \lambda)$ -ES is used in the following as an illustrative example. The fitness environment considered is the sphere model with $g(\mathbf{y}) = -\|\mathbf{y} - \hat{\mathbf{y}}\|^2$. The quality gain for the $(\mu/\mu_l, \lambda)$ -ES is defined as the expected change

$$\begin{aligned} \overline{\Delta Q} &:= E\left[-\|\langle \mathbf{y}^{(g+1)} \rangle - \hat{\mathbf{y}}\|^2 - \left(-\|\langle \mathbf{y}^{(g)} \rangle - \hat{\mathbf{y}}\|^2\right)\right] \\ &= E[\|\langle \mathbf{y}^{(g)} \rangle - \hat{\mathbf{y}}\|^2 - \|\langle \mathbf{y}^{(g+1)} \rangle - \hat{\mathbf{y}}\|^2] =: E[(R^{(g)})^2 - (R^{(g+1)})^2] =: E[R^2 - r^2] \end{aligned} \quad (78)$$

of the squared distances of two consecutive centroids $\langle \mathbf{y} \rangle = (1/\mu) \sum_{m=1}^{\mu} \mathbf{y}_m$ to the optimizer $\hat{\mathbf{y}}$. The determination of the quality gain requires the determination of the expected value of $E[r^2]$, the squared distance of the centroid of the μ best offspring. An offspring l is created by adding a *mutation vector* \mathbf{x}_l to the centroid of the parent population $\langle \mathbf{y} \rangle$: $\mathbf{y}_l = \langle \mathbf{y} \rangle + \mathbf{x}_l$. Due to its form, the sphere model allows for a very useful simplification of the representation of the original N -dimensional system by a change of the coordinate system: At generation g , the

population's centroid is in a position $\langle \mathbf{y} \rangle$. The distance vector to the optimizer $\hat{\mathbf{y}}$ is well defined and given by \mathbf{R} . First of all, every vector can be expressed by another vector with origin in \mathbf{R} . The vector \mathbf{R} also defines a perpendicular plane. Together, the vector and the base of the plane build an alternative base for the N -dimensional space. Changing the coordinate system, every other vector can be expressed by a vector with origin in \mathbf{R} and with a component in \mathbf{R} -direction and a perpendicular component.

This holds also for \mathbf{r}_l , the distance vector of an offspring l , which can be written as $\mathbf{r}^l = \mathbf{R} - x_R^l \mathbf{e}_R + \mathbf{h}_R^l$ with $x_R^l \mathbf{e}_R$ the part in the plane of \mathbf{R} and \mathbf{h}_R^l in the perpendicular plane (see Fig. 3). The same decomposition can be applied to the distance vector \mathbf{r} of the centroid which is given by $\mathbf{r} = \langle \mathbf{y} \rangle - \hat{\mathbf{y}} + \langle \mathbf{x} \rangle = \mathbf{R} + \langle \mathbf{x} \rangle$. The vector $\langle \mathbf{x} \rangle$ can be decomposed into a part $\langle x_R \rangle \mathbf{e}_R$ in the direction of \mathbf{R} and into a perpendicular part $\langle \mathbf{h}_R \rangle$. The squared length is therefore

$$\begin{aligned} r^2 &= \mathbf{r}^T \mathbf{r} = (\mathbf{R} - \langle x_R \rangle \mathbf{e}_R + \langle \mathbf{h}_R \rangle)^T (\mathbf{R} - \langle x_R \rangle \mathbf{e}_R + \langle \mathbf{h}_R \rangle) \\ &= R^2 - 2R\langle x_R \rangle + \langle x_R \rangle^2 + \langle \mathbf{h}_R \rangle^2 \end{aligned} \quad (79)$$

The vector $\langle \mathbf{x} \rangle$ consists of the μ best mutations $\mathbf{x}_{m;\lambda}$, $m = 1, \dots, \mu$

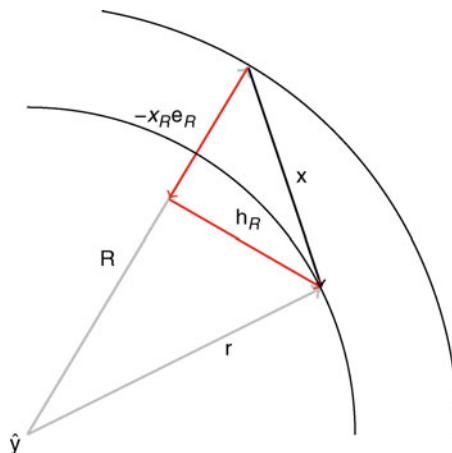

$$\langle \mathbf{x} \rangle = \frac{1}{\mu} \sum_{m=1}^{\mu} \mathbf{x}_{m;\lambda} \quad (80)$$

with $\mathbf{x}_{m;\lambda}$ standing for the m th best mutation with respect to the fitness change. The determination of the expected value of r^2 requires the determination of the expectation of the central component $\langle x_R \rangle$, that is, of the mean of the central components of the μ best mutations and of the square of the radial component $\langle \mathbf{h}_R \rangle^2$. Let one first consider $\langle \mathbf{h}_R \rangle^2$. The expectation reads

$$\overline{\langle \mathbf{h}_R \rangle^2} = E \left[\frac{1}{\mu^2} \sum_{m=1}^{\mu} \sum_{k=1}^{\mu} \mathbf{h}_{m;\lambda}^T \mathbf{h}_{k;\lambda} \right] = E \left[\frac{1}{\mu^2} \sum_{m=1}^{\mu} (\mathbf{h}_{m;\lambda})^2 \right] + E \left[\frac{1}{\mu^2} \sum_{m=1}^{\mu} \sum_{k=2, k \neq m}^{\mu} \mathbf{h}_{m;\lambda}^T \mathbf{h}_{k;\lambda} \right] \quad (81)$$

Fig. 3

The decomposition of the mutation vector in the case of the sphere model.

The expectation of the latter part is zero since $E[\mathbf{h}_{m;\lambda}^T \mathbf{h}_{k;\lambda}]$ for $m \neq k$. The perpendicular parts are selectively neutral and thus independent. Therefore,

$$\overline{\langle \mathbf{h}_R \rangle^2} = E\left[\frac{1}{\mu^2} \sum_{m=1}^{\mu} (\mathbf{h}_{m;\lambda})^2\right] = \frac{1}{\mu} \overline{\langle \mathbf{h}_R^2 \rangle} \quad (82)$$

holds. To obtain the expected value of the central and radial components of the μ best mutations, one considers the mutation-induced change of the fitness. The squared distance r_l^2 of an offspring is given by

$$r_l^2 = R^2 - 2Rx_R^l + (x_R^l)^2 + (\mathbf{h}_R^l)^2 \quad (83)$$

Without loss of generality, due to the isotropy of the mutations, one assumes that \mathbf{e}_R aligns with the first component of the coordinate system. The first component is therefore normally distributed with standard deviation σ . The radial component consists of the remaining $(N-1)$ -components – each also normally distributed

$$r_l^2 = R^2 - 2R\sigma z_x + \sigma^2 z_x^2 + \sigma^2 \sum_{i=2}^N \mathcal{N}_i(0, 1)^2 \quad (84)$$

with $z_x \sim \mathcal{N}(0, 1)$. In the following, a normalization for σ is introduced, setting $\sigma^* := \sigma N/R$. Therefore, the equation changes to

$$\begin{aligned} r_l^2 &= R^2 - 2\frac{R^2}{N} \sigma^* z_x + \frac{R^2}{N^2} \sigma^{*2} z_x^2 + \frac{R^2}{N^2} \sigma^{*2} \sum_{i=2}^N \mathcal{N}_i(0, 1)^2 \\ &= R^2 - 2\frac{R^2}{N} \sigma^* z_x + \frac{R^2}{N^2} \sigma^{*2} \sum_{i=1}^N \mathcal{N}_i(0, 1)^2 \end{aligned} \quad (85)$$

The determination of the quality gain is restricted to $N \gg 1$. According to the law of large numbers, $\sum_{i=1}^N \mathcal{N}_i(0, 1)^2/N$ goes to $E[\mathcal{N}(0, 1)^2] = 1$ for $N \rightarrow \infty$. Therefore, $(R^2/N^2) \sigma^{*2} \sum_{i=1}^N \mathcal{N}_i(0, 1)^2$ approaches $(R^2/N)\sigma^{*2}$ for increasing N . Furthermore, according to the central limit theorem, $(1/N) \sum_{i=1}^N \mathcal{N}_i(0, 1)^2$ approaches $\mathcal{N}(1, (2/N))$. Therefore, the contribution of the fluctuations of the squared random variables can be neglected and only the mean must be taken into account

$$r_l^2 = R^2 - 2\frac{R^2}{N} \sigma^* z_x + \frac{R^2}{N} \sigma^{*2} \quad (86)$$

The same holds for the contribution of $\overline{\langle \mathbf{h}_R^2 \rangle}$ which approaches

$$\frac{R^2}{N\mu} \sigma^{*2} \quad (87)$$

for increasing N . Only the contribution of the central component has to be considered. In the case of a single offspring, $z_x \sim \mathcal{N}(0, 1)$ is the only remaining random variable. The m th best offspring or mutation is characterized by having the m th smallest r_l^2 or the m th largest z_x value, out of λ random samples from the standard normal distribution. The expected value of $\langle z_x \rangle$ is thus the mean of the expectation of the first μ order statistics $u_{1;\lambda}, \dots, u_{\mu;\lambda}$ of the standard normal distribution

$$\overline{\langle z_x \rangle} = \frac{1}{\mu} \sum_{m=1}^{\mu} E[u_{m;\lambda}] = \frac{1}{\mu} \sum_{m=1}^{\mu} \int_{-\infty}^{\infty} up_{m;\lambda}(u) du \quad (88)$$

The m th order statistic $u_{m;\lambda}$ is associated with the m th largest outcome. In other words, $(m - 1)$ values must be larger than $u_{m;\lambda}$, and $(\lambda - m)$ values must be smaller. For this constellation, there are $\binom{\lambda - 1}{m - 1}$ different possibilities. Since there are λ trials, it follows

$$p_{m;\lambda}(u) = \lambda \binom{\lambda - 1}{m - 1} \frac{e^{-\frac{u^2}{2}}}{\sqrt{2\pi}} (1 - \Phi(u))^{m-1} \Phi(u)^{\lambda-m} \quad (89)$$

with $\Phi(u)$ the cumulative distribution function (cdf) of the standard normal distribution. The expectation of the mean reads

$$\begin{aligned} \overline{\langle z_x \rangle} &= \frac{1}{\mu} \sum_{m=1}^{\mu} \int_{-\infty}^{\infty} u \frac{e^{-\frac{u^2}{2}}}{\sqrt{2\pi}} \lambda \binom{\lambda - 1}{m - 1} (1 - \Phi(u))^{m-1} \Phi(u)^{\lambda-m} du \\ &= \int_{-\infty}^{\infty} u \frac{e^{-\frac{u^2}{2}}}{\sqrt{2\pi}} \mu \sum_{m=1}^{\mu} \binom{\lambda - 1}{m - 1} (1 - \Phi(u))^{m-1} \Phi(u)^{\lambda-m} du \end{aligned} \quad (90)$$

Let one first consider the sum in $\textcircled{2}$ Eq. 90

$$\begin{aligned} \sum_{m=1}^{\mu} \binom{\lambda - 1}{m - 1} (1 - \Phi(u))^{m-1} \Phi(u)^{\lambda-m} &= \sum_{m=0}^{\mu-1} \binom{\lambda - 1}{m} (1 - \Phi(u))^m \Phi(u)^{\lambda-m-1} \\ &= 1 - \sum_{m=\mu}^{\lambda-1} \binom{\lambda - 1}{m} (1 - \Phi(u))^m \Phi(u)^{\lambda-m-1} \end{aligned} \quad (91)$$

This sum can be expressed by an integral. To this end, the regularized incomplete beta function $I_x(a, b)$ is considered

$$I_x(a, b) := \frac{1}{B(a, b)} \int_0^x t^{a-1} (1-t)^{b-1} dt \quad (92)$$

with $B(a, b) = \Gamma(a)\Gamma(b)/\Gamma(a+b)$ as the complete beta function. The function $\Gamma(a)$ is the Gamma function with $\Gamma(a) = (a-1)!$ for $a \in \mathbb{N}$. The series representation of $\textcircled{2}$ Eq. 92 reads

$$I_x(a, b) := \sum_{j=a}^{a+b-1} \binom{a+b-1}{j} x^j (1-x)^{a+b-1-j} \quad (93)$$

(see, e.g., Abramowitz and Stegun 1984). The sum $\textcircled{2}$ Eq. 91 is therefore

$$\begin{aligned} \sum_{m=1}^{\mu} \binom{\lambda - 1}{m - 1} (1 - \Phi(u))^{m-1} \Phi(u)^{\lambda-m} &= \sum_{m=0}^{\mu-1} \binom{\lambda - 1}{m} (1 - \Phi(u))^m \Phi(u)^{\lambda-m-1} \\ &= 1 - \sum_{m=\mu}^{\lambda-1} \binom{\lambda - 1}{m} (1 - \Phi(u))^m \Phi(u)^{\lambda-m-1} \\ &= 1 - I_{1-\Phi(u)}(\mu, \lambda - \mu) \end{aligned} \quad (94)$$

Since $I_x(a, b) = 1 - I_{1-x}(b, a)$, one has

$$\begin{aligned} \sum_{m=1}^{\mu} \binom{\lambda - 1}{m - 1} (1 - \Phi(u))^{m-1} \Phi(u)^{\lambda-m} &= \sum_{m=0}^{\mu-1} \binom{\lambda - 1}{m} (1 - \Phi(u))^m \Phi(u)^{\lambda-m-1} \\ &= I_{\Phi(u)}(\lambda - \mu, \mu) \\ &= \frac{(\lambda - 1)! \int_0^{\Phi(u)} t^{\lambda-\mu-1} (1-t)^{\mu-1} dt}{(\lambda - \mu - 1)! (\mu - 1)!} \end{aligned} \quad (95)$$

The expectation (Eq. 90) therefore reads

$$\overline{\langle z_x \rangle} = \int_{-\infty}^{\infty} \frac{ue^{-\frac{u^2}{2}}}{\sqrt{2\pi}} \left(\frac{\lambda}{\mu} \right) \frac{(\lambda-1)!}{(\lambda-\mu-1)!(\mu-1)!} \int_0^{\Phi(u)} t^{\lambda-\mu-1} (1-t)^{\mu-1} dt du$$

Changing the integration order leads to

$$\overline{\langle z_x \rangle} = \frac{\lambda!}{(\lambda-\mu)!\mu!} \int_0^1 \left(\int_{\Phi^{-1}(t)}^{\infty} \frac{ue^{-\frac{u^2}{2}}}{\sqrt{2\pi}} du \right) t^{\lambda-\mu-1} (1-t)^{\mu-1} dt$$

Setting $t := \Phi(x)$, $dt = \exp(-x^2/2)/\sqrt{2\pi} dx$ leads to

$$\begin{aligned} \overline{\langle z_x \rangle} &= \frac{\lambda!}{(\lambda-\mu-1)!\mu!} \int_{-\infty}^{\infty} \int_x^{\infty} \frac{ue^{-\frac{u^2}{2}}}{\sqrt{2\pi}} du \Phi(x)^{\lambda-\mu-1} (1-\Phi(x))^{\mu-1} \frac{e^{-\frac{x^2}{2}}}{\sqrt{2\pi}} dx \\ &= \frac{\lambda!}{(\lambda-\mu-1)!\mu!} \int_{-\infty}^{\infty} \Phi(x)^{\lambda-\mu-1} (1-\Phi(x))^{\mu-1} \frac{e^{-\frac{x^2}{2}}}{2\pi} dx \\ &= (\lambda-\mu) \binom{\lambda}{\mu} \int_{-\infty}^{\infty} \Phi(x)^{\lambda-\mu-1} (1-\Phi(x))^{\mu-1} \frac{e^{-\frac{x^2}{2}}}{2\pi} dx =: c_{\mu/\mu,\lambda} \end{aligned} \quad (96)$$

In general, the integral (Eq. 96) cannot be solved analytically – only numerically. It is a special case of the so-called generalized progress coefficients introduced in Beyer (1995b). Plugging Eqs. 96 and 87 into Eq. 78, the expected value of the squared distance r^2 becomes

$$E[r^2] = R^2 - 2 \frac{R^2}{N} \sigma^* c_{\mu/\mu,\lambda} + \frac{R^2}{N\mu} \sigma^{*2} \quad (97)$$

leading to the quality gain

$$\overline{\Delta Q} = R^2 - E[r^2] = R^2 \left(\frac{2\sigma^*}{N} c_{\mu/\mu,\lambda} - \frac{\sigma^{*2}}{\mu N} \right) \quad (98)$$

Using the normalization $\overline{\Delta Q^*} := N\overline{\Delta Q}/(2R^2)$ gives the final expression

$$\overline{\Delta Q^*} = c_{\mu/\mu,\lambda} \sigma^* - \frac{\sigma^{*2}}{2\mu} \quad (99)$$

Note, due to the normalization, this quality gain is asymptotically equal to the normalized progress rate φ^* .

The result (Eq. 99) can be used to discuss the influence of the normalized mutation strength on the performance, to determine optimal values, and to compare different evolution strategies. Since the derivation assumed a large search space dimensionality, Eq. 99 is asymptotically exact for $N \rightarrow \infty$. In the case of small N , Eq. 99 may be regarded as a simple approximation of the real quality gain. The quality gain Eq. 99 consists of two parts: a linear gain part and a nonlinear loss part. Therefore, Eq. 99 adheres to the *evolutionary progress principle* (EPP) which states that any evolutionary progress is a combination of progress gain and progress loss (see, e.g., Beyer 2001b, p. 20). Another effect that appears in Eq. 99 is the so-called *genetic repair effect* due to intermediate recombination. Recombination reduces the loss part, as indicated by the factor $1/\mu$. As a result, the ES can operate with larger mutation strengths. A more complete discussion of the genetic repair effect can be found in the following section.

2.3 Undisturbed Fitness Environments

This section describes the results obtained so far for undisturbed fitness environments. The overview starts with the sphere model and then proceeds to the discussion of other fitness functions. Afterward, analyses devoted to the step-size adaptation mechanisms are presented.

2.3.1 Sphere Model

The main focus of analyses on the undisturbed sphere concerns the derivation and analysis of the progress rate φ . This progress measure is of great importance because it can be used:

- To derive evolution criteria which have to be fulfilled for a convergence of the strategy
- To derive conditions for optimal performance
- To examine and compare the efficiency of different strategies
- To analyze the effects of recombination and
- To derive recommendations for population sizing

The sphere model was analyzed considering the following evolution strategies:

- The $(1 + 1)$ -ES (Beyer 1989)
- The $(1 + \lambda)$ -ES and the $(1, \lambda)$ -ES (Beyer 1993)
- The (μ, λ) -ES (Beyer 1995b)
- The $(\mu/\mu, \lambda)$ -ES (Beyer 1995a, 1996a) and
- The (λ_{opt}) -ES (Arnold 2006b)

One of the first analyses concerned the $(1 + 1)$ -ES (Beyer 1989). In contrast to other evolution strategies, this single point ES allows for an exact treatment with the caveat that the progress rate can only be obtained by numerical integration. The derivation relied on

- (a) the decomposition of the mutation vector introduced in the previous section and
- (b) on the *success probability*, that is, the probability that the mutation-created offspring substitutes the parent.

The analysis led to the following findings: Firstly, the progress rate rises steeply with the mutation strength to a clearly defined maximal value before it gradually declines. Secondly, the limit curve for $N \rightarrow \infty$ is already usable for search space dimensionalities greater than 30. This justifies the determination and analysis of an analytical expression of the progress rate for infinite-dimensional search spaces.

As first introduced in Beyer (1989), a step-by-step approach can be followed extracting the important characteristics of the process to develop a geometrically motivated model. This approach was applied in Beyer (1993) to derive an asymptotical progress rate for $(1, \lambda)$ - and $(1 + \lambda)$ -ESs.

First consider the $(1 + 1)$ -ES. The approach followed relied again on the decomposition of the mutation vector into two parts: one into the direction of the objective and the other in the perpendicular plane. The length of the mutation vector or of its $(N - 1)$ -dimensional perpendicular part can be replaced with its expected value when considering $N \rightarrow \infty$. This simplified the calculations. Next, normalized quantities were introduced, that is, normalized with respect to the distance to the objective and the search space dimensionality. Further derivations relied on expanding several expressions into their Taylor series. The higher order

parts of these series scale with at least $1/N$. For $N \rightarrow \infty$, their contributions can be neglected. The approach gives the (normalized) asymptotical progress rate formula (Beyer 2001b, p. 67) which was already derived by Rechenberg (1973) following a different approach. The asymptotical progress rate (see [Table 3](#)) is decomposed into a gain and a loss part as indicated by the evolutionary progress principle (EPP). The loss part is weighted by the success probability. Interestingly, the gain part stems from the mutation component in the direction of the objective, whereas the loss part is the result of the perpendicular part. Both parts are zero for zero mutation strength and increase at first with the normalized mutation strength – the gain part linearly and the loss part quadratically. When the mutation strength increases further, both terms are damped more and more so that the progress rate goes to zero for $\sigma^* \rightarrow \infty$, (see [Fig. 4a](#)). This can be explained as follows (Beyer 2001b): Large mutation strengths cause more unsuccessful mutations on average since it becomes harder to hit the region of success (cf. [Fig. 4b](#)). The parent survives for a longer time and the progress is close to zero (cf. [Fig. 4a](#)). The progress rate is significantly positive (>0) only for mutation strengths in the so-called *evolution window* (Rechenberg 1973). There exists an optimal mutation strength of around 1.224, which leads to a maximal progress rate of 0.202 (see [Fig. 4a](#)).

The approach described above can also be used to determine the progress rate for $(1, \lambda)$ -ESs (see [Table 3](#)). And its application to $(\mu/\mu_I, \lambda)$ -ESs has been discussed in the preceding subsection containing the progress rate of the $(1, \lambda)$ -ES as a special case displayed in [Table 3](#). In the progress rate formula, the so-called *progress coefficient* $c_{1,\lambda}$ appears. Mathematically, this is the expectation of the largest $x_{\lambda,i}$ order statistic taken from λ standard, normally and independently distributed random trials (see [Sect. 5](#)).

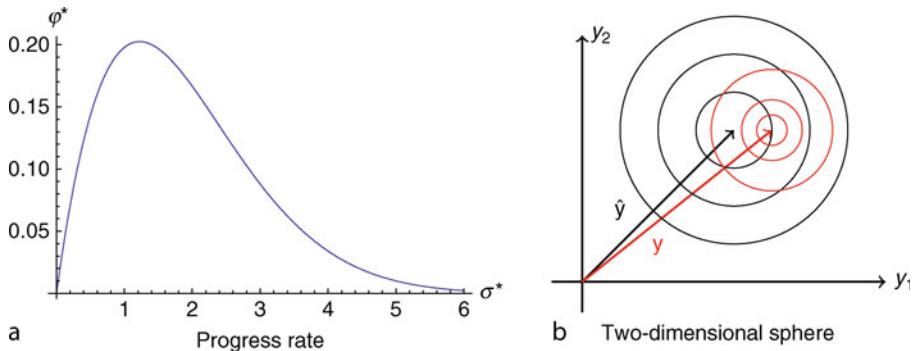

Table 3

Asymptotical progress rates and success probabilities for the sphere model. The normalizations are $\sigma^* = \sigma N/R$ and $\varphi_R^* = \varphi_R N/R$. The $c_{1,\lambda}$ is the progress coefficient (Beyer 2001b, p. 78) whereas $d_{1+\lambda}^{(1)}(x)$ denotes the first order progress function (Beyer 1993) or (Beyer 2001b, p. 78). The progress coefficient, $c_{\mu,\lambda}$, is a function of nine generalized progress coefficients ([Eq. 101](#)) and μ . See [Sect. 5](#) for a definition of the progress coefficients

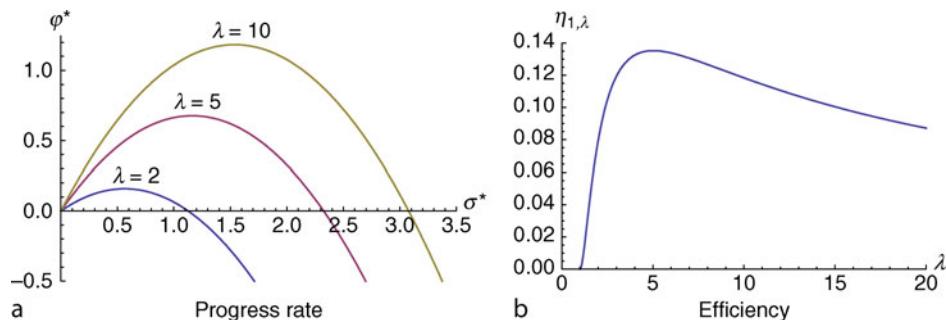

ES	Progress rate	Success probability
$(1 + 1)$ -ES	$\varphi_R^* = \frac{\sigma^*}{\sqrt{2\pi}} e^{-\frac{\sigma^{*2}}{8}} - \frac{\sigma^{*2}}{2} \left(1 - \Phi\left(\frac{\sigma^*}{2}\right)\right)$	$P_s = 1 - \Phi\left(\frac{\sigma^*}{2}\right)$
$(1 + \lambda)$ -ES	$\varphi_R^* = \sigma^* d_{1+\lambda}^{(1)}\left(\frac{\sigma^*}{2}\right) - \frac{\sigma^{*2}}{2} \left(1 - \Phi\left(\frac{\sigma^*}{2}\right)^\lambda\right)$	$P_s = 1 - \Phi\left(\frac{\sigma^*}{2}\right)^\lambda$
$(1, \lambda)$ -ES	$\varphi_R^* = c_{1,\lambda} \sigma^* - \frac{\sigma^{*2}}{2}$	–
(μ, λ) -ES	$\varphi_R^* = c_{\mu,\lambda} \sigma^* - \frac{\sigma^{*2}}{2}$	–
$(\mu/\mu_I, \lambda)$ -ES	$\varphi_R^* = c_{\mu/\mu_I, \lambda} \sigma^* - \frac{\sigma^{*2}}{2\mu}$	–
$(\mu/\mu_D, \lambda)$ -ES	$\varphi_R^* = c_{\mu/\mu_D, \lambda} \sqrt{\mu} \sigma^* - \frac{\sigma^{*2}}{2}$	–

Fig. 4

The asymptotical progress rate φ^* of the $(1 + 1)$ -ES on the sphere, (a) The progress rate is a nonlinear function of the normalized mutation strength, σ^* , with an optimal value of around 0.202 for $\sigma^* \approx 1.224$. (b) shows a two-dimensional sphere. The optimizer is located at \hat{y} . The ES is currently in position y . Operating with higher mutation strengths enlarges the region around y in which mutations most likely will fall.

**Fig. 5**

(a) The asymptotical progress rate φ^* for the $(1, \lambda)$ -ES on the sphere (b) and the efficiency as a function of λ .

The progress rate of the $(1, \lambda)$ -ES reveals a striking difference to that of the $(1 + 1)$ -ES: The progress rate may become negative, which indicates divergence (see [Fig. 5](#)). This leads to the necessary *evolution criterion* which states that the mutation strength must be smaller than a strategy-specific limit (see [Table 4](#)). The limit increases with the population size (see [Fig. 5](#)). Again, the evolutionary progress principle is present in the progress rate expression. The progress rate consists of a (linear) gain part and a (quadratic) loss part. As long as the normalized mutation strength is small, the gain part outweighs the loss part. Increasing the mutation strength changes the relation: Finally, the progress rate becomes smaller than zero. The progress rate has a maximal value and an optimizer. Both depend on the strategy. The maximal value increases with the number of offspring and the location of the optimizer moves upward. While this would indicate that an increase in the number of offspring would be profitable, the increased costs of operating with larger populations have to be considered. These considerations introduce the concept of the progress rate per fitness

Table 4

Several characteristic quantities for ES on the sphere model

ES	Evolution criterion	Maximal progress	Opt. mutation strength	Serial efficiency	Time complexity
$(1, \lambda)$	$\sigma^* < 2c_{1,\lambda}$	$\varphi_{\max}^* = \frac{c_{1,\lambda}^2}{2}$	$\sigma_{\max}^* = c_{1,\lambda}$	$\eta_{1,\lambda} = \frac{c_{1,\lambda}^2}{2\lambda}$	$G_{1,\lambda} = \mathcal{O}\left(\frac{N}{\ln(\lambda)}\right)$
$(\mu/\mu, \lambda)$	$\sigma^* < 2\mu c_{\mu/\mu, \lambda}$	$\varphi_{\max}^* = \frac{\mu c_{\mu/\mu, \lambda}^2}{2}$	$\sigma_{\max}^* = \mu c_{\mu/\mu, \lambda}$	$\eta_{\mu/\mu, \lambda} = \frac{\mu c_{\mu/\mu, \lambda}^2}{2\lambda}$	$G_{\mu/\mu, \lambda} = \mathcal{O}\left(\frac{N}{\lambda}\right)$
(μ, λ)	$\sigma^* < 2c_{\mu, \lambda}$	$\varphi_{\max}^* = \frac{c_{\mu, \lambda}^2}{2}$	$\sigma_{\max}^* = c_{\mu, \lambda}$	$\eta_{\mu, \lambda} = \frac{c_{\mu, \lambda}^2}{2\lambda}$	$G_{\mu, \lambda} = \mathcal{O}\left(\frac{N}{\ln(\lambda)}\right)$

evaluation φ^*/λ (Beyer 2001b, p. 73), which leads to the *serial efficiency* $\eta_{1,\lambda} := \varphi_{\max}^*/\lambda$ with φ_{\max}^* referring to the maximal progress rate for the specific $(1, \lambda)$ -ES. Using numerical maximization, one finds that the efficiency has its maximum at $\lambda \approx 5$. This leads in turn to the conclusion that the $(1, 5)$ -ES is the most efficient $(1, \lambda)$ -ES (see Fig. 5b). The asymptotical behavior of the progress coefficient $c_{1,\lambda}$ can be used to derive expressions for the maximal progress rate and the efficiency. These are $c_{1,\lambda} = \mathcal{O}(\sqrt{\ln(\lambda)})$, $\varphi_{\max}^* = \mathcal{O}(\ln(\lambda))$, and $\eta_{1,\lambda} = \mathcal{O}(\ln(\lambda)/\lambda)$. The progress rate can also be used to estimate the *EA time complexity*

$$G := \frac{N}{\varphi^*(\sigma^*)} \ln\left(\frac{R^{(g_0)}}{R^{(g)}}\right) \quad (100)$$

Since the progress rate scales with $\ln(\lambda)$, the EA time complexity of the $(1, \lambda)$ -ES is of the order $G_{1,\lambda} = \mathcal{O}(N/\ln(\lambda))$.

The concepts developed for the $(1+1)$ -ES and the $(1, \lambda)$ -ES have also been applied to derive the progress rate for the $(1+\lambda)$ -ES (see Table 3). As for the $(1+1)$ -ES, the progress rate approaches zero for increasing normalized mutation strengths. Considering the progress per fitness evaluation, it can be seen that operating with $\lambda > 1$ does not make any sense on the undisturbed sphere unless the algorithm is parallelized. It holds that the progress rate of the $(1+\lambda)$ -ES is greater than (or equal to) the progress rate of the $(1, \lambda)$ -ES. Furthermore, concerning evolution strategies with a single parent on the undisturbed sphere, the $(1+1)$ -ES is the most efficient ES.

In Beyer (1995b), the theory was extended to the (μ, λ) -ES. The progress rate in this case is defined as the expected change of the average distance to the optimizer. The derivation of the progress rate is inherently more difficult since the parent population must be modeled. The distribution of the parents is generation dependent and unknown. Leaving this difficulty aside, the determination of the progress rate requires obtaining the pdf (probability density function) of the distribution of the m th best offspring for which order statistics are to be used. To this end, the density of the offspring population $p(r)$ is needed, which changes from generation to generation. In general, there is no chance to get analytical exact solutions, approximations must be derived instead. Therefore, the random variables are standardized and expanded into a Gram–Charlier series with the normal distribution as reference. The expansions are cut off after the fourth term assuming that the unknown distributions are similar to a normal distribution; however, with a slight skewness.

The approach requires the determination of the mean, the standard deviation, and the third central moment. As a first step, the density of a single offspring $p(r | R_m)$, given a parent

R_m that is randomly drawn from the population, is considered. Any of the parents is drawn with the same probability. The offspring density, given the parent population, is therefore the mixture $p(r|R_1, \dots, R_\mu) = (1/\mu) \sum_{m=1}^\mu p(r|R_m)$ of the μ densities.

In this manner, the required moments can be obtained conditional to the distances of the μ parents. These, however, are random variables themselves produced by the random dynamics from the previous step and were selected as the μ best candidate solutions.

Determining the expectation requires a μ -fold integration and the determination of the joint density of the R_1, \dots, R_μ . In this expression, the pdf and cdf of the offspring of the previous generation appear. The moments of generation $g+1$ depend, therefore, on the distribution of generation g . The next steps aim to express the moments as functions of the previous moments. To this end, the same series expansion for the pdf and cdf at time g is applied.

As a result, one obtains a mapping of the distribution parameters from generation g to $g+1$. Assuming that the distributions approach a time-invariant limit distributions leads to nonlinear fix-point equations for the moments. The nonlinearity concerns primarily the parameter stemming from the third central moment. Assuming that the skewness of the distribution is not large, all higher order terms containing the expectation of this parameter can be dropped. The calculations still require the determination of the expectation of concomitants of order statistics and are quite lengthy. Finally, this leads to the progress rate for the (μ, λ) -ES and to the definition of the *generalized progress coefficients*

$$e_{\mu, \lambda}^{\alpha, \beta} = \frac{\lambda - \mu}{\sqrt{2\pi^{\alpha+1}}} \binom{\lambda}{\mu} \int_0^\infty t^\beta e^{-\frac{\alpha+1}{2}t^2} \Phi(t)^{\lambda-\mu-1} (1 - \Phi(t))^{\mu-\alpha} dt \quad (101)$$

(Beyer 1995b) which reappear in the analysis of other strategies. The progress rate (see ➤ Table 3) itself depends on several generalized progress coefficients, which are finally aggregated in one general $c_{\mu, \lambda}$ -coefficient. It behaves asymptotically as $c_{\mu, \lambda} \sim \sqrt{2 \ln(\lambda/\mu)}$ for $\lambda \gg 1$ (Beyer 1996a). This scaling behavior shows that in the non-noisy case, retaining more than the best candidate solution does not lead to any advantage. As a consequence, see ➤ Table 4, the $(1, \lambda)$ -ES and the (μ, λ) -ES share the same time complexity.

In (Beyer 1995a, 1996a), multi-recombinative evolution strategies were analyzed. Two types of recombinations were considered: dominant or discrete recombination and intermediate recombination. As for dominant recombination, the recombinant is created component-wise by choosing for each coordinate one of the parents randomly and copying the value. Evolution strategies with dominant/discrete recombination are denoted as $(\mu/\mu_D, \lambda)$ -ESs. In the case where intermediate recombination is used, the recombination result is the centroid. These ESs are denoted as $(\mu/\mu_I, \lambda)$ -ESs.

Let one first consider the progress rate of $(\mu/\mu_I, \lambda)$ -ESs: Again, not only the distribution for the largest of λ trials has to be determined but also for all m th largest trials up to μ . For a $(\mu/\mu_I, \lambda)$ -ES, the progress rate is defined as the expected change of the distance of the centroid for two consecutive generations. The new search point is generated by adding the centroid of the μ best mutations to the centroid of the previous generations. As the mutation vector in previous analyses, it can be decomposed into a component pointing toward the optimizer and into a perpendicular part. This decomposition followed by determining the pdf and cdf for the m th best offspring leads, finally, via several Taylor series expansions and neglection of higher order terms to the progress rate of the $(\mu/\mu_I, \lambda)$ -ES (see ➤ Table 3). The derivation of the progress rate revealed an important performance-improving property regarding the perpendicular parts of the mutation vectors of the group of the μ best offspring: The sphere model is

symmetric and the perpendicular parts are therefore selectively neutral when having the same length. The mutations are isotropic and all the directions are equally probable. The conclusion is that the perpendicular parts are statistically independent and the expected value of the product of two different vectors is zero. This results in

$$\overline{\langle \mathbf{h}_R \rangle^2} = \frac{1}{\mu} \langle \overline{\mathbf{h}_R^2} \rangle \quad (102)$$

This will be important when discussing the effects of intermediate recombination.

The progress rate can be used to investigate whether recombinative $(\mu/\mu_b, \lambda)$ -ESs have an advantage over nonrecombinative (μ, λ) -ESs. To ensure a fair comparison, several requirements (Beyer 1995a) should be met:

1. Problem equivalence: This states that the same fitness function and initial conditions should be used. Furthermore, the fitness function should not favor one of the algorithms per se.
2. Resource equivalence: Here, this may be satisfied by using the same number of offspring.
3. Maximal performance: Each algorithm should operate with its maximal performance (Beyer 1995a).

The comparison made for $\lambda = 50$ and $N = 100$ showed that the maximal progress rate of the recombinative strategies exceeds that of nonrecombinative strategies for all choices of μ , except $\mu = 1$. The $(1, \lambda)$ -ES is the best performing nonrecombinative (μ, λ) -ES and is still outperformed by $(\mu/\mu_b, \lambda)$ -ES for a wide range of μ . The maximal performance curve of ES with intermediate recombination indicates that an optimal value of μ exists with the largest maximal progress. Further investigations reveal that the optimal value depends on the search space dimensionality and the population size and increases with both.

The question remains, why recombinative ESs outperform the nonrecombinative comma strategies. This can be traced back to the *genetic repair principle* (GR). Intermediate recombination enables an ES to operate with larger mutation strengths. But why? Comparing the progress rates of the $(\mu/\mu_b, \lambda)$ -ES with that of the (μ, λ) -ES reveals that the main factor to which ESs with intermediate recombination owe their better performance is the reduction of the loss part by $1/\mu$. The loss part of the progress rate stems from the perpendicular parts of the mutation vectors. They enter the derivation of the progress rate over the expected value of the squared length of their average. Intermediate recombination reduces this length to $1/\mu$ th of the average of the squared lengths. This is beneficial: the perpendicular components deteriorate the progress. Let one compare two mutations which result in the same movement in the direction of the optimizer. If the perpendicular parts differ, the mutation with the larger perpendicular part results in a greater distance to the optimizer. Recombination reduces this harmful perpendicular part and offers a kind of *statistical error correction* (Beyer 1995a).

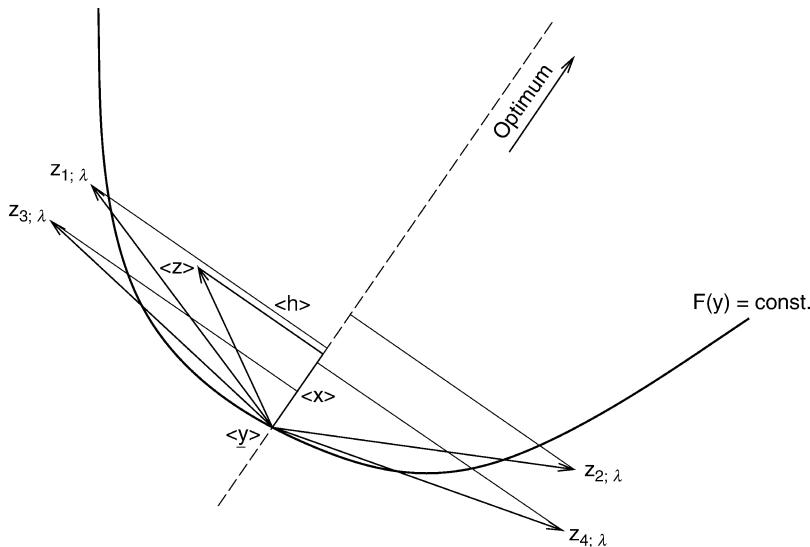

Figure 6 illustrates this mechanism graphically.

Evolution strategies with dominant/discrete recombination remain to be discussed. To enable a comparison with intermediate recombination, the progress rate is defined in the same manner. The calculation of the progress rate appears more difficult than in the previous case. The analysis requires the determination of the distribution of the parent and/or the offspring populations.

The analysis pursued in Beyer (1995a) considers the final effect of recombination and mutation as if it were a result of a *single* random variation. Thus, the concept of *surrogate mutations* was introduced. The surrogate mutations are applied to a virtual parental centroid.

Fig. 6

A visualization of the genetic repair effect for intermediate recombination on the sphere. The ES is a $(4/4, \lambda)$ -ES. The mutations, $z_{1;\lambda}$ to $z_{4;\lambda}$, which correspond to the four best offspring are displayed with their decompositions. As can be seen, intermediate recombination reduces the contribution of the harmful, perpendicular components (see Beyer and Schwefel 2002).

This enables us to decompose the mutation vector in the usual manner. However, the determination of the density of the surrogate mutations still remains. Its calculation appears very demanding and has not been solved for finite N , up until now. However, for $N \rightarrow \infty$ the progress rate can be determined: Within the limit, selection does not have a significant influence on the distribution of the offspring population. To determine the density of the population, the influence of selection can be neglected and only considered again for the progress rate.

The derivation of the distribution for the surrogate mutation vector leads to a very interesting finding: The distribution forgets any initialization effects and shrinks or expands to a limit distribution as $g \rightarrow \infty$. The standard deviation of the components approaches

$$\sigma_s := \sigma\sqrt{\mu} \quad (103)$$

being the “mutation strength” of the surrogate mutations.

The resulting progress rate differs from the progress rate for intermediate recombination in two ways (see [Table 3](#)): The loss part is not reduced by $1/\mu$. Instead, the gain part is increased by the factor $\sqrt{\mu}$. As a result, using intermediate recombination and using discrete recombination should lead to the same maximal performance. A closer look, though, reveals that this is not the case. The observed and better performance of $(\mu/\mu_i, \lambda)$ -ESs is attributed to the explicit genetic repair (GR) present in intermediate recombination (Beyer 1995a).

However, genetic repair can be argued to be present implicitly in dominant recombination – leading to the *GR hypothesis for dominant recombination*. The surrogate mutations combine dominant recombination and mutation. Dominant recombination samples coordinate points

from the μ parents. The mean of this sampling distribution is the respective coordinate point of the centroid. The drawn sample provides an estimate for the sampling distribution – mean included. Afterward mutation is applied. Mutation introduces no bias and therefore leaves the first moment of the distribution unchanged. The outcome of the mutation is again a sample providing an estimate for the distribution, the center of which is still the centroid of the parents – providing a kind of implicit center building and implicit genetic repair. Since it is a statistical estimate with statistical deviations, implicit genetic repair cannot work as well as explicit genetic repair.

Dominant recombination introduces a new hypothesis, the so-called *mutation-induced speciation by recombination* (MISR). In short this is a result of the limit value of the surrogate mutations (Beyer 1995a). Even without selection, recombination results in a stationary distribution with finite standard deviation (☞ Eq. 103): The offspring generated show cohesion. This can be interpreted as a kind of species formation.

The questions remain whether recommendations with regard to population sizing or truncation ratios, $\vartheta = \mu/\lambda$, can be given. Both recombination types achieve the same maximal progress for $N \rightarrow \infty$. The results have been used to determine the optimal truncation ratio $\vartheta_{\text{opt}} = 0.27$ with a resulting serial efficiency of $\eta_{\mu/\mu,\lambda} = 0.202$. Comparing the result with the $(1+1)$ -ES reveals that the recombinative ES achieves the same efficiency as the $(1+1)$ -ES. Interestingly, the optimal success probability of the $(1+1)$ -ES equals the optimal truncation ratio of the $(\mu/\mu, \lambda)$ -ES. The $(\mu/\mu, \lambda)$ -ES can, therefore, be claimed to be the equivalent of the $(1+1)$ -ES for multi-parent strategies. As a consequence, using recombination does not improve the efficiency above that of the $(1+1)$ -ES, unless parallel computation comes into play.

Arnold (2006b) investigated the performance of an ES with intermediate recombination, which uses weighted recombination taking *all* λ offspring into account. The progress vector $\langle \mathbf{z} \rangle$ is obtained by

$$\langle \mathbf{z} \rangle = \sum_{k=1}^{\lambda} w_{k;\lambda} \mathbf{z}_{k;\lambda} \quad (104)$$

The weights, $w_{k;\lambda}$, depend on the rank of the candidate solution. As performance measure, the quality gain was considered. The results were used to determine the optimal mutation strength and quality gain, which depends on the setting of the weights. The best performance is achieved by choosing the weights $w_{k;\lambda}$ proportionally to the expected values of the corresponding orders statistics $z_{\lambda+1-k:\lambda}$ of the standard normal distribution. This (λ_{opt}) -ES is able to outperform the $(\mu/\mu, \lambda)$ -ES and the $(1+1)$ -ES.

2.3.2 General Quadratic and Non-quadratic Functions

The progress rate approach may be difficult for nonspherical fitness functions. Candidate solutions are selected based on the fitness values. Therefore, the induced order statistics appear in the determination of the progress rate: the distribution of μ distances connected with the μ best fitness values has to be obtained. On the sphere both quantities are monotonously related since the fitness is a monotonous function of the distance. But this is rather an exception than a rule. The quality gain, the expected change of the fitness for two consecutive generations, may behave differently and often the related optimizers of the strategy parameter do not agree with each other.

In Beyer (1994), the quality gain was derived for the $(1, \lambda)$ -ES and the $(1 + \lambda)$ -ES. The derivation of the quality gain requires the determination of the density of the fitness of the best offspring. This can be done by using order statistics. One of the tasks remaining is then, to find general expressions for the pdf and cdf of the fitness of a mutation-created offspring. The idea is to standardize the variable as a first step with its mean and standard deviation. Afterward, the distribution is expanded into a Gram–Charlier series with the standard normal distribution as a baseline. To this end, higher order moments or cumulants of the unknown distribution are to be determined.

This can be done for $(1 + \lambda)$ strategies yielding general results which are not specific for a fitness function. An application, however, requires the computation of the mean, standard deviation and higher order moments. The convergence of the series expansion toward the unknown true distribution and the convergence speed depends on the fitness function considered. Therefore, the approximation quality and the point where the expansion can be cut off are function specific. Example applications (Beyer 1994) include the pseudo Boolean function OneMax $F(\mathbf{b}) = \sum_{i=1}^l b_i$ with $b_i \in \{0, 1\}$, biquadratic functions, and general quadratic fitness functions (see \blacktriangleright Table 5).

Arnold (2007) analyzed the performance of the $(\mu/\mu_b, \lambda)$ -ES on a class of positive definite quadratic forms (PDQFs)

$$f(\mathbf{y}) = \xi \sum_{i=1}^{N\vartheta} y_i^2 + \sum_{i=N\vartheta+1}^N y_i^2 \quad (105)$$

with $\vartheta \leq 1$, $N\vartheta$ a natural number, and $\xi \geq 1$. The aim was to study the response to varying degrees of ill-conditioning. The condition number of a positive definite matrix is defined as the ratio of the largest eigenvalue to the smallest. In the case of \blacktriangleright Eq. 105, it is controlled by ξ .

Table 5

The quality gain of the $(1, \lambda)$ -ES for exemplary fitness functions. The symbols S_Q and M_Q denote the standard deviation and mean of the mutation-induced fitness change Q and κ_k the k th cumulant. The normalizations read $\sigma^* = \sigma \text{Tr}[Q]/\|\mathbf{a}\|$ and $\overline{\Delta Q^*} = \overline{\Delta Q \text{Tr}[Q]}/\|\mathbf{a}\|$ for general quadratic functions. In the case of biquadratic functions, they are given by $\sigma^* = \sigma \sqrt[3]{3 \sum_i c_i / \|\mathbf{a}\|}$ and $\overline{\Delta Q^*} = \frac{\overline{\Delta Q}}{\|\mathbf{a}\|} \sqrt[3]{3 \sum_i c_i / \|\mathbf{a}\|}$. For OneMax, they are defined as $\sigma^* = \sqrt{p_m/l} (2^{\frac{F_0}{l}} - 1)$ and $\overline{\Delta Q^*} = 2\overline{\Delta Q} (2^{\frac{F_0}{l}} - 1)$ with l the string length, p_m the bit-flipping probability, and F_0 the function value of the parent

ES	Fitness function	Quality gain
$(1, \lambda)$ -ES	General functions	$\overline{\Delta Q}_{1,\lambda} = M_Q + S_Q \frac{\kappa_3}{6} + c_{1,\lambda} S_Q \left(1 + \frac{5\kappa_3^2}{36} - \frac{\kappa_4}{8} \right) + S_Q d_{1,\lambda}^{(2)} \frac{\kappa_3}{6} + d_{1,\lambda}^{(3)} S_Q \left(\frac{\kappa_4}{24} - \frac{\kappa_3^2}{18} \right) + \dots$
$(1, \lambda)$ -ES	General quadratic functions	$\overline{\Delta Q^*} = c_{1,\lambda} \sigma^* - \frac{\sigma^{*2}}{2}$
$(1, \lambda)$ -ES	Biquadratic functions	$\overline{\Delta Q^*} = c_{1,\lambda} \sigma^* - \sigma^{*4}$
$(1, \lambda)$ -ES	OneMax	$\overline{\Delta Q^*} = c_{1,\lambda} \sigma^* - \frac{\sigma^{*2}}{2}$

Larger values of ξ correspond with higher degrees of ill-conditioning. The performance measure used in Arnold (2007) was

$$\Delta = E \left[-\ln \left(\frac{f(\mathbf{y}^{(g+1)})}{f(\mathbf{y}^{(g)})} \right) \right] \quad (106)$$

a logarithmic quality gain – being asymptotically equal to $E[(f(\mathbf{y}^{(g)}) - f(\mathbf{y}^{(g)}))/f(\mathbf{y}^{(g)})]$ for $N \rightarrow \infty$. Reconsidering [Eq. 105](#) shows that it is the sum of two spheres $f(R_1, R_2) = \xi R_1^2 + R_2^2$ – one $N\vartheta$ -dimensional, the other $N(1-\vartheta)$ -dimensional and evolution takes place in two subspaces. The mutation vector of an offspring can be decomposed into two parts, one for each sphere. Then, the same decomposition as in the case of the sphere can be used with respect to the distance vectors to the centers of the spheres. This allows the determination of the quality change of an offspring as a function of two random components. The same decomposition can be applied to the progress vectors required for the determination of $E[R_1^2]$ and $E[R_2^2]$.

The resulting quality gain

$$\Delta^* = \frac{c_{\mu/\mu,\lambda}\sigma^*}{\sqrt{1 + \left(\frac{R_1}{R_2\xi}\right)^2}} - \frac{\sigma^{*2}}{2\mu} \quad (107)$$

with $\sigma^* := \sigma N\vartheta/R_1$ and $\Delta^* := \Delta N\vartheta/2$ can be used to determine the optimal mutation strength and quality gain as a function of the condition number. For most values of ξ , these values can only be obtained numerically. For large ξ -values, asymptotical expressions can be derived (see [Table 9](#)).

2.3.3 Ridge Functions

Ridge functions ([76](#)) can be considered using the progress rate approach. The concept of the progress rate, however, has to be widened since ridge functions do not have any finite optimum. The form of the ridge functions automatically leads to the definition of two performance measures. One component of the ridge is made up by the position on y_1 or parallel to the axis. The respective progress rate, the *axial progress rate* φ_{y_1} gives the expectation of the change of this component during one generation. The other component can be interpreted as a distance R of the remaining $N-1$ dimensions to the axis. In this case, the *radial progress rate* φ_R measures the expected change of two consecutive distances.

The optimization of ridge functions consists of two subgoals: (a) decreasing the radial distance to the axis – optimizing the sphere component, (b) enlarging the axis position – optimizing the linear part.

Ridge functions without noise were considered in the following publications:

- Oyman et al. (1998, 2000) considered the performance of the $(1, \lambda)$ -ES and $(1 + \lambda)$ -ES on the parabolic ridge.
- Oyman and Beyer (2000) investigated the $(\mu/\mu, \lambda)$ -ES on the parabolic ridge.
- Beyer (2001a) considered the $(1, \lambda)$ -ES on general ridge functions.
- Arnold (2006a) analyzed the $(\mu/\mu_b, \lambda)$ -ES on general ridge functions.

[Table 6](#) shows the progress rates obtained. Oyman et al. (1998) analyzed the performance of the $(1, \lambda)$ -ES and $(1 + \lambda)$ -ES on the parabolic ridge. Not considering any step-size adaptation mechanism, the following results were obtained: The axial progress rate is always nonnegative. Provided that the step-size adaptation mechanism generates positive mutation strengths,

Table 6

Radial and axial progress rates φ_R and φ_{y_1} for ridge functions. Explanation of variables and notation: $c_{\mu/\mu,\lambda}$ progress coefficient (see [Sect. 5](#)), σ^* normalized mutation strength (with respect to distance to optimizer and search space dimensionality N)

ES	Ridge		Progress rate
(1, λ)-ES	Parab.	Asymp.	$\varphi_{y_1}(\sigma) = \frac{c_{1,\lambda}\sigma}{\sqrt{1 + (2dR)^2}}$
(1, λ)-ES	Parab.		$\varphi_{y_1}(\sigma) = \frac{c_{1,\lambda}\sigma}{\sqrt{1 + (2dR)^2 + 2d^2(N - 1)\sigma^2}}$
(μ/μ_r , λ)-ES	Parab.		$\varphi_{y_1}(\sigma) = \frac{c_{\mu/\mu,\lambda}\sigma}{\sqrt{1 + (2dR)^2 + 2d^2(N - 1)\sigma^2}}$
(μ/μ_D , λ)-ES	Parab.		$\varphi_{y_1}(\sigma) = \frac{c_{\mu/\mu,\lambda}\sqrt{\mu}\sigma}{\sqrt{1 + (2dR)^2 + 2\mu d^2(N - 1)\sigma^2}}$
(μ/μ_r , λ)-ES	Gen.	Asymp.	$\varphi_{y_1}^*(\sigma^*) = \frac{c_{\mu/\mu,\lambda}\sigma^*}{\sqrt{1 + \alpha^2 d^2 R^{2x-2}}}$
(μ/μ_r , λ)-ES	Gen.	Asymp.	$\varphi_R^*(\sigma^*) = \frac{\alpha d R^{x-1} c_{\mu/\mu,\lambda} \sigma^*}{\sqrt{1 + \alpha^2 d^2 R^{2x-2}}} - \frac{\sigma^{*2}}{2\mu}$

the ES progresses in axis direction. Evolution strategies generally show a stationary state of the R -dynamics after a transient phase. That is, after a while, the ES fluctuates at a certain distance to the ridge and travels on an average, parallel to the axis. The progress that is achieved depends on two quantities: the residual distance and the mutation strength. The analysis considered large mutation strengths and a large ridge parameter d . Under these conditions, the linear y_1 component can be treated as noise and the ridge appears as a sphere. This assumption enables us to determine the residual distance to the axis in analogy to the sphere model. The axial progress rate for the $(1, \lambda)$ -ES is then obtained by using the following argument: in the steady state of the R -dynamics, the isofitness landscape appears locally as a hyperplane. Progress in gradient direction can therefore be determined as the hyperplane progress rate φ_{hp} multiplied with the gradient direction as $\varphi_{hp} \nabla F / \| \nabla F \|$. The axial progress is then given as the scalar product of the first unit vector with the progress in gradient direction.

The results show an interesting response of the progress rate with respect to increasing mutation strengths: The progress rate reaches a finite strategy-dependent limit.

Comparing experimentally the performance of the $(1, \lambda)$ -ES and the $(1 + \lambda)$ -ES reveals an interesting behavior: The performance of the nonelitist $(1, \lambda)$ -ES increases with the mutation strength to a limit value. In contrast, the progress of the elitist strategy is below the progress of the $(1, \lambda)$ -ES, and decreases with the mutation strength. The $(1 + \lambda)$ -ES emphasizes the short-term goal of minimizing the distance to the axis. This goal is better achieved by elitist strategies. Performing one generation experiments with a static mutation strength and measuring the quality gain starting from various distances show that the optimization behavior of $(1 + \lambda)$ -ES achieves a larger quality gain. The progress in axis direction is a “byproduct of the selection process” (Oyman et al. 1998) and is smaller than that of the $(1, \lambda)$ -ES.

The analysis was extended in Oyman et al. (2000) considering the $(1, \lambda)$ -ES in more detail. The focus lay on obtaining and analyzing the progress rate, the quality gain, the success

probability, and the success rate. In the case of the $(1, \lambda)$ -ES, the success probability denotes the probability that the selected offspring has a better fitness than the parent, whereas the success rate gives the probability of progress by a single mutation (Oyman et al. 2000).

The progress rate was not obtained using a local approximation with a hyperplane. Instead the local quality function and order statistics were used. The so obtained progress rate depends on the distance to the axis and decreases with increasing distance. Therefore, an expression for the stationary distance was obtained by considering the evolution of the distance to the axis and applying a steady state criterion. The experimental comparison of the $(1, \lambda)$ -ES with the $(1 + \lambda)$ -ES again revealed progress deficiencies for the $(1 + \lambda)$ -ES. This is also present in the success probability and success count. Both values deteriorate faster with the normalized mutation strength. This can be traced back to the optimization behavior of the $(1 + \lambda)$ -ES. Further experiments revealed the existence of a stationary distance, which is smaller than for $(1, \lambda)$ -ES. After this stationary state is reached, progress in axis direction is only small since the smaller distance lowers the success probability.

Oyman and Beyer (2000) presented an analysis of the $(\mu/\mu, \lambda)$ -ES on the parabolic ridge. Two types of recombination: intermediate and dominant were considered.

The analysis aimed at providing insights in the progress behavior of these strategies using the axial progress rate and the steady state distance to the ridge axis. The results can be used to give recommendations with regard to the truncation ratio and for a comparison with the progress of the $(1, \lambda)$ -ES on the one hand and for a comparison of the two recombination types on the other.

The analysis approach made use of the methods established for the sphere (Beyer 1995a). The analysis for intermediate recombination required the determination and approximation of the local quality function, the mutation-induced fitness change. First of all, the general function was expanded into its Taylor series and the resulting series was cut off after the quadratic term. In this approximation, the local quality function is a quadratic polynomial in the mutation vectors components. This was used to determine the required cdfs and pdfs in the derivation of the progress rate via a normal approximation of the true distribution.

The case of dominant recombination was treated using the result for intermediate recombination and applying the concept of surrogate mutations (Beyer 1995a), that is, the step size of the surrogate mutation $\sigma_S = \sqrt{\mu}\sigma$ is plugged into the progress rate for the intermediate case.

So far, the steady state dynamics of the distance to the ridge were not included in the analysis. Considering the square of the distance and following a similar approach as for the sphere model leads to an expression for the residual distance for the $(\mu/\mu_D, \lambda)$ -ES. The distance depends on the population parameters μ and λ , on the search space dimensionality, on the mutation strength, and on the ridge parameter d . For $d \rightarrow \infty$, the residual distance approaches the mutation-induced residual distance of the sphere model $(N - 1)\sigma/(2\mu c_{\mu/\mu, \lambda})$. Recombination reduces the distance to the axis. This is similar to the genetic repair effect on the sphere model. Considering the distance to the axis, the mutation vector and the progress vector can be written again as the direct sum of two perpendicular components: one pointing to the axis and the perpendicular part. Averaging effectively reduces the perpendicular parts. The stationary distance for the $(\mu/\mu_D, \lambda)$ -ES is obtained in a similar manner as before. Comparing the distances exemplarily reveals that the intermediate ES achieves smaller distances to the axis than the $(\mu/\mu_D, \lambda)$ -ES.

In order to compare the stationary progress rates, the obtained residual distances are plugged into the respective formulas. In the case of intermediate recombination, the resulting

axial progress rate shows a saturation behavior for increasing mutation strengths. Instead of increasing indefinitely, a strategy-dependent limit value is approached. A similar behavior was found for the $(1, \lambda)$ -ES. Comparing these limits leads to the conjecture that the performance of the $(\mu/\mu, \lambda)$ -ES exceeds that of the $(1, \lambda)$ -ES if the mutation strength is large and $\mu c_{\mu/\mu, \lambda}^2 > c_{1, \lambda}^2$, holds.

The result for the $(\mu/\mu_D, \lambda)$ -ES is interesting since it indicates that using dominant recombination instead of intermediate recombination is beneficial on the parabolic ridge: The progress curve for dominant recombination is above the curve for intermediate recombination, a gap which closes for increasing mutation strengths.

In Beyer (2001a), the performance of the $(1, \lambda)$ -ES on general ridge functions was analyzed for the case of finite N and constant mutation strength. The analysis provided a simple but more accurate approach that allowed a treatment of the radial dynamics. It was shown that the y_1 -dynamics are controlled by the R -dynamics whereas the latter do not depend on the former. First of all, the progress rates were determined. The results were then used to discuss the general properties, and the mean value and steady state behavior of the ES.

The axial progress rate depends on the distance to the ridge. The asymptotical behavior for $R \rightarrow 0$ and $R \rightarrow \infty$ depends on the ridge topology parameter α . For $\alpha > 1$, for instance, the progress rate for the hyperplane is obtained for $R \rightarrow 0$, whereas for $\alpha < 1$, it appears as the limit for $R \rightarrow \infty$.

Any discussion of the mean value dynamics of the y_1 -evolution requires a closer investigation of the R -dynamics. Experiments showed that the R -evolution approaches a steady state, that is, a time-invariant limit distribution, and the mean value converges to a constant. This results in a linear progress of the mean value of the y_1 -dynamics after a transient phase.

The velocity by which the ES travels along the ridge axis depends on the value of the stationary distance R . Using the radial progress rate and setting it to zero gives a general equation to be solved for the stationary distance. However, the mutation strength appears as an unknown variable.

The steady state progress was also considered. For the sharp and the parabolic ridge, the influence of the distance can be eliminated, yielding analytically expressions for the steady state progress as functions of the mutation strength. This allows for an analysis of the influence of the mutation strength.

Other values of α have to be treated numerically. The size of α determines the qualitative behavior of the progress rate with respect to the mutation strength. While the progress rate increases continuously for $\alpha < 2$, it appears to reach a saturation behavior for $\alpha = 2$. Increasing α further leads to a unimodal progress rate with an optimal mutation strength.

Arnold (2006a) considered the general ridge function class. He derived the axial progress rate and a stationary condition for the distance to the ridge axis. The results were used to determine optimal values for the mutation strength, residual distance, and progress rate (see  [Table 10](#)).

2.3.4 Step-Size Adaptation Mechanisms

In the following, the results of applying the dynamical systems approach in the analysis of step-size mechanisms is described. First, some results for self-adaptation are presented, before the cumulative step-size adaptation is considered.

Table 7

Self-adaptation response functions (SARs) for different fitness environments. Explanation of variables and notation: σ^* normalized mutation strength (with respect to distance to optimizer and search space dimensionality). For the coefficients $c_{\mu/\mu,\lambda}$, $e_{\mu,\lambda}^{1,1}$ and $d_{1,\lambda}^{(2)}$ see [Sect. 5](#)

Fitness	ES	SAR
Sphere	$(1, \lambda)$ -ES	$\psi(\sigma^*) = \tau^2 \left(d_{1,\lambda}^{(2)} - \frac{1}{2} - c_{1,\lambda} \sigma^* \right)$
Sphere	$(\mu/\mu, \lambda)$ -ES	$\psi(\sigma^*) = \tau^2 \left(\frac{1}{2} + e_{\mu,\lambda}^{1,1} - c_{\mu/\mu,\lambda} \sigma^* \right)$
Ridge	$(\mu/\mu, \lambda)$ -ES	$\psi(\sigma^*) = \tau^2 \left(\frac{1}{2} + e_{\mu,\lambda}^{1,1} - c_{\mu/\mu,\lambda} \sigma^* \sqrt{\frac{\alpha^2 d^2 R^{2x-2}}{(1 + \alpha^2 d^2 R^{2x-2})}} \right)$
PDQF	$(\mu/\mu, \lambda)$ -ES	$\psi(\sigma^*) = \tau^2 \left(\frac{1}{2} + e_{\mu,\lambda}^{1,1} - c_{\mu/\mu,\lambda} \sigma^* \frac{\vartheta(\xi - 1) + 1}{\vartheta\xi \sqrt{1 + \xi^2}} \right)$

Self-Adaptation

Self-adaptation was considered in the following publications:

- Beyer ([1996b](#)) was the first analysis of the self-adaptation mechanism and introduced the analysis approach also followed in later analyses. The evolution strategy considered was the $(1, \lambda)$ -ES.
- In Meyer-Nieberg and Beyer ([2005](#)), the analysis was extended to the $(\mu/\mu_b, \lambda)$ -ES on the sphere.
- Meyer-Nieberg and Beyer ([2007](#)) and Beyer and Meyer-Nieberg ([2006b](#)) provided an analysis of the self-adaptive $(\mu/\mu_b, \lambda)$ -ES on ridge functions.
- And Beyer and Finck ([2009](#)) extended the method to PDQFs.

An overview of the self-adaptation response functions obtained is given in [Table 7](#). The analyses aimed to provide insights on the functioning of self-adaptation, to analyze the influence of the learning parameter τ , and the effects of recombination. Primarily, the analyses are devoted to the log-normal operator, cf. [Table 1](#), which is a very common choice. The two-point rule was considered in Beyer ([1996b, 2001b](#)). Most of the results for the log-normal operator can be expected to be transferred for the two-point rule rather easily. In the case of the $(1, \lambda)$ -ES, the correspondence between the mutation operator was shown in Beyer ([1996b](#)). In the following, the results for the sphere are described before considering ridge functions.

On the sphere, self-adaptation generally drives the mutation strength to scale with the distance to the optimizer (disregarding fluctuations of course). Using the distance as normalization, leads to the finding that the normalized mutation strength reaches a stationary state. In Beyer ([1996b](#)), the deterministic evolution equations were used to model the ES's time dynamics. To this end, the self-adaptation response function ([68](#)) had to be obtained which can be approximated as a linear function of the mutation strength for small learning parameters. The evolution equations were then used to determine conditions for the stationary state. As it has been shown, self-adaptation steers the normalized mutation strength toward a stationary point between the second zero point of the progress rate and the zero

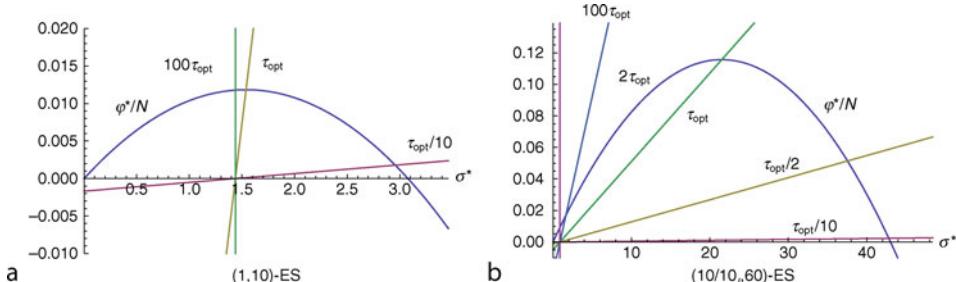

point of the self-adaptation response. On the sphere, it always holds that the zero point of the self-adaptation response is smaller than that of the progress rate. In this process, the learning parameter τ serves as control parameter: For large values of τ , the stationary normalized mutation strength is close to the zero of the SAR. Conversely, it is close to the zero of the progress rate if τ is small. Therefore, for small values of τ , there is nearly no progress at all. The maximum of the progress rate lies in between the two zeros. Therefore, a value of τ exists for which optimal expected progress can be obtained (Beyer 1996b). [Figure 7a](#) illustrates the behavior. It can be shown that choosing $\tau \propto 1/\sqrt{N}$ is roughly optimal which provides a theoretical basis for Schwefel's recommendation for choosing the learning parameter. If τ is increased above this value, the zero of the SAR is approached. This does not deteriorate the performance significantly: The zero of the SAR is close to the optimal point of the progress rate. This provides an explanation as to why $(1, \lambda)$ -ESs are robust with respect to the choice of the learning parameter.

This is not the case anymore if $(\mu/\mu_b, \lambda)$ -ESs are considered: As Grünz and Beyer found experimentally, $(\mu/\mu_b, \lambda)$ -ESs are very sensitive with respect to the choice of τ (Grünz and Beyer 1999). Instead of still showing nearly optimal progress if τ is chosen too large, these evolution strategies slow down: Nearly optimal behavior of an ES is only attainable for a narrow range of learning parameters.

In Meyer-Nieberg and Beyer (2005), an explanation has been provided. The decisive point is that the zero of the SAR is not close to the optimizer of the progress rate anymore. Increasing the number of parents usually shifts the optimizer to larger values. That is, intermediate recombination enables the ES to work with higher mutation strengths which transfers to the optimal point. The zero of the SAR does not behave accordingly, though. It is less sensitive toward variations of the parent number and, even worse, it tends to decrease for the usual choices. There is a widening gap between the zero of the SAR and the optimizer if the number of parents is increased. The consequences of this are twofold: on the one hand, there is still an optimal choice of the learning rate, on the other hand deviating from this choice will soon result in severe progress deterioration. Self-adaptation

Fig. 7

The influence of the learning rate, τ , on the stationary state of the mutation strength σ^* on the sphere. The case of a $(1,10)$ -ES is depicted in (a), (b) shows a multi-parent ES. The stationary state is governed by the equation $-\psi(\sigma^*) = \varphi^*(\sigma^*)/N$, that is, by the intersection of the negative self-adaptation response with the progress rate φ^* (divided by the search space dimensionality N). The SAR is linear in the mutation strength. The slope and the y-axis intercept are scaled with τ^2 . Shown are the progress rate and several SARs for different choices of τ . The search space dimensionality is $N = 100$.

as a mechanism still works, however. The progress remains positive and the ES moves toward the optimizer. However, as Fig. 7b shows exemplarily, it is important to choose τ close to the optimal value. Provided that the parent number is neither too close to one nor too close to the number of offspring, $\tau \approx 1/\sqrt{2N}$ leads to nearly optimal progress for large search space dimensionalities.

One question that remains is, why is the zero of the SAR behaving in this manner? The answer lies in reconsidering the mechanism of self-adaptation. The mutation strength is variated *before* the recombination of the object parameters. No detailed information is passed to the self-adaptation of the mutation strength that – due to intermediate recombination – higher mutation strengths are possible. The feedback is only indirect over the selection of the individuals with higher fitness.

In Beyer (1996b), the dynamical behavior of the $(1, \lambda)$ -ES with self-adaptation was considered. Two approaches have been pursued: One using the deterministic evolution equations, the other using the second-order approach – modeling the perturbation parts of the evolution equations with normally distributed random variables. The induced stochastic process was studied by considering some moments – the mean for most cases.

In the case of the evolution of the distance R , it was shown that the mean converges log-linearly as soon as the normalized mutation strength has reached its stationary state. Using the deterministic approximation, it can be shown that the time an ES needs to approach the steady state depends on $1/\tau^2$. As a result, the τ -scaling law $\tau \propto 1/\sqrt{N}$ causes the ES to have an adaptation time $g_A \propto N$. This might take too long for large search space dimensionalities. A short adaptation time and an optimal performance in the stationary state cannot be reached with a single learning parameter τ . This leads to the recommendation that in the initial phase, an N -independent learning parameter should be used and when approaching the steady state, one should switch to $\tau \propto 1/\sqrt{N}$.

The second-order approach provides an explanation for the observation that the experimentally measured rate is somewhat smaller than the theoretically expected value. The random dynamics of the mutation strength introduce a detrimental variance term to the average progress rate

$$\overline{\varphi_R^*(\sigma^{*(g)})} = c_{1,\lambda} \overline{\sigma^{*(g)}} - \frac{(\overline{\sigma^{*(g)}})^2}{2} - \frac{D^2[\sigma^{*(g)}]}{2} \quad (108)$$

The R -dynamics are driven by the mutation strength. Obtaining expressions for the mean and higher moments proved difficult in the case of the mutation strength because lower order moments depend functionally on higher order moments. Therefore, an *ansatz* using the log-normal distribution can serve as an approximation of the true density. The results were used to show that the stationary mean value of the normalized mutation strength is always less than the deterministic prediction due to the fluctuations. Furthermore, the scaling law of the learning parameter also proved to be valid for this second-order model.

In Beyer and Meyer-Nieberg (2006b) and Meyer-Nieberg and Beyer (2007), ridge functions were considered: the sharp ridge and $(1, \lambda)$ -ESs in Beyer and Meyer-Nieberg (2006b) and $(\mu/\mu_i, \lambda)$ -ESs and additionally the parabolic ridge in Meyer-Nieberg and Beyer (2007). Both ridge functions must be described by two state variables, the distance to the ridge (radial) and the position parallel to the axis direction (axial). Three state variables are therefore decisive: the axial position, the radial position, and the mutation strength. The analyses (Beyer and Meyer-Nieberg 2006b; Meyer-Nieberg and Beyer 2007) revealed that the evolution of the axial position does not influence any other evolution. That is, there is no direct feedback

from the present axial position. Only the mutation strength and the radial distance are the governing forces of the evolution. Therefore, in terms of a self-adaptive ES, a ridge appears as a distorted sphere.

Similar to the sphere, self-adaptation steers the mutation strength to scale on average with the distance to the ridge with the result that a stationary state of the normalized mutation strength is approached in the long run. And as before, self-adaptation drives the mutation strength toward a stationary point between the zero of the self-adaptation response (SAR) and the zero of the radial progress rate.

As for the sharp ridge ($\alpha = 1$) two quantitatively different behaviors can be observed: The ES either converges toward the axis or diverges from it. If it converges, the scaling of the mutation strength with the distance results in mutation strengths that are far too small for any significant axial progress: The search stagnates. Divergence, on the other hand, is coupled with an increasing mutation strength leading on an average to a positive quality or fitness change. The questions remain why the ES shows these different behaviors and what is the factor deciding which one occurs? These questions are answered by taking a closer look at the stationary state behavior.

In the case of the parabolic ridge, the ES attains a stationary state of the mutation strength and the distance (see [Table 8](#)). That is, there are (R, σ^*) -combinations which are stationary states of the R -evolution (zero progress $\varphi_R^* := \varphi_R/N$) and the σ^* -evolution ($\sigma^* = \sigma/N$, zero SAR ψ) (see [Fig. 8](#)). In the case of the sharp ridge, no such states exist. Other than $R = 0$ and $\sigma^* = 0$, no combination fulfills simultaneously both stationary state criteria. The ES either converges or diverges. The parameter d of the ridge function is the decisive parameter which determines the behavior. It can be shown that for a strategy-dependent critical value, the lines for $\varphi_R^* = 0$ and $\psi = 0$ overlap. If d is larger than this critical value, the line for $\varphi_R^* = 0$ is consistently above the line for $\psi = 0$. This is a similarity to the sphere model, where the second zero of the progress rate is always larger than the zero of the SAR. Depending on the choice of the learning rate τ , a self-adaptive ES adapts a normalized stationary mutation strength somewhere between these values. The attained mutation strength is connected with a positive radial progress, that is, the ES moves in expectation toward the axis. In [Fig. 9](#), this indicates that the ES moves into the inner cone delimited by $\varphi_R^* = 0$ and $\psi = 0$. If d is smaller than the critical value, however, the situation is reversed. The line for $\psi = 0$ is above the line for $\varphi_R^* = 0$. Instead of operating with mutation strengths that are connected with positive progress, the ES adapts mutation strengths which lead toward a divergence from the axis.

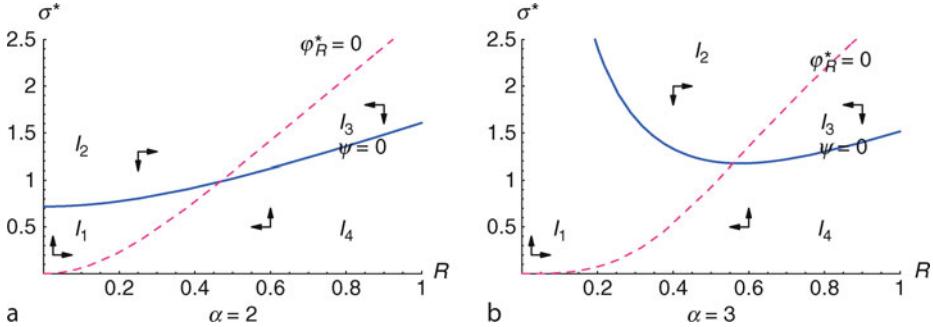

Table 8

Stationary state values of the self-adaptive $(\mu/\mu_i, \lambda)$ -ES on ridge functions. The normalizations are $\sigma^* := \sigma R/N$ with R the distance to the axis, $\varphi_{y_1}^* := \varphi_{y_1} R/N$, and $\varphi_R^* := \varphi_R R/N$

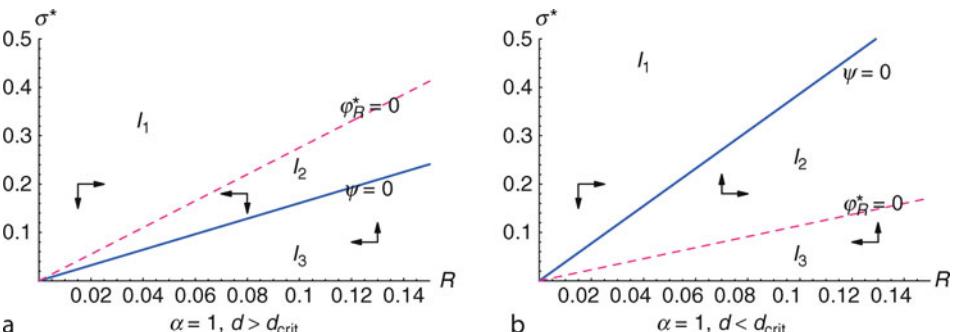

Mutation strength	$\sigma^* = \sqrt{2\mu(1/2 + e_{\mu,\lambda}^{1,1})} \left(\frac{1/2 + e_{\mu,\lambda}^{1,1}}{\alpha^2 d^2 (2\mu c_{\mu/\mu,\lambda}^2 - 1/2 - e_{\mu,\lambda}^{1,1})} \right)^{1/(2\alpha-2)}$
Distance	$R = \left(\frac{1/2 + e_{\mu,\lambda}^{1,1}}{\alpha^2 d^2 (2\mu c_{\mu/\mu,\lambda}^2 - 1/2 - e_{\mu,\lambda}^{1,1})} \right)^{1/(2\alpha-2)}$
Progress	$\varphi_{y_1}^* = \sqrt{(1/2 + e_{\mu,\lambda}^{1,1})(2\mu c_{\mu/\mu,\lambda}^2 - 1/2 - e_{\mu,\lambda}^{1,1})} \left(\frac{1/2 + e_{\mu,\lambda}^{1,1}}{\alpha^2 d^2 (2\mu c_{\mu/\mu,\lambda}^2 - 1/2 - e_{\mu,\lambda}^{1,1})} \right)^{1/(2\alpha-2)}$

Fig. 8

(σ^*, R) -combinations with $\psi = 0$ and $\varphi_R^* = 0$ for (1, 10)-ES with $d = 1$. Shown are the cases for two ridge functions: $\alpha = 2$ in (a) and $\alpha = 3$ in (b). The normalizations are $\sigma^* := \sigma/N$ and $\varphi_R^* := \varphi_R/N$. The intersection indicates the stationary state. The lines divide the (σ^*, R) -phase space into several regions: Region I_1 is characterized by positive expected changes of R , $\Delta R > 0$, and positive changes of σ^* , $\Delta\sigma^* > 0$, I_2 by $\Delta R < 0$, $\Delta\sigma^* > 0$, I_3 by $\Delta R < 0$, $\Delta\sigma^* < 0$, and finally I_4 by $\Delta R > 0$, $\Delta\sigma^* < 0$. The system either leaves every region I_k again, that is, it oscillates, or it converges to the equilibrium point.

**Fig. 9**

(σ^*, R) -combinations for zero progress and zero SAR for (1, 10)-ES on the sharp ridge. The normalizations are $\sigma^* := \sigma/N$ and $\varphi_R^* := \varphi_R/N$. The zero expected change combinations subdivide the (σ^*, R) -phase space. In (a) where $d > d_{\text{crit}}$ region I_1 is characterized by $\Delta R > 0$, $\Delta\sigma^* < 0$, I_2 by $\Delta R < 0$, $\Delta\sigma^* < 0$, and I_3 by $\Delta R < 0$, $\Delta\sigma^* > 0$. Possible movements between the regions are $I_3 \rightarrow I_2$ and $I_1 \rightarrow I_2$. It is easy to see that I_1 and I_3 will be left eventually. The region I_2 cannot be left and the system in σ^* and R approaches the origin. In (b) where $d < d_{\text{crit}}$ region I_1 is characterized by $\Delta R > 0$, $\Delta\sigma^* < 0$, I_2 by $\Delta R > 0$, $\Delta\sigma^* > 0$, and I_3 by $\Delta R < 0$, $\Delta\sigma^* > 0$. Possible movements are $I_1 \rightarrow I_2$ and $I_3 \rightarrow I_2$, but I_2 cannot be left. The system diverges to infinity.

Cumulative Step-Size Adaptation

In Arnold and Beyer (2004), the performance of $(\mu/\mu_b, \lambda)$ -ES on the sphere was investigated for the undisturbed and the noisy case. Concerning the noise-free case, the analysis is aimed at investigating whether the CSA succeeds in adapting a mutation strength that guarantees optimal progress and deriving recommendations for appropriate population sizes.

During an evolutionary run, the ES approaches a steady state: The squared length of the accumulated progress vector, its signed length, and the normalized mutation strength attain a limit distribution. The CSA should strive to increase too small mutation strengths and to decrease too large mutation strengths. In the analysis, the logarithmic adaptation response

$$\Delta_\sigma = \log\left(\frac{\sigma^{(g+1)}}{\sigma^{(g)}}\right) \quad (109)$$

which compares two succeeding mutation strengths is used. The target mutation strength of the CSA is the optimal mutation strength with respect to the progress rate. The ES does not succeed in realizing this objective: Due to the dynamically changing distance to the optimizer, the adaptation of the mutation strength lags behind and the target mutation strength is not reached. The realized normalized mutation strength exceeds the target by a factor of $\sqrt{2}$. In the undisturbed case, the ES with CSA achieves a progress rate of approximately 83% of the optimal progress rate (Arnold and Beyer 2004). Since the optimal mutation strength is not realized, the recommendations (Arnold and Beyer 2002b) for the population sizing with respect to maximal efficiency are slightly to be revised. However, basically the same conclusions as for the sphere can be drawn: The optimal number of offspring is well below the search space dimensionality and increases gradually with it. Furthermore, the recommendation of choosing the truncation ratio about $\mu/\lambda = 0.27$ applies as well.

Arnold (2007) considered the performance of the $(\mu/\mu_b, \lambda)$ -ES on positive quadratic forms (Eq. 73). Being based on the analysis of the expected quality change, the asymptotically optimal mutation strength and the quality gain have been derived as a function of large ξ -values (see Table 9). After a transient phase, the $(\mu/\mu_b, \lambda)$ -ES with CSA yields a stationary mutation strength. This mutation strength and the quality gain depend on the condition number. For $\xi = 1$, the same findings as for the sphere are recovered: The generated mutation strengths are too large by a factor of $\sqrt{2}$. For the asymptotic $\xi \rightarrow \infty$, the ES generates too small mutation strengths (see Table 9). However, the adaptation mechanism still works in that, mutation strengths are realized with result in positive quality gain.

Arnold (2006a) investigated the performance of the $(\mu/\mu_b, \lambda)$ -ES with CSA on the (nearly) complete ridge function class. First, the case of static mutation strengths was considered. After obtaining the axial progress rate and a stationarity condition for the standardized distance to the ridge, optimal values for the progress, distance, and mutation strength can be determined. Optimal refers here to optimal axial progress. The results are given in Table 10 and are applicable for general $\alpha > 2$. As it can be seen, they depend on the value of α . The CSA algorithm would work perfectly on the ridge function class if it succeeded in adopting the optimal mutation strength. This is, however, not the case. An ES using CSA tracks the ridge in unit standardized distance, regardless of α . This in turn results in an α -independent

Table 9

Optimal settings and realized values of the CSA-ES for the quality gain on PDQFs with large condition numbers ξ . The values are normalized quantities $\sigma^* := \sigma N \vartheta / R_1$ and $\Delta^* := \Delta N \vartheta / 2$

Opt. mutation strength	Optimal quality gain	Mut. strength (CSA)	Quality gain (CSA)
$\sigma_{\text{opt}}^* = 2\mu c_{\mu/\mu_b, \lambda}$	$\Delta_{\sigma, \text{opt}}^* = \frac{2\mu c_{\mu/\mu_b, \lambda}^2}{\xi}$	$\sigma_{\text{CSA}}^* = \sqrt{2}\mu c_{\mu/\mu_b, \lambda}$	$\Delta_{\sigma, \text{CSA}}^* = \frac{\mu c_{\mu/\mu_b, \lambda}^2}{\xi}$

Table 10

The $(\mu/\mu_\lambda, \lambda)$ -ES with CSA on the ridge function class. Shown are the values for optimal axial progress and the values achieved by the CSA-mechanism. The following normalizations and abbreviations were used: $\rho = (\alpha d)^{1/(\alpha-1)} R$, $\sigma^* = \sigma N(\alpha d)^{1/(\alpha-1)} / (\mu c_{\mu/\mu_\lambda})$, $\varphi^* = \varphi N(\alpha d)^{1/(\alpha-1)} / (\mu c_{\mu/\mu_\lambda})^2$ (Arnold 2006a)

	Distance	Mutation strength	Progress
Optimal	$\rho = \left(\frac{\alpha}{\alpha - 2} \right)^{\frac{1}{2(\alpha-1)}}$	$\sigma^* = \sqrt{\frac{2\alpha^{\frac{\alpha}{\alpha-1}}}{(\alpha-1)(\alpha-2)^{\frac{1}{\alpha-1}}}}$	$\varphi^* = \frac{\alpha^{\frac{\alpha}{2(\alpha-1)}}(\alpha-2)^{\frac{\alpha-2}{2(\alpha-1)}}}{\alpha-1}$
CSA	$\rho = 1$	$\sigma^* = \sqrt{2}$	$\varphi^* = 1$

normalized mutation strength and progress. For small α , this causes a severe underestimation of the optimal values which gradually diminishes with increasing α .

2.4 Uncertain Environments

This section considers the optimization in uncertain environments, that is, noisy and robust optimization. If noise is involved, the optimizer is often required to show a robustness against perturbations, that is, its quality should decrease only gradually (Beyer and Sendhoff 2006, 2007a; Jin and Branke 2005). Noise is a common problem in practical optimization tasks. Noise may occur for various reasons, for instance, measurement errors or limitations, production tolerances, or incomplete sampling of large search spaces. Noise may also be encountered when optimizing parameters in computer simulations where either numerical errors appear or the simulation technique itself may lead to stochastic results (Arnold and Beyer 2006a; Beyer 2000).

2.4.1 Preliminaries: Accounting for Noise

In the following, several approaches to model noisy fitness measurements are described. Since the noise is modeled by random variable(s) its distribution must capture the main characteristics of real-world situations, for example, an unbiased measurement error. Furthermore, one has to decide how the noise influences the fitness evaluation. For instance, is the noise added afterward, does noise impair the exact localization in the search space or does it even change the functional structure of the fitness function?

Noise Distributions

In order to model practical situations where noise occurs, several noise distributions may be regarded. Each assumes different characteristics of the noise which range from a symmetric distribution without bias over the occurrence of outliers to skewed noise.

The most common noise model is normally distributed noise with zero mean and standard deviation σ_ϵ

$$Z \sim \mathcal{N}(0, \sigma_\epsilon^2), \quad p(z) = \frac{1}{\sqrt{2\pi}\sigma_\epsilon} e^{-\frac{z^2}{2\sigma_\epsilon^2}} \quad (110)$$

The standard deviation σ_ε is usually referred to as the *noise strength*. However, as remarked in Arnold and Beyer (2006a), the Gaussian noise model may not be sufficient to model all practically relevant cases. Not only may the noise be highly non-normal, but also the assumption of a finite variance may be too restrictive. Recommendations obtained for Gaussian noise may not hold, for instance, for noise distributions with heavy tails and frequently occurring outliers. An alternative to using Gaussian noise is to assume Cauchy distributed noise. Its pdf and cdf read

$$p(z) = \frac{\sigma_\varepsilon}{\pi(z^2 + \sigma_\varepsilon^2)} \quad (111)$$

$$P(z) = \frac{1}{2} + \frac{1}{\pi} \arctan\left(\frac{z}{\sigma_\varepsilon}\right) \quad (112)$$

The Cauchy distribution has usually two parameters, the *location parameter*, set to zero in [Eqs. 111](#) and [112](#), and the *scale parameter* σ_ε . The Cauchy distribution has a far heavier tail than the normal distribution and can therefore be used as a model for noise with frequently occurring outliers. All moments, including mean and variance, are undefined. The median, however, exists and is equal to the location parameter. Cauchy distributed noise is symmetric around the location parameter.

To model biased and skewed noise, the χ_1^2 distribution may be considered. The χ_1^2 distribution appears when taking the square of a normally distributed random variable. The pdf is

$$p(z) = \frac{e^{-\frac{z}{2\sigma_\varepsilon}}}{\sqrt{2\pi\sigma_\varepsilon} z} \text{ for } z \geq 0 \quad (113)$$

Since the distribution is not symmetric, it matters whether the random term is added or subtracted to the fitness function, or in other words, whether the noise term itself or its negative is χ_1^2 -distributed.

Noise Models

The *standard noise model* assumes that noise is added to the result of the fitness evaluation

$$F_\varepsilon(\mathbf{x}) = F(\mathbf{x}) + z(\varepsilon, g) \quad (114)$$

where the noise term, $z(\varepsilon, g)$, may follow one of the distributions above. As the assumption of Gaussian noise, the additive noise model may be insufficient to capture all characteristics of real-word situations.

The additive noise model may be regarded as a special case of the *general noise model*

$$F_\varepsilon(\mathbf{x}) = F(\mathbf{x}, z(\varepsilon, g)) \quad (115)$$

In this case, the noise may directly influence the fitness function itself. As a result, the fitness function has to be interpreted as a random function. The approach provides more flexibility. For any computations, however, assumptions must be made.

A special case of [Eq. 115](#) is *systematic noise* (or *actuator noise*) which refers to noise on the coordinates of the objective

$$F_\varepsilon(\mathbf{x}) = F(\mathbf{x} + \mathbf{z}(\varepsilon, g)) \quad (116)$$

(Beyer and Sendhoff 2007b). Actuator noise is often considered in the context of *robust optimization*. Robustness means that the obtained solution is relatively stable with respect to perturbations. Several measures can be introduced to evaluate the quality of a solution. In the context of robust optimization, several types of probabilistic criteria can be distinguished, for example: *threshold measures* and *statistical momentum measures*. The former require that the probability of F -realizations below a certain threshold is maximal

$$P(\{F \leq q|\mathbf{y}\}) \rightarrow \max \quad (117)$$

if minimization is considered. The *statistical momentum measures*

$$\mathbb{E}[F^k|\mathbf{y}] \rightarrow \min \quad (118)$$

require minimality with respect to the k th moment (see, e.g., Beyer and Sendhoff 2006, 2007a).

2.4.2 Noise and Progress

In the following, some results from analyses of the influence of noise on the local performance starting with the sphere model are presented. The first task is usually to obtain expressions for the progress rate or the quality gain, which can be used, for instance, to derive necessary or sufficient convergence criteria. Further points include examining the effects of recombination, the efficiency of resampling compared to operating with larger offspring populations, and determining appropriate population sizes.

Sphere Model and Linear Functions

The effects of noise on the progress of an ES were analyzed in the following publications

- Beyer (1993) considered the performance of the $(1, \lambda)$ -ES and the $(1 + \lambda)$ -ES.
- Arnold and Beyer (2002a) analyzed the effects of overvaluation in the $(1 + 1)$ -ES.
- In Arnold and Beyer (2001b), the local performance of the $(\mu / \mu_b, \lambda)$ -ES in infinite-dimensional search spaces was investigated.
- Arnold and Beyer (2002b) extended the analysis of Arnold and Beyer (2001b) to an analysis in N -dimensional search spaces.
- Arnold (2002a) and Arnold and Beyer (2001a, 2003a) considered the behavior of the (μ, λ) -ES.
- In Arnold and Beyer (2006a), several noise distributions were considered. Deriving the progress rates provides a means to investigate the implications of different distributions on the behavior of the ES.

In Beyer (1993), the influence of noise on the performance of evolution strategies with only one parent was analyzed. Two strategies were considered: the $(1, \lambda)$ -ES and the $(1 + \lambda)$ -ES. The first task was to obtain the progress rate (see  Table 11). The analysis used again, the decomposition of the mutation vectors and applied order statistics to derive the final expressions. Due to the noise, induced order statistics, also referred to as noisy order statistics, were used (see Arnold 2002a). Instead of considering the fitness change induced by mutation, the perceived fitness change had to be taken into account. Therefore, two random processes: mutation and noise have to be considered.

The progress rate of the $(1, \lambda)$ -ES consists again of an approximately linear gain part and a quadratic loss part (cf. evolutionary progress principle (EPP)). Only the gain part is

Table 11

Asymptotical progress rates for the ES on the noisy sphere. Here, noise type *standard* refers to the additive noise model (☞ 114) whereas *systematic* is described by ☞ Eq. 116

ES	Noise type	Progress rate
(1, λ)-ES	Standard	$\varphi_R^* = \frac{c_{1,\lambda} \sigma^{*2}}{\sqrt{\sigma^{*2} + \sigma_e^{*2}}} - \frac{\sigma^{*2}}{2}$
(1 + 1)-ES	Standard	$\varphi_R^* = \frac{\sigma^*}{\sqrt{2\pi}} \cdot \frac{\exp\left[-\frac{1}{2}\left(\frac{\sigma^*/2}{\sqrt{1+2\left(\frac{\sigma_e^*}{\sigma^*}\right)^2}}\right)\right]}{\sqrt{1+2\left(\frac{\sigma_e^*}{\sigma^*}\right)^2}}$ $- \frac{\sigma^{*2}}{2} \left(\left(1 - \Phi\left(\frac{\frac{\sigma^*}{2}}{\sqrt{1+2\left(\frac{\sigma_e^*}{\sigma^*}\right)^2}}\right) \right) \right)$
(μ/μ_r , λ)-ES	Standard	$\varphi_R^* = \frac{c_{\mu/\mu_r, \lambda} \sigma^{*2}}{\sqrt{\sigma^{*2} + \sigma_e^{*2}}} - \frac{\sigma^{*2}}{2\mu}$
(μ/μ_r , λ)-ES	Standard	$\varphi_R^* = \frac{c_{\mu/\mu_r, \lambda} \sigma^{*2} \left(1 + \frac{\sigma^{*2}}{2\mu N}\right)}{\sqrt{1 + \frac{\sigma^{*2}}{\mu N}} \sqrt{\sigma^{*2} + \sigma_e^{*2} + \frac{\sigma^{*4}}{2N}}} - N\left(\sqrt{1 + \frac{\sigma^{*2}}{2\mu N}} - 1\right)$
(μ/μ_r , λ)-ES	Systematic	$\varphi_R^* = \frac{c_{\mu/\mu_r, \lambda} \sigma^{*2} \left(1 + \frac{\sigma^{*2}}{2\mu N}\right)}{\sqrt{1 + \frac{\sigma^{*2}}{\mu N}} \sqrt{\sigma^{*2} + \sigma_e^{*2} + \frac{(\sigma^{*2} + \sigma_e^{*2})^2}{2N}}} - N\left(\sqrt{1 + \frac{\sigma^{*2}}{2\mu N}} - 1\right)$

influenced by the noise. Noise decreases the gain part which can be measured by the so-called selection sharpness

$$S := \frac{1}{\sqrt{1 + (\sigma_e^*/\sigma^*)^2}} \quad (119)$$

where σ_e^* is the normalized noise strength which reads for the sphere model (☞ 71)

$$\sigma_e^* = \frac{N\sigma_e}{R \left| \frac{dg}{dR} \right|} \quad (120)$$

For “comma” strategies, there is a certain critical noise strength above which any positive mutation strength causes negative progress and expected divergence. The transition at which this appears is determined by the necessary evolution criterion. Below the critical noise strength, there are regions of (σ^*, σ_e^*) -combinations which allow positive progress. Clearly, the border is defined by zero progress rate. The critical noise strength can be used to determine the *residual location error*, the stationary expected distance to the optimizer. The residual location error depends on σ and σ_e . The mutation strength σ can generally be obtained only by analyzing the step-size adaptation mechanism.

Since the necessary evolution criterion depends on the size of the population, one way to increase the convergence region of the $(1, \lambda)$ -ES would be to increase λ . It can be shown, however, that this is not very efficient. Another way to cope with noise is to reduce the noise

strength itself which can be done by m -times resampling and averaging (provided that the statistical moments of the noise exist). The analysis revealed that except for small values of λ and m , a $(1, \lambda)$ -ES with a lower population size but with repeated resampling and averaging might be preferable.

In the case of the $(1 + \lambda)$ -ES, the perceived fitness of the apparent best offspring is compared with the perceived fitness of the parent. In Beyer (1993), it was assumed that the parent is evaluated anew when comparing it with the offspring. To determine the progress rate, the apparent or perceived success probability had to be obtained. The calculations led to an asymptotical progress rate, which revealed that in contrast to the non-noisy case, the expected progress can be negative – depending on the noise and mutation strength. Due to the nature of the integrals involved, the numerical determination of the progress rate is cumbersome. For the special case of $(1 + 1)$ -ES, the calculations could be performed and analytical results obtained. Interestingly, the perceived success probability increases with the noise strength. That is, the offspring increasingly replaces the parent – without being necessarily better. This can be counteracted to some extent with an increase of the mutation strength – albeit only to a certain point. Depending on the normalized noise strength, there is an optimal success probability that guarantees optimal progress. However, this is only possible up to a certain noise limit. The success probabilities obtained lead to the conclusion that the 1/5th-rule with the standard settings should be applied. Instead of lowering the success probability for noise closer to the limit value, resampling and averaging should be applied to decrease the noise strength (Beyer 2001b, p. 99).

Beyer (1993) considered the case that the fitness of the parent is reevaluated every time it is compared to the offspring. This results in more fitness evaluations than usually necessary. Since fitness evaluations are costly, the question arises whether the $(1 + 1)$ -ES benefits from reevaluations. Arnold and Beyer (2002a) investigated the local performance of the $(1 + 1)$ -ES on the sphere without reevaluation. If the parent is not evaluated anew, the fitness of the parent is systematically overvalued. Accounting for this effect makes the analysis more difficult than before. The degree of overvaluation Ξ of the parent is defined as the difference between the ideal, true fitness, and the perceived fitness. Likewise, ξ denotes the degree of overvaluation of the offspring. For the offspring, ξ is normally distributed. In the case of the parent, selection influences the distribution. Obtaining this distribution proved to be quite difficult; therefore, a Gram–Charlier expansion was used. This also required the determination of several moments of the unknown series. Following Beyer (1995b), self-consistency conditions were imposed, that is, it was assumed that a time-invariant distribution is approached and that the moments do not change over time. Investigations revealed that cutting off the series after the second term, thus, assuming a normal distribution, yields already good results. The remaining task consisted in determining the mean and variance of the distribution of the parent's degree of overvaluation.

The analysis revealed that in the case of the $(1 + 1)$ -ES with reevaluation, noise increases the probability of an offspring replacing the parent. Without reevaluation, noise has the opposite effect. As a result, an ES with reevaluation shows negative quality gains for a wide range of the mutation strength once the noise strength is above a limit. Without reevaluation, the quality gain remains positive.

Comparing the two strategies using their respective optimal mutation strength showed that the ES with reevaluation never outperforms the ES without reevaluation. Its performance is even inferior for noise larger than a limit value. This can be traced back to the reduced success probabilities for ESs without reevaluation, which are caused by the systematic

overvaluation of the parent. Since the parent is overvaluated, an offspring is only accepted if the perceived fitness gain is relatively large. In this case, the perceived better fitness has a good chance to be actually better. The ES is less biased to accept offspring, which have a truly smaller fitness than the parent. However, overvaluation also means that many offspring with true but small fitness improvements may not be accepted.

The question remained what degree of overvaluation may be useful provided that it could be calibrated. The analysis in Arnold and Beyer (2002a) showed that an ES may profit from occasional reevaluations. The frequency of reevaluation, however, depends on the mutation strength and therefore on the step-size adaptation mechanism. Experiments with the 1/5th-rule revealed that this mechanism is not suited for a $(1 + 1)$ -ES without reevaluation, if the noise strengths are larger than a limit: The 1/5th-rule tries to achieve a certain success probability. If the success probabilities are too small, the rule reduces the mutation strength. If the parent is not reevaluated, the target success probability is simply not reachable once the noise is too large. The ES reduces the mutation strength permanently and the search stagnates.

So far the discussion has been on strategies with only one parent. Arnold and Beyer (2001b) considered the performance of the $(\mu/\mu_b, \lambda)$ -ES in infinite-dimensional search spaces. The analysis led to an evolution criterion, that is, a maximal noise strength for a nonnegative quality gain, which depends on the population parameters. Keeping the truncation ratio fixed, it can be seen that the effects of any noise strength can be counteracted by increasing the population size. A further result was that the $(\mu/\mu_b, \lambda)$ -ES showed an improved performance in comparison with the $(1, \lambda)$ -ES. This can be traced back to the genetic repair effect and the resulting larger mutation strengths. Larger mutation strengths decrease the noise-to-signal ratio, which improves the progress.

Arnold and Beyer (2002b) carried the analysis over to finite-dimensional search spaces and derived an asymptotically correct expression for the progress rate (see Table 11). This could be used to give more accurate estimates for the (σ^*, σ_e^*) -combinations guaranteeing positive progress. It was found that increasing the number of parents widens the convergence region. The efficiency $\eta = \max_{\sigma^*} \varphi^*(\sigma^*)/\lambda$ is also influenced by the parent number with an optimal efficiency for a truncation ratio of 0.27 (Arnold and Beyer 2002b). In contrast to the finding in Arnold and Beyer (2001b), the efficiency does not increase indefinitely with the number of offspring. Using optimal values for the mutation strength and parent number, it was shown that an optimal number of offspring exists which depends on the noise strength and search space dimensionality.

In the case of the undisturbed sphere, the $(1 + 1)$ -ES is the most efficient of the standard types of evolution strategies. Using common multi-parent strategies does not have any advantage unless the algorithm makes use of parallel computation. This changes in the presence of noise. The efficiency of multi-parent strategies exceeds the efficiency of point-based strategies – except for low noise levels. On the one hand, this can be traced back to the genetic repair effect, which is caused by intermediate recombination. On the other hand, the question remains whether evolution strategies without recombination, but with populations, may also achieve a better performance than the $(1 + 1)$ -ES. Experiments had already shown that retaining more than the best candidate solution can lead to an improved performance.

In Arnold (2002a) and Arnold and Beyer (2001a, 2003a) the behavior of the (μ, λ) -ES was analyzed in more detail. As in the non-noisy case, the determination of the progress rate or quality gain is a demanding task. The distribution of the apparently μ best offspring has to be derived or approximated. This not only requires the use of noisy order statistics, but also

the treatment of the parental states as random variables. The time-variant distributions of succeeding populations under the influence of mutation, noise, and selection have to be taken into account and modeled. Usually, however, as in the non-noisy case, the assumption can be made that a time-invariant limiting distribution is approached. The ES populations are samples drawn from this distribution. Therefore, the moments of the population also approach a limit distribution.

In Arnold (2002a) a first moment-based analysis was presented. In a first step, infinite noise strength was assumed. In this case, selection becomes purely random and can be neglected. This allows for an exact determination of the expectation of central moments. Extending the analysis to the case of finite noise, the determination of the joint distributions of noisy order statistics is necessary, which complicates the calculations. An approximation of the density of the offspring distribution from which the candidates are drawn can be obtained using the Gram–Charlier series. This yields the expectation of the central moments of the population at generation $g + 1$ as a function of this expansion and the moments at generation g . The latter are of course random variables. In Arnold (2002a), a simple approach was followed by ignoring all fluctuations of these terms and considering only their expected values. This leads to a quality gain expression for linear fitness functions which agrees well with the result of experiments.

Arnold and Beyer (2001a, 2003a) analyzed the (μ, λ) -ES on a noisy linear function and the sphere model with respect to whether the use of populations is beneficial and how this comes to pass. Therefore, the (μ, λ) -ES was compared to the $(\mu/\mu_0, \lambda)$ -ES. The analysis followed the approach introduced in Beyer (1995b). The distribution of the offspring cannot be determined exactly. Therefore, it was expanded into derivatives of a normal distribution. To this end, the moments had to be obtained. The approach presented in Arnold (2002a) differs from Beyer (1995b). Instead of considering a skewed distribution, it was assumed that the derived random variables are normally distributed. Therefore, only the mean and variance of the population have been calculated using the respective values of the parent population and taking the effect of mutation into account.

The linear function, $f(\mathbf{y}) = \mathbf{a}^T \mathbf{y}$, effectively projects candidate solutions onto a line defined by the direction of \mathbf{a} . The problem is, therefore, basically one-dimensional and the quality gain and progress rate can be defined straightforwardly. In analogy to the axial progress rate for ridge functions, the progress rate measures the expected change of the position. First, a general expression for the mean and variance of the offspring population must be derived. Due to the assumption that the distribution of the offspring is normal, a result obtained in Arnold (2002a) for noisy order statistics can be directly applied, leading to the quality gain and the progress rate. Both depend on the progress coefficient

$$c_{\mu/\lambda}(\theta) = \frac{1 + \kappa_2}{\sqrt{1 + \kappa_2 + \theta^2}} e_{\mu,\lambda}^{1,0} \quad (121)$$

with $\theta = \sigma_e/\sigma$ the noise-to-signal ratio and $\kappa_2 = D^2/\sigma^2$. The parameter D^2 denotes the variance of the parent population. The result can be used to discuss the effects of operating with a population of $\mu > 1$. Without noise, the increase of the population variance with its size μ is counterbalanced by the decrease of the progress coefficient $e_{\mu,\lambda}^{1,0}$. Noise increases the population variance additionally. Furthermore, evolution strategies with populations operate with a different noise-to-signal ratio. While this value is $\theta = \sigma_e/\sigma$ for the $(1, \lambda)$ -ES, it is $\theta/\sqrt{1 + \kappa_2}$ for the (μ, λ) -ES. That is, (μ, λ) -ESs algorithmically decrease the noise-to-signal ratio.

As for the calculation of the parental population variance and mean, the approach of Beyer (1995b) was applied. This led to fix-point or self-consistent equations to be solved. The result showed that the population variance increases with the size of the population and with the noise. A comparison with experiments showed that the normality assumption for the offspring distribution is usually not sufficient for higher noise strengths and population sizes.

A similar approach can be applied to the sphere model using the decomposition technique for the mutation vectors. The analysis is based on the assumption that the distance to the objective exceeds the population variance. To this end, large search space dimensionalities and population sizes μ , not too large, must be assumed in conjunction with a normal approximation of the offspring distribution. Experiments showed that the resulting progress rate formula is an accurate predictor.

The progress rate can be used to compare several strategies using the efficiency as comparison measure. It was found that for each λ and noise strength σ_e^* an optimal μ exists, which is usually between 0.1λ and 0.3λ . Using this optimal μ , the efficiency of the $(\mu_{\text{opt}}, \lambda)$ -ES and the $(1, \lambda)$ -ES can be compared. The efficiency of the $(\mu_{\text{opt}}, \lambda)$ -ES is greater than that of the $(1, \lambda)$ -ES except for small noise strengths. Retaining more than one offspring enables the ES to operate with smaller offspring populations in the presence of noise. Considering a $(1 + 1)$ -ES showed that the single point strategy is only superior for very small normalized noise strengths and shows worse performance for larger noise strengths.

Regarding the efficiency of the (μ, λ) and the $(\mu/\mu_b, \lambda)$ -ES, it can be stated that both strategies are able to operate with a reduced noise-to-signal ratio. The efficiency formulas read

$$\eta_{\mu, \lambda} = \frac{1}{\lambda} \left(\frac{1 + \kappa_2}{\sqrt{1 + \kappa_2 + \theta^2}} \sigma^* e_{\mu, \lambda}^{1,0} - \frac{\sigma^{*2}}{2} \right) \quad (122)$$

$$\eta_{\mu/\mu_b, \lambda} = \frac{1}{\lambda} \left(\frac{\sigma^* e_{\mu, \lambda}^{1,0}}{\sqrt{1 + \theta^2}} - \frac{\sigma^{*2}}{2\mu} \right) \quad (123)$$

The mechanisms by which the improved efficiency is obtained differ: The (μ, λ) -ES reduces the noise-to-signal ratio by an increase of the population variance which enhances the effect of the mutations. The $(\mu/\mu_b, \lambda)$ -ES reduces the ratio by operating with higher mutation strengths made possible by means of the genetic repair effect.

Arnold (2006b) investigated the (λ_{opt}) -ES on the noisy sphere. This ES-type uses a weighted multi-recombination taking the whole offspring population into account. Optimal weights $w_{k, \lambda}$ are given by the expected value of the $(\lambda + 1 - k)$ th order statistic of the standard normal distribution. It was shown that the (λ_{opt}) -ES does not benefit from the genetic repair effect. However, a rescaling of the weights $w_{k, \lambda} \rightarrow w_{k, \lambda}/\kappa$, with $\kappa > 1$ can be applied. This leaves the optimal quality gain unchanged in the noise-free case (for $N \rightarrow \infty$). The optimal mutation strength, however, increases with the scaling factor κ . An increase of the mutation strength lowers the noise-to-signal ratio. Obtaining the quality gain for the (λ_{opt}) -ES on the noisy sphere, it could be shown that the ES is capable of maintaining a positive quality change up to a normalized noise strength of $\sigma_e^* = 2\kappa$. The analysis indicated that large values of κ should be preferred.

Arnold and Beyer (2003b) analyzed the effects of outliers on the outcome of optimization. To simulate a noise distribution with frequently occurring outliers, the Cauchy distribution was chosen. The analysis was extended in Arnold and Beyer (2006a). Three noise distributions were compared for the $(\mu/\mu_b, \lambda)$ -ES: normally distributed noise, Cauchy noise, and χ_1^2

distributed noise. In the latter case, two different cases were considered: adding the noise term to the fitness function, which results in a random variable with a mean greater than the actual value, and subtracting the noise term leading to a random variable with a smaller mean.

One aim was to investigate whether the assumption of a Gaussian noise model is too restrictive to allow a transfer of the obtained results to other situations. For each model, the first task was to derive the progress rate. The results can be used to investigate:

- The effects of varying noise levels
- The influence of population sizing, the truncation ratio, and the number of offspring
- The efficiency of reevaluation/resampling of search points compared to upgrading offspring population sizes

and to compare the results with respect to transferability from one noise model to another.

As shown in Arnold and Beyer (2006a), Cauchy noise leads to similar qualitative responses of the ES as Gaussian noise. It should be noted that in the case of Cauchy noise, the role of the noise strength is different. Instead of being the standard deviation of the noise, it should be regarded as a scale parameter. (Actually, this interpretation can also be applied to the Gaussian noise case, thus, allowing for a direct comparison of the performances.) Therefore, a comparison of the scaling behavior has been made (Arnold and Beyer 2006a). As for Gaussian noise, progress is only possible up to a maximal normalized noise strength. This quantity depends on the truncation ratio and on the size of the offspring population. Strategies with a ratio of 0.5 achieve the best results. Increasing offspring population sizes appears to increase the maximal admissible noise strength. To achieve optimal performance, the truncation ratio has to be variated with respect to the noise level starting with 0.27 for zero noise and going up to 0.5 for the upper noise limit. The difference between Gaussian and Cauchy noise lies only in the shape of the response curves.

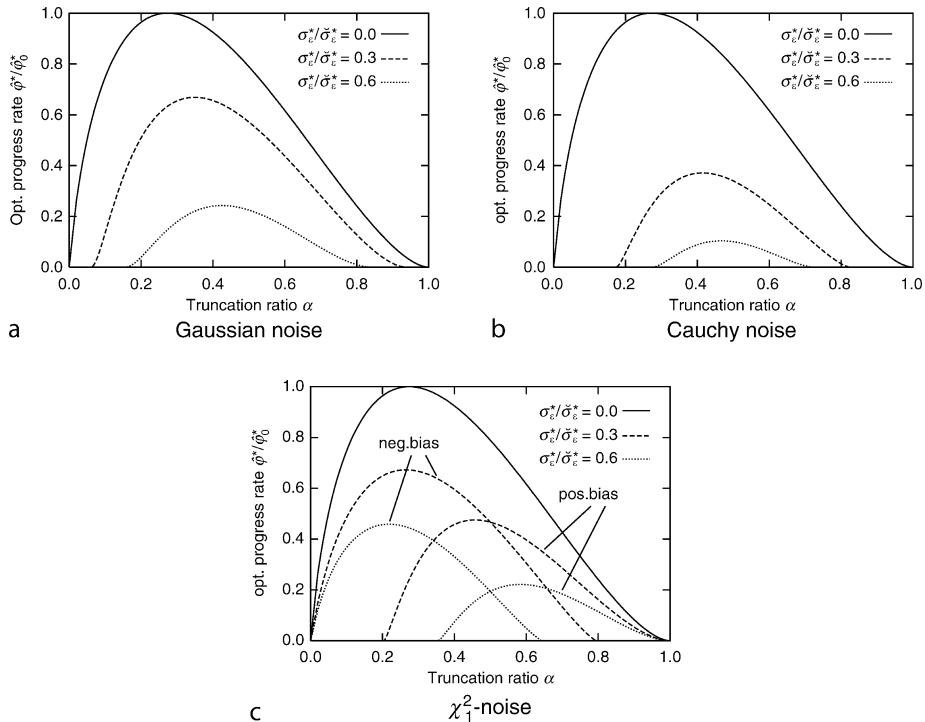

The question remains for which ranges of the truncation ratios positive progress occurs. For both distributions, the range narrows with increasing noise levels to smaller and smaller intervals, which encompass 0.5 (see Fig. 10a, b). The similarities between the two noise models transfers to the question whether resampling is more efficient than using an ES with a larger offspring population. For both noise models, this can be negated. Comparing ESs with the same computational costs and varying resampling sizes showed that larger populations have to be preferred. The difference between the approaches is more pronounced for Cauchy noise, however (Arnold and Beyer 2006a). For Gaussian noise, the ES benefits from averaging over the reevaluations of search points since the variance of the noise is reduced. For Cauchy noise, averaging has no effect since the resulting distribution is exactly the same.

One major difference between Gaussian and Cauchy noise exists. This is caused by a different response toward vanishing noise-to-signal ratios. In the case of Gaussian noise, the effects of the noise may be nearly eliminated, if the population size and the mutation strength are sufficiently large. In the case of Cauchy noise, this does not hold anymore. Increasing the population sizes will not allow the strategy to operate as if noise were not present.

Noise with a χ_1^2 -distribution leads to two possible cases: adding (positively biased noise) or subtracting the random term (negatively biased noise). The ES accordingly responds in different ways. First of all, increasing the offspring population size still increases the limit noise strength. However, the first difference appears in the optimal truncation ratio and its response to varying noise levels (see Fig. 10c). For neither case of χ_1^2 -distributed noise, does the truncation ratio approach 0.5. As for Cauchy and Gaussian noise, increasing noise narrows the band of truncation ratios for which positive progress is possible. Unlike the previous cases, however,

Fig. 10

The progress rate $\hat{\varphi}^*$ for optimal mutation strengths as a function of the truncation ratio α (Arnold and Beyer 2006a). The y-axis is scaled with the maximal progress rate $\hat{\varphi}_0^*$ obtained for the noise-free case and a truncation ratio of 0.27. Shown are the curves for three different noise strength σ_e^* to limit noise strength $\check{\sigma}_e^*$ ratios. Figure (a) depicts the case of Gaussian noise, (b) the case of Cauchy noise, and (c) shows the case of a χ_1^2 distributed noise.

only one boundary of the interval moves: Positively biased noise extends upward to a ratio of 1.0, whereas negatively biased noise stretches downward to zero (Arnold and Beyer 2006a).

Comparing the efficiency of strategies with resampling and strategies with larger population sizes leads to the same finding as before: An increased population size is preferable. Noise with a χ_1^2 -distribution has a similarity with Gaussian noise: The effects of noise can be eliminated with vanishing noise-to-signal ratio.

General Quadratic Functions and Other Functions

In Beyer and Meyer-Nieberg (2004), the quality gain of the $(1, \lambda)$ -ES was derived under the assumption of additive, normally distributed noise. The approach used the concept of noisy order statistics and a Gram–Charlier expansion for the pdf of the fitness values. The result

$$\overline{AQ_{1,\lambda}} = \frac{S_Q^2}{\sqrt{S_Q^2 + \sigma_e^2}} c_{1,\lambda} + M_Q \quad (124)$$

with mean M_Q and standard deviation S_Q of the local quality change, that is, of the fitness change induced by a mutation – strongly resembles the progress rate equation for the noisy

sphere. Instead of the mutation strength, the standard deviation of the local quality change appears. Noise only influences the first part in [Eq. 124](#) and not the mean M_Q . A sufficient evolution criterion is obtained by demanding that $\overline{\Delta Q_{1,\lambda}} \geq 0$, leading to $S_Q^2 / \sqrt{S_Q^2 + \sigma_\varepsilon^2} c_{1,\lambda} \geq -M_Q$ (Beyer and Meyer-Nieberg [2004](#)).

The remaining task for this kind of analysis is to determine the mean and standard deviation for the respective fitness function. This has been done for general quadratic, biquadratic, the L_1 -norm, and – to test the ranges of the applicability – for the bit-counting function OneMax (see [Table 12](#)). For all these functions, the mean of the fitness corresponds with a negative, nonlinear loss term.

Ridge Functions

As in the undisturbed case, the ES is faced with two subgoals in the optimization process. Accordingly, there are two variables that have to be considered: The position on the y_1 axis and the distance R to the y_1 axis. In the long run, the latter (usually) approaches a stationary distribution, whereas the y_1 -evolution continues to progress. The question remains how noise influences the stationary distribution of the distance and what the consequences are for the axial progress. The first question is similar to determining the localization error for the sphere model. The result, however, determines the axial progress, that is, the performance of the ES.

Table 12

Quality change formulae for different fitness environments. Explanation of variables and notation: $c_{\mu/\mu,\lambda}$ progress coefficient ([Eq. 132](#), see Beyer [\(2001b, p. 172\)](#)), σ^* normalized mutation strength, σ_ε^* standard deviation of noise distribution (normalized), higher order progress coefficients $d_{1,\lambda}^{(k)}$ ([Eq. 129](#)) or see Beyer [\(2001b p. 119\)](#), S_Q and M_Q standard deviation and mean of the mutation-induced fitness change Q , κ_k k th cumulant. The normalizations are as follows:

(a) **sphere** $\sigma^* = \sigma N/R$, $\sigma_\varepsilon^* = \sigma_\varepsilon N/R$, $\overline{\Delta Q^*} = \overline{\Delta QN}/(Rg'(R))$ (b) **quadratic functions**

$\sigma^* = \sigma \text{Tr}[Q]/\|Q(y - \hat{y})\|$, $\sigma_\varepsilon^* = \sigma_\varepsilon \text{Tr}[Q]/(2\|Q(y - \hat{y})\|^2)$, $\overline{\Delta Q^*} = \overline{\Delta Q}/(2\|Q(y - \hat{y})\|^2)$ (c) **biquadratic functions**

$\sigma^* = \sigma^3 \sqrt{3 \sum_i c_i / \|a\|^4}$, $\sigma_\varepsilon^* = \sigma_\varepsilon^3 \sqrt{3 \sum_i c_i / \|a\|^4}$, $\overline{\Delta Q^*} = \overline{\Delta Q} \sqrt[3]{3 \sum_i c_i / \|a\|^4}$, and

(d) **OneMax** $\sigma^* = \sqrt{lp_m} 2(2F_0/I - 1)$, $\sigma_\varepsilon^* = \sigma_\varepsilon 2(2F_0/I - 1)$, $\overline{\Delta Q^*} = \overline{\Delta Q} 2(2F_0/I - 1)$ with F_0 the fitness of the parent, p_m the bit-flipping probability, and I the string length

Fitness	ES	Quality gain
General functions	$(1, \lambda)$ -ES	$\overline{\Delta Q_{1,\lambda}} = \frac{c_{1,\lambda} S_Q}{\sqrt{S_Q^2 + \sigma_\varepsilon^2}} + M_Q$
Quadratic functions	$(1, \lambda)$ -ES	$\overline{\Delta Q^*} = \frac{c_{1,\lambda} \sigma^*}{\sqrt{\sigma^{*2} + \sigma_\varepsilon^{*2}}} - \frac{\sigma^{*2}}{2}$
Biquadratic functions	$(1, \lambda)$ -ES	$\overline{\Delta Q^*} = \frac{c_{1,\lambda} \sigma^{*2}}{\sqrt{\sigma^{*2} + \sigma_\varepsilon^{*2}}} - \sigma^{*4}$
OneMax	$(1, \lambda)$ -ES	$\overline{\Delta Q^*} = \frac{c_{1,\lambda} \sigma^{*2}}{\sqrt{\sigma^{*2} + \sigma_\varepsilon^{*2}}} - \frac{\sigma^{*2}}{2}$
Sphere	$(\mu/\mu, \lambda)$ -ES	$\overline{\Delta Q^*} = \frac{c_{\mu/\mu,\lambda} \sigma^{*2}}{\sqrt{\sigma^{*2} + \sigma_\varepsilon^{*2}}} - \frac{\sigma^{*2}}{2\mu}$

Arnold and Beyer (2008) analyzed evolution strategies on the noisy parabolic ridge. The noise model considered was an additive, normally distributed noise model with different functional dependencies of the noise strength: constant noise strength, noise strength scaling quadratically with the distance, and noise scaling cubically with the distance.

Using the same decomposition of the progress vector as in the non-noisy case, the axial progress rate could be obtained (see \blacktriangleright Table 13). Instead of determining the radial progress rate, the expected change of the square of the distance was determined leading to an expression for the standardized distance to the ridge which is a polynomial of order four and influenced by the noise strength and the mutation strength.

Let one first consider the case of constant noise strength. In this case, increasing the mutation strength increases the performance as in the non-noisy case. Large mutation strengths achieve a better noise-to-signal ratio $\theta = \sigma_e/\sigma$. Increasing the mutation strength eventually eliminates virtually the influence of noise on the progress. Furthermore, the ES achieves a stationary distance of $R_\infty = \sigma N / (\mu c_{\mu/\mu,\lambda})$ and accordingly an axial progress rate of nearly $\varphi_{\max} = \mu c_{\mu/\mu,\lambda}^2 / (dN)$. By increasing μ and λ , the location error to the axis can be decreased – if σ is constant. This is coupled with an increase of the performance. As on the sphere, it is optimal to choose a truncation ratio of $\mu / \lambda = 0.27$, since this maximizes $\mu c_{\mu/\mu,\lambda}^2$ (Arnold and Beyer 2008).

For quadratic noise strengths, an increase of the mutation strength is also beneficial and connected with an increased performance. While for the constant noise case the increase of the mutation strength eventually enabled the ES to reach nearly the same progress as in the undisturbed case, this is not the case for quadratic noise strengths. Increasing the mutation strength also increases the distance to the axis. Since the noise scales quadratically, the noise-to-signal ratio cannot be driven to zero by an increase of the mutation strength. Instead, a positive limit value is reached and the progress rate approaches a saturation value. The maximal achievable progress rate decreases with the noise. Furthermore, positive progress is only possible up to a certain noise level $\mu c_{\mu/\mu,\lambda} / (dN)$, with d the scaling parameter of the squared distance in \blacktriangleright Eq. 76. The noise level depends on the ES.

The case of cubic noise strengths is more involved. The stationary condition leads to two potential stationary solutions. For small mutation strengths, the smaller solution represents a stable stationary point, whereas the larger is unstable. Increasing the mutation strength increases the stable solution until it finally coincides with the unstable point. Thus, for

Table 13

Asymptotical axial progress rates for the noisy parabolic ridge in the stationary case. The normalizations read $\varphi_{y_1}^* := \varphi_{y_1} dN / (\mu c_{\mu/\mu,\lambda}^2)$, $\sigma^* := \sigma dN / (\mu c_{\mu/\mu,\lambda})$, and $\sigma_e^* := \sigma_e dN / (\mu c_{\mu/\mu,\lambda})$ for constant noise. In the case of quadratic noise, $\sigma_e^* = \zeta \rho^2$, $\zeta^* := \zeta dN / (\mu c_{\mu/\mu,\lambda})$ with ρ the standardized distance to the axis $\rho := 2Rd$

Noisy type	Progress rate
Constant noise	$\varphi_{y_1}^* = \frac{\sigma^{*2}}{\frac{\sigma^{*2}}{2} + \sqrt{\frac{\sigma^{*4}}{4} + \sigma^{*2} + \sigma_e^{*2}}}$
Quadratic noise	$\varphi_{y_1}^* = \frac{\sigma^*(1 - \zeta^{*2})}{\frac{\sigma^{*2}}{2} + \sqrt{\frac{\sigma^{*4}}{4} + 1 - \zeta^{*2}}}$

mutation strengths above a noise-dependent limit value, no (stable) stationary solution exists. The ES diverges from the axis. The case of cubic noise is interesting, since it results in a new behavior of the noise-to-signal ratio. Here, increasing the mutation strength increases the ratio indefinitely. The influence of noise cannot be counteracted with an increase of the mutations strength as usual, but only with a decrease: the larger the noise, the smaller the mutation strength has to be. Depending on the noise, an increase of the mutation strength is only beneficial up to a certain limit. This limit decreases with the noise.

2.4.3 Residual Location Error and Fitness Error

Noise does not only influence the local performance of an ES but also the final solution quality. Provided that the noise strength is constant, the ES is unable to locate the optimizer. Instead, it typically converges to a time-invariant limit distribution. On an average, a residual location error, the expected distance to the optimizer and a residual fitness error, the expected difference between outcome and the optimum, are observed. In the following, how the local progress measures may be used to derive these values is described. The expressions can then be used to derive recommendations for population sizing with respect to the solution quality. As it will be shown, optimal settings with respect to the solution quality usually correspond to nonoptimal progress. Therefore, a compromise between convergence speed and solution quality must be made.

Sphere Model

The analyses for the sphere model aim to derive lower bounds for the residual location and fitness error and to investigate the influence of the truncation ratio. An important tool is the evolution criterion gained by the progress rate which gives the maximal noise strength (normalized). The limit noise strength corresponds with zero progress and therefore with a stationary state of the evolution of the distance. Undoing the normalization leads to an inequality in which the distance appears as the unknown. Therefore, solving the distance gives a lower bound for the residual location error.

In Arnold and Beyer (2002b), the simple sphere $f(R) = \beta R^\alpha$ was considered yielding lower bounds for the residual location error (see \circledast Table 14). The lower bound increases linearly with the noise strength and search space dimensionality. Further influences are the parent and offspring population sizes. Minimal values are obtained for truncation ratios of 0.5. The lower

\blacksquare Table 14

Noise and residual location errors for the sphere. See \circledast Table 11 for the definition of the noise type. The progress coefficient is given by \circledast Eq. 132

Fitness function	Noise type	Residual location error
Sphere	Systematic	$R_\infty \geq \frac{N\sigma_e}{\sqrt{8\mu c_{\mu/\mu,\lambda}}} \sqrt{1 + \sqrt{1 + \frac{8\mu^2 c_{\mu/\mu,\lambda}^2}{N}}}$
Sphere	Standard	$R_\infty = \sqrt{\frac{N\sigma_e}{4\mu c_{\mu/\mu,\lambda}}}$

bound approximates the residual location error very closely. This is caused by the step-size adaptation mechanisms which operate with comparatively low mutation strengths as experiments showed.

General Quadratic Fitness Model

The analysis of general quadratic fitness models (☞ 73) is more difficult than the simple sphere model. While the residual location error can be obtained rather easily if the function is of the form $f(R) = \beta R^2$, the general model requires more effort. Usually, the residual fitness error is derived instead of the location error. One approach, followed in Beyer and Arnold (1999, 2003a), is analogous to the sphere model case. The same evolution criterion is used substituting the radius with the mean radius to be obtained using differential geometry methods. This leads finally to a stationarity condition for general quadratic fitness functions. Switching to the eigen space of the \mathbf{Q} -matrix simplifies the calculations.

In Beyer and Arnold (2003a) steady state conditions for the $(\mu/\mu_b, \lambda)$ -ES were derived (see ☞ Table 15). Using the sphere model evolution criterion for this ES (Arnold and Beyer 2002b), an inequality for the square of the transformed location error $\|\mathbf{Q}(\mathbf{y} - \hat{\mathbf{y}})\|$ can be derived. Taking the expectation of the transformed location error leads to an expression that can be interpreted as the variance $E[(y_i - \hat{y}_i)^2]$ of the object vector component y_i in the eigen space of \mathbf{Q} , centered about the optimizer \hat{y}_i . Using the *equipartition assumption* which states that in expectation, every weighted component $q_i(y_i - \hat{y}_i)^2$ contributes the same amount to the fitness error, a lower bound for the fitness error could be derived. The equipartition assumption is similar to the equipartition assumption in statistical thermodynamics. Up to now, it has not been proven formally, but the following plausibility argument can be made (Beyer and Arnold 2003a): The ES is in the steady state. The mutations which generate the object vector components are not directed. Selection is not influenced by a single component since it only experiences the fitness as a whole and thus does not prefer a single weighted component. If one component dominated the rest, the corresponding individual would go extinct since this results in lower fitness values. The components fluctuate independently around the optimizer.

Table 15

Noise and residual fitness errors for some fitness functions. The trace of the matrix \mathbf{Q} is defined as $\text{Tr}[\mathbf{Q}] = \sum_{i=1}^N (\mathbf{Q})_{ii}$, where $(\mathbf{Q})_{ii}$ are the diagonal elements of \mathbf{Q}

Fitness function	Noise type	Residual fitness error
Biquadratic functions	Standard	$E[4F] \geq \frac{3\sigma_e N}{40\mu c_{\mu/\mu,\lambda}}$
L_1 -norm	Standard	$E[4F] \geq \frac{\sigma_e N}{\pi\mu c_{\mu/\mu,\lambda}}$
General quadratic functions	Standard	$E[4F] \geq \frac{\sigma_e N}{4\mu c_{\mu/\mu,\lambda}}$
General quadratic functions	Actuator	$E[4F] \geq \sigma_e^2 \text{Tr}[\mathbf{Q}] + \frac{N\sigma_e^2 \text{Tr}[\mathbf{Q}]}{8\mu^2 c_{\mu/\mu,\lambda}^2} \times \left(1 + \sqrt{1 + \frac{8\mu^2 c_{\mu/\mu,\lambda}^2 \text{Tr}[\mathbf{Q}^2]}{\text{Tr}[\mathbf{Q}]^2}} \right)$

For this reason, selection does not prefer any particular search direction. If there were such a preference, the ES would still exhibit a directed movement and would not have arrived at the steady state.

The lower bound obtained by the equipartition assumption depends linearly on the noise strength, on the search space dimensionality, and on the population parameters (see  [Table 15](#)). Interestingly, there is no influence of the matrix \mathbf{Q} . That is, the result holds for all ellipsoidal quadratic success domains. The agreement of the lower bound with experimentally determined residual fitness errors is quite good (Beyer and Arnold [2003a](#)).

Other Fitness Models

Beyer and Meyer-Nieberg ([2005](#)) considered the residual fitness error of the biquadratic functions, and the L_1 -norm. The expressions were obtained for the $(1, \lambda)$ -ES. With a simple analogy argument, the results were transferred to the $(\mu/\mu_t, \lambda)$ -ES which enabled a determination of the optimal truncation ratio.

The quality gain obtained in Beyer and Meyer-Nieberg ([2004](#)) can be used to derive a necessary evolution criterion $S_F^2 \geq \sigma_e |M_F| / c_{1,\lambda}$. Under certain conditions, this lower bound can be assumed to be sharp. To obtain the fitness error, the mean and the standard deviation of the fitness value must be determined. For the fitness functions considered, the stationary state criterion is a nonlinear expression of the object vector components and the mutation strength. The determination of the fitness error requires some simplifications and assumptions, especially the equipartition assumption. All the function classes considered have a final fitness error of the form $E[\Delta F] = \sigma_e N/(Cc_{1,\lambda})$, with C depending on the fitness function. Substituting $c_{1,\lambda}$ with $\mu c_{\mu/\mu_t, \lambda}$ gives the result for the intermediate ES. Owing to the form of the fitness error, the results obtained for the sphere can be transferred to biquadratic functions and the L_1 -norm: A truncation ratio of $1/2$ is optimal with respect to the fitness error. Since working with $\mu/\lambda = 0.27$ does not significantly degrade the solution quality, this truncation ratio can still be used.

2.4.4 General and Systematic Noise

In the case of general noise, the fitness function itself is a random function F_ϵ which makes a general treatment difficult. In Beyer et al. ([2003](#)), however, the authors present a decomposition technique. Instead of using the exact random function, an approximate model is utilized. The random function F_ϵ is decomposed into two parts: a deterministic part, that is, the expectation $E[F_\epsilon|\mathbf{y}]$, and a stochastic part. The stochastic part is expanded into an Edgeworth or Gram–Charlier series. In a first approximation, this leads to a normal distribution

$$F_a(\mathbf{y}) = E[F_\epsilon|\mathbf{y}] + \mathcal{N}(0, \text{Var}[F_\epsilon|\mathbf{y}]) \quad (125)$$

Thus, on the one hand, the conditional expectation and variance of F_ϵ given the state \mathbf{y} have to be obtained. On the other hand, it is possible to apply the analysis techniques developed for the additive noise model.

Systematic noise was considered under the following aspects:

1. Beyer et al. ([2003](#)) introduced the decomposition approach.
2. Sendhoff et al. ([2002](#)) analyzed functions with noise-induced multi-modality (FNIMs).
3. Beyer et al. ([2004](#)) considered systematic noise on the quadratic sphere.

4. Beyer (2004) addressed actuator noise on general quadratic functions.
5. Beyer and Sendhoff (2006) introduced and analyzed a class of test functions for evolutionary robust optimization.

Beyer et al. (2003) considered the behavior of the $(\mu/\mu_r, \lambda)$ -ES in two uncertain environment types, the sphere with actuator noise and a mixed noise model

$$F(\mathbf{y}) = a - (z + 1)\|\mathbf{y}\|^x + bz \quad \text{with} \quad z \sim \mathcal{N}(0, \sigma_e^2) \quad (126)$$

The task in this case is to maximize the fitness values. Two classes of probabilistic performance criteria, threshold measures (Eq. 117) and statistical momentum measures (Eq. 118), were applied in the analysis. In the case of the sphere model, it followed that the robust optimizer with respect to both measures equals $\mathbf{y} = \mathbf{0}$. A lower bound for the residual location error was obtained with a quite accurate predictive power. Again, the minimal location error is obtained for a truncation ratio of 1/2. The standard recommendation $\mu / \lambda = 0.27$ still applies as a reasonable setting since the solution quality is only slightly degraded and the convergence velocity to the steady state is larger.

A further point of the analysis concerned the online fitness behavior and the robustness with respect to the statistical momentum measures. In the stationary state, the fitness values fluctuate around a mean value. In Beyer et al. (2003), the mean and the standard deviation of the fitness values were obtained. Using an *ansatz* for the variance of a single component of the centroid in object parameter space, it was possible to derive estimates for the expected value and standard deviation. Again, an ES with a truncation ratio of 1/2 achieves the smallest mean and standard deviation.

Concerning Eq. 126, the analysis showed that threshold measures are not suitable as conflicting information from a distance increase or decrease. Consequently, there is no unique value of an optimal distance. Therefore, only momentum measures should be taken into account. However, this approach also leads to ambiguities. While the first moment can be decreased by a decrease in the distance, this results in an increased variance. The variance has a minimal value for $R^x = b$. The analysis revealed that the ES shows a bifurcation behavior depending on the size of f

$$\frac{2\alpha\mu c_{\mu/\mu_r, \lambda}}{\sigma_e N} \quad (127)$$

If Eq. 127 is larger than one, only one stationary point exists and the ES shows a stable behavior with a well-defined lower bound for the residual location error. For values of Eq. 127 smaller than one, the system switches from having only one steady state to two steady states. Whether the ES converges or diverges depends on the initial distance. If the ES does not diverge, it compromises, in a sense, between a fitness maximal distance and a variance minimal distance: The residual location error lying somewhere in between and the population parameters can be used to bias the ES toward either of the extremes.

In Beyer et al. (2004), the influence of systematic noise on the performance and steady state behavior of ESs on the quadratic sphere was considered. The analysis was focused on the following questions:

1. Efficiency.
2. What are sufficient evolution criteria considering the dynamical behavior of the ES? That is, under which conditions do the ES *not* diverge?

3. What does this imply for σ control rules? And are there differences between CSA and σ SA control?

Using the decomposition technique from above, it is possible to derive the progress rate showing close resemblance to the case of additive noise.

The progress rate obtained, the question of efficiency defined by $\eta = \max_{\sigma} \varphi(\sigma) / \lambda$ could be discussed. However, due to the form of the progress rate, the maximal efficiency can only be determined for cases where the noise strength scales with the distance to the optimizer. This special case leads to the recommendation of a truncation ratio $\mu/\lambda = 0.27$.

Considering general noise again, the progress rate allows for a derivation of a sufficient evolution criterion which leads to two main findings:

1. To increase the convergence probability in cases with high noise levels, any σ control mechanism should produce small step sizes. This, however, comes at the cost of reduced convergence speed. Again, there is a trade-off between convergence reliability and convergence speed.
2. Problems with higher search space dimensionality are evolutionarily more stable (Beyer et al. 2004).

The analysis then considered the case of constant noise strength. A steady state, that is zero progress, is attained if the equal sign in the evolution criterion is exactly fulfilled. As investigated empirically, both CSA and σ SA eventually steer the ES toward the zero progress region. The criterion of zero progress can then be used to derive lower bounds for the residual location error yielding two results: First, the residual location error scales linearly with the noise strength. Second, recommendations concerning μ and λ can be given. It is optimal to have a truncation ratio of $\mu/\lambda = 1/2$. The region around the optimal truncation ratio is rather flat, allowing the use of smaller ratios with better efficiency. Furthermore, keeping the truncation ratio fixed, increasing the population size decreases the location error.

In Beyer (2004), the effects of actuator noise on the stationary state behavior of intermediate evolution strategies were considered using the general quadratic fitness model (🔗 73). The analysis showed that the expected deviation from the actual optimum consists of two parts: one part which is independent of the ES and depends only on the function and on the noise strength, and one part that can be influenced by the ES. Using a truncation ratio of 1/2 yields a minimal deviation from the actual optimum. This ratio is valid as long as the assumption of (at least asymptotical) normality is guaranteed.

In Beyer and Sendhoff (2006), a new test function class, functions with noise-induced multi-modality (FNIMs), was introduced and analyzed. The criteria for the analysis were moment-based measures and threshold measures. The authors succeeded in developing a test function that captures the important properties of general FNIMs while being amenable to a theoretical analysis. The steady state performance of the $(\mu/\mu_b, \lambda)$ -ES was investigated yielding the following findings:

- The resampling size should be kept as small as possible.
- A truncation ratio of about 0.3 is a good compromise between convergence speed and solution quality.
- Comparing σ SA and CSA showed that each mechanism has its advantages and disadvantages: While using CSA leads to a faster convergence, σ SA provides a better exploration behavior in the stationary state, albeit, with the risk of oscillatory behavior.

2.4.5 Noise and Step-Size Adaptation

This section considers the behavior of step-size adaptation mechanisms in the case of noisy fitness evaluations. Two mechanisms were primarily considered, self-adaptation and cumulative step-size adaptation. First, the results for self-adaptation are described.

Self-Adaptation

In Beyer and Meyer-Nieberg (2006a), the self-adaptive $(1, \lambda)$ -ES on the noisy sphere was considered. The first task was to determine the self-adaptation response (see [Table 18](#)). Afterwards, the deterministic evolution equations were used in the analysis. The evolution equations model the dynamical behavior of the normalized mutation strength, the distance to the optimizer, and the normalized noise strength. It can be shown that the evolution of the normalized mutation strength and noise strength do not depend on the distance R . Therefore, the analysis can be restricted to the two-dimensional system of σ^* and σ_ε^* .

Three phases of the evolution can be distinguished for constant noise strength σ_ε .

- A first phase, characterized by large distances to the optimizer in which the ES nearly behaves as if the fitness evaluations were exact.
- A transient phase, in which the ES is more and more influenced by the noise as it moves toward the optimizer.
- A stationary state in which no progress on average occurs. In this case, the dynamics of the mutation strength σ^* and σ_ε^* approach stationary distributions.

The progress rate and the self-adaptation response can be used to determine the $(\sigma^*, \sigma_\varepsilon^*)$ -combinations, which equal zero progress and zero expected change of the mutation strength. This leads to expressions for the stationary mutation strength, noise strength, and the residual location error, displayed in [Table 16](#). In contrast to the result obtained in Beyer (1993), the nonzero mutation strength introduces a correction factor which increases the residual location error. However, the deviation is not large, that is, self-adaptation does not lead to a significant degradation of the solution quality.

There is a peculiarity in the behavior of the $(1, \lambda)$ -ES: if the noise strength becomes too large, the ES loses step-size control. The mutation strength exhibits a random walk-like behavior biased toward small mutation strengths. This behavior cannot be predicted by the deterministic approach used in Beyer and Meyer-Nieberg (2006a). In spite of that, an explanation for this behavior can be given by considering the probability of a decrease in the mutation strength under random selection. This probability equals $1/2$. Selection changes the situation. The $(1, \lambda)$ -ES accepts a decrease of the mutation strength with high probability.

Table 16

The stationary state values of the $(1, \lambda)$ -ES with σ -self-adaptation on the sphere $g(R) := -cR^\alpha$. The normalizations read $\sigma^* := \sigma N / R$ and $\sigma_\varepsilon^* := \sigma_\varepsilon N / (c\alpha R^\alpha)$

Mutation strength	Noise strength	Location error
$\sigma^* = \frac{2c_{1,\lambda}}{\sqrt{2(2c_{1,\lambda}^2 + 1 - d_{1,\lambda}^{(2)})}}$	$\sigma_\varepsilon^* = 2c_{1,\lambda} \sqrt{1 - \frac{1}{2(2c_{1,\lambda}^2 + 1 - d_{1,\lambda}^{(2)})}}$	$R = \sqrt{\frac{\sigma_\varepsilon N}{c\alpha 2c_{1,\lambda}}} \sqrt{\frac{2(2c_{1,\lambda}^2 + 1 - d_{1,\lambda}^{(2)})}{2(2c_{1,\lambda}^2 + 1 - d_{1,\lambda}^{(2)}) - 1}}$

Large mutation strengths coincide more often with a selective disadvantage and are punished on average. This results in a tendency of the $(1, \lambda)$ -ES toward smaller mutation strengths: The ES performs some kind of biased random walk.

The aforementioned deficiency of $(1, \lambda)$ -ESs leads to the question whether intermediate recombination ESs exhibit similar erratic behaviors. Interestingly, this is not the case. These strategies are biased (in probability) toward an increase of the mutation strength resulting in a more stable σ -adaptation behavior.

In Meyer-Nieberg and Beyer (2008) the performance of the $(\mu/\mu_b, \lambda)$ -ES on the noisy sharp ridge was investigated (see [Tables 17](#) and [18](#)). The analysis provided an unexpected result: on the sharp ridge, noise can increase the performance. In order to understand this interesting property, one has to recall that the optimization consists of two subgoals:

1. Reducing the distance to the axis, that is, optimizing the embedded sphere model
2. Enlarging the linear axis component

Given a fixed strategy, the ridge parameter d decides which subgoal dominates the other. If d is large, the ES tries to optimize the sphere model which ultimately results in stagnation, since the mutation strength is decreased accordingly. Additive noise prevents the ES from achieving this subgoal. It attains a positive stationary $\sigma > 0$ and a “residual location error” (fluctuating at a certain distance from the ridge axis). Due to the positive mutation strength, the ES can serve the second subgoal: the enlargement of the linear part. Putting it another way, larger noise strengths result in worse achievements of the sphere subgoal which correspond to greater axial progress. Axial progress, mutation strength, and distance scale linearly with the noise. A remark concerning recombination is to be added. Recombination reduces the residual location error. This goes along with reduced mutation strengths and axial progress rates.

Table 17

The stationary state values of the $(\mu/\mu_b, \lambda)$ -ES with σ -self-adaptation on the sharp ridge. Shown are the approximate values obtained for large population sizes λ and appropriate choices of μ . The normalizations read $\sigma^* := \sigma N / R$ and $\varphi^* := \varphi N / R$

Mutation strength	Distance	Progress
$\sigma^* = \sqrt{\mu}$	$R = \frac{\sigma_e N}{2d\mu c_{\mu/\mu_b, \lambda}}$	$\varphi^* = \frac{1}{2d}$

Table 18

Self-adaptation response functions (SARs) for different fitness environments. Explanation of variables and notation: $c_{\mu/\mu_b, \lambda}$ progress coefficient (see [Sect. 5](#)), σ^* normalized mutation strength (with respect to distance to optimizer and search space dimensionality), σ_e^* standard deviation of noise distribution (normalized), d and α parameters of the ridge function

Fitness	SAR
Sphere	$\psi(\sigma^*) = \tau^2 \left(\frac{1}{2} + \frac{e_{\mu/\mu_b, \lambda}^{1,1} \sigma^{*2}}{\sigma^{*2} + \sigma_e^{*2}} - \frac{c_{\mu/\mu_b, \lambda} \sigma^{*2}}{\sqrt{\sigma^{*2} + \sigma_e^{*2}}} \right)$
Ridge	$\psi(\sigma^*) = \tau^2 \left(\frac{1}{2} + \frac{e_{\mu/\mu_b, \lambda}^{1,1} (1 + \alpha^2 d^2 R^{2\alpha-2}) \sigma^{*2}}{(1 + \alpha^2 d^2 R^{2\alpha-2}) \sigma^{*2} + \sigma_e^{*2}} - \frac{\alpha d R^{\alpha-1} c_{\mu/\mu_b, \lambda} \sigma^{*2}}{\sqrt{(1 + \alpha^2 d^2 R^{2\alpha-2}) \sigma^{*2} + \sigma_e^{*2}}} \right)$

However, recombination is necessary, since the $(1, \lambda)$ -ES experiences a loss of step-size control. Therefore, the use of small truncation ratios $> 1/\lambda$ is recommended.

Cumulative Step-Size Adaptation (CSA)

Arnold and Beyer (2000, 2004, 2008) and Beyer and Arnold (2003b) analyzed the performance of the $(\mu/\mu_b, \lambda)$ -ES with cumulative step-size adaptation (CSA). As far as the noise-free case is concerned, the reader is referred to [Sect. 2.3.4](#). The work done focused on a deeper discussion of the underlying philosophy of CSA, progress rate optimality, and population sizing. Several fitness environments were considered, starting with the sphere (Beyer and Arnold 2003b; Arnold and Beyer 2004) and continuing to ridge functions Arnold and Beyer (2008).

This paragraph starts with the sphere model and the additive Gaussian noise model. In Arnold and Beyer (2000) a first analysis of the performance of adaptive $(\mu/\mu, \lambda)$ -ESs was provided. Two major step-size adaptation mechanisms were considered: self-adaptive ESs (with arithmetic and geometric recombination of the mutation strength) and ESs with cumulative step-size adaptation on the noisy sphere. The noise strength was set to scale with the distance to the optimizer, that is, the normalized noise strength is constant. Demanding positiveness of the progress rate yields the necessary evolution criterion, that is, a criterion that must be fulfilled to have convergence to the optimizer at all. As a consequence, there is a maximal normalized noise strength above which the strategy diverges. This maximal noise strength depends on the population parameters and the fitness function. Experiments showed that the adaptation mechanisms encounter problems when noise comes into play. In the absence of noise, the algorithms achieve linear convergence order. For lower levels of noise, nearly optimal mutation strengths are generated. Increasing the noise level degrades the performance. For high noise-levels, the CSA generates decreasing normalized mutation strengths which first results in slower convergence and finally stagnation, if the noise-levels become too high. In contrast to the CSA-ES, the self-adaptive $(\mu/\mu_b, \lambda)$ -ES achieves a stationary normalized mutation strength which results in divergent behavior.

In Arnold and Beyer (2004), the authors performed an in-depth analysis of the $(\mu/\mu_b, \lambda)$ -CSA-ES on the sphere using the Gaussian noise model. The ES approaches a steady state which means that the progress vector, its length, and the normalized mutation strength have a time-invariant limit distribution. Calculating the target mutation strength, that is, the normalized mutation strength the value of which the CSA mechanism does not change in expectation, leads to a value smaller than the optimal mutation strength needed to maximize the progress rate. Furthermore, the logarithmic adaptation response indicates that for mutation strengths, which are significantly below the optimal value, there is only a small tendency toward an increase. This can be explained by the way the cumulative step-size adaptation works: It tries to adapt σ as if consecutive progress vectors were uncorrelated. Since noise overshadows the information gained from smaller step sizes, steps for small mutation strengths become nearly random and correlations disappear. This is in accordance with the CSA design philosophy, but the resulting search behavior is not always that what users desire when optimizing in noisy environments.

As in the non-noisy case, the ES cannot realize the target mutation strength in the steady state and it is usually not optimal. The mutation strength is too small for large noise strengths and too large for small noise strengths. The resulting convergence velocity is about 20–30% smaller than the optimum. Concerning the question of the population size, keeping the best 25–30% of the offspring population is a good choice.

In Beyer and Arnold (2003b), the fundamental working premises of the CSA algorithm were examined in detail. The analysis concerned the $(\mu/\mu_b, \lambda)$ -ES on the *static* noisy sphere and tried to shed light on the question whether the perpendicularity or uncorrelation condition of the CSA guarantees optimal progress and if not to identify the reasons. As a first step in the analysis, the perpendicularity condition (Hansen 1998), stating that the expectation of the scalar product of two consecutive step vectors $\mathbf{z}^{(g)}$ (Eq. 2) is zero, was revisited. Considering two consecutive generations and decomposing the second search step, the angle between the two vectors can be calculated. Perpendicularity is achieved for a certain mutation strength which depends on the population parameters and the noise strength: In the absence of noise, the perpendicularity condition leads to an asymptotically optimal adaptation of the mutation strength. In the presence of noise, however, the optimal mutation strength is not reached. The perpendicularity condition leads to a CSA evolution criterion (see Table 19) resulting in a maximally admissible noise strength, which is only half the limit value necessitated by the *ES evolution criterion*. If the noise strength is in between, the CSA realizes angles below 90° . To “cope” with the apparently too large mutation strength, the CSA responds by reducing the mutation strength continuously to zero. This explains the observations made in experiments.

In Arnold (2006b), the performance of the (λ_{opt}) -ES with CSA and weight rescaling was investigated on the noisy sphere. The realized mutation strength of the CSA differs from the optimal mutation strength. Again, there is a certain performance loss. However, it can be reduced by working with a large rescaling factor κ .

In Arnold and Beyer (2008), the performance of the $(\mu/\mu_b, \lambda)$ -ES with CSA was analyzed for the noisy parabolic ridge. Three model functions describing different scalings of the standard deviation σ_e (also referred to as noise strength) of the normally distributed noise have been investigated: (a) constant, (b) quadratically scaled, and (c) cubically scaled noise strengths. In the case of (b) and (c), the noise strength increases with the distance to the ridge axis. The steady state distance to the ridge axis, the mutation strength, and the axial progress rate were determined. Interestingly, it was found that the ES with CSA tracks the axis with a distance that is independent of the noise type. In the noise-free case, the $(\mu/\mu_b, \lambda)$ -ES with CSA achieves a progress rate that is half the optimum. In the presence of noise, only for low levels of noise, a stationary distance and positive progress can be achieved.

For constant noise strength, see Table 20, this means that above a certain strategy-dependent noise strength, progress is not possible. Note that the analysis part, without considering step-size adaptation mechanisms, indicates that an ES could cope with any noise strength by increasing the mutation strength. However, this property cannot be

Table 19

The perpendicularity condition of the CSA mechanism. According to the CSA philosophy, the expected angle, $\bar{\beta}$, between the parental change vector, and the local vector to the optimizer should be 90° . That is, $\cos(\bar{\beta}) = 0$ leads to the second column and in turn to the third

Angle	Mutation strength	CSA evolution criterion	ES evolution criterion
$\cos(\bar{\beta}) = \sigma^* \sqrt{\frac{\mu}{N} \left(\frac{1}{\mu} - \frac{c_{\mu/\mu,\lambda}}{\sqrt{\sigma^*{}^2 + \sigma_e^*{}^2}} \right)}$	$\sigma^* = \sqrt{\mu^2 c_{\mu/\mu,\lambda}^2 - \sigma_e^*{}^2}$	$\sigma_e^* < \mu c_{\mu/\mu,\lambda}$	$\sigma_e^* < 2\mu c_{\mu/\mu,\lambda}$

Table 20

The $(\mu/\mu_b, \lambda)$ -ES with CSA on the noisy parabolic ridge in the case of constant noise $\sigma_e = \text{const}$

Distance	Mutation strength	Progress
$R = \frac{1}{2d}$	$\sigma = \sqrt{\frac{\mu^2 c_{\mu/\mu_b, \lambda}^2}{2d^2 N^2} - \frac{\sigma_e^2}{2}}$	$\varphi = \frac{\mu c_{\mu/\mu_b, \lambda}^2}{2dN} - \frac{\sigma_e^2 dN}{2\mu}$

conserved when switching the CSA part on. Increasing the strength of the noise results in a decrease of the mutation strength. Therefore, the CSA-ES fails to track the axis for higher noise strengths. Similar findings hold for the quadratically and cubically scaled noise cases. Above a certain limit of the scaling parameter, the CSA-ES fails to generate useful mutation strengths. This limit can be shifted to larger values by increasing the population sizes accordingly.

2.5 **Dynamical Optimization: Optimum Tracking**

This section considers *dynamical optimization* problems which arise in many practical optimization situations. In contrast to conventional, static optimization where the problem does not change with time, dynamical optimization considers problems where the position of the optimizer changes – either randomly or deterministically. While in static optimization, the goal is to locate the optimizer fast and reliably, the task in dynamical optimization is to track the moving optimizer closely. That is, the task is not to converge to a fixed state, but to adapt fast to dynamically changing environments. Examples of dynamical optimization problems include online job scheduling with new jobs arriving in the course of optimization or dynamical routing problems.

In Arnold and Beyer (2002c, 2006b), the dynamical systems approach was applied to two examples of dynamical optimization problems: a sphere model with a randomly moving target (Arnold and Beyer 2002c) and a sphere model with linearly moving target (Arnold and Beyer 2006b). The analyses aimed at answering the following questions:

1. Are ES with cumulative step length adaptation (CSA) capable of dealing with dynamical problems – although the CSA rule was designed for static optimization?
2. What are the effects of using populations and recombination?

In Arnold and Beyer (2002c), the performance of the $(\mu/\mu_b, \lambda)$ -ES with CSA was investigated considering a sphere with random movements of the optimizer. Assuming that there exists a steady state of the ES once initialization effects have faded, an expression for the stationary tracking distance can be derived. The tracking distance depends on the mutation strength. Computing the derivative of the distance (with respect to the mutation strength) and setting it to zero, an optimal mutation strength and the minimal tracking error can be calculated (see [Table 21](#)). The question arises whether the CSA mechanism is able to tune the mutation strength to its optimal value. This is indeed the case (Arnold and Beyer 2002c). Therefore, it can be concluded that the CSA mechanism works perfectly for the $(\mu/\mu_b, \lambda)$ -ES for tracking a randomly moving target.

In Arnold and Beyer (2006b), the analysis was extended to the tracking of a linearly moving target. The tracking distance of the stationary state of the ES as a function of the

Table 21

Tracking behavior of the $(\mu/\mu_\lambda, \lambda)$ -CSA-ES on a randomly moving target (Arnold and Beyer 2002c) and a linearly moving target (Arnold and Beyer 2006b). The parameters μ and λ denote the sizes of the parent and offspring populations, N the search space dimensionality, c_{μ/μ_λ} is the progress coefficient (see [Sect. 5](#)), and δ denotes the speed of the dislocation of the objective. As for the random case, δ is the standard deviation of the random change of a single component of the optimizer, that is, $\hat{y}_i^{(g+1)} = \hat{y}_i^{(g)} + \mathcal{N}(0, \delta^2)$. In the linear case, δ is simply the velocity of change, that is, $\hat{y}^{(g+1)} = \hat{y} + \delta v$ with v the unit vector

Dynamics	Tracking distance	Optimal track. distance	Optimal mutation strength	Mutation strength realized
Random	$R = \frac{N}{2c_{\mu/\mu_\lambda}} \left(\frac{\sigma}{\mu} + \frac{\delta^2}{\sigma} \right)$	$R = \frac{N\delta}{\sqrt{\mu} c_{\mu/\mu_\lambda}}$	$\sigma = \sqrt{\mu}\delta$	$\sigma = \sqrt{\mu}\delta$
Linear	$R = \frac{N\sigma^3 c_{\mu/\mu_\lambda}}{2\mu(\sigma^2 c_{\mu/\mu_\lambda}^2 - \delta^2)}$	$R = \frac{3\sqrt{3}N\delta}{4\mu c_{\mu/\mu_\lambda}^2}$	$\sigma = \frac{\sqrt{3}\delta}{c_{\mu/\mu_\lambda}}$	$\sigma = \frac{\sqrt{2}\delta}{c_{\mu/\mu_\lambda}}$

mutation strength, the optimal mutation strength, and distance were determined. Considering the CSA-rule, it was found that an ES with CSA is able to track the linearly moving target. However, the mutation strength adapted is not optimal. The ES realizes the same mutation strength as in the static case.

Summarizing, it was found that ESs with CSA are capable of tracking dynamically moving targets. In the case of randomly moving targets, the CSA even succeeds in adapting the optimal mutation strength. In both cases, recombination improves the behavior of the ES: Evolution strategies that make use of parent populations with size greater than one and of recombination track the target more closely than $(1, \lambda)$ -ESs. These theoretical results are also of certain interest for other EAs, such as GAs, where it has been reported that dynamical problems often degrade the performance severely. As to the cases investigated so far, the ES does not experience such problems.

3 The Dynamical Systems Approach in Comparison

The approach presented so far used local progress measures to obtain analytical solutions, which can be used to discuss the dynamical behavior and convergence properties of the EAs. On the one hand, this enables us to consider the process in more detail: It is possible to analyze the relationship between parameter settings and the performance of the evolution strategy. On the other hand, due to the simplifications applied and assumptions made, ultimately, a “model” of the actual ES behavior is analyzed. The derivation of the model aims to take all important characteristics of the true ES into account and to transfer them to the final result. The most important assumption is the consideration of large search space dimensionalities N . This allows for the derivation of asymptotical progress measures, that is, measures obtained for infinite-dimensional search spaces. The so derived conclusions are valid as long as N is large. Considering small N will lead to deviations and usually the error made cannot be quantified analytically. That is why, the theoretical results must be supplemented with experiments.

Most analyses of self-adaptation consider only the expected changes. The ES dynamics are treated as if they were stemming from a deterministic model which may not be sufficient to capture all important characteristics of the process as the $(1, \lambda)$ -ES on the noisy sphere has revealed.

Auger and Hansen (2006) presented a discussion on the limitations of the progress rate theory on the sphere model for the $(1, \lambda)$ -ES. As they pointed out, for finite search space dimensionalities the usual definition of the progress rate theory corresponds to a *convergence in mean*. Connected with *almost sure convergence* is the *logarithmic progress rate* $\varphi_{\ln} = E[\ln(R^{(g)}/R^{(g+1)})]$, instead. However, the discrepancy between both measures decreases with increasing search space dimensionality, and in the asymptotical limit, both measures are the same. While, using the logarithmic progress rate has a certain appeal (and it is implicitly used when plotting fitness dynamics in logarithmic scale), up until now, there is no method to calculate it analytically for finite N sphere. Monte Carlo simulations must be used for a quantification. This diminishes the usefulness of that progress measure.

While using local performance measures and treating the ES as a dynamical system has proven as a very fruitful approach yielding results of practical relevance, it is not the only one. Analysis methods from the field of stochastic systems have been tried as well. These either used the theory of Markov processes (Bienvenüe and François 2003; Auger 2005) or studied the induced supermartingales (Semenov 2002; Semenov and Terkel 2003; Hart et al. 2003). However, nearly all attempts had to resort to numerical Monte Carlo methods at some point. Therefore, also those results are not exact in that, the correctness of their conclusions can only be guaranteed probabilistically, that is, with a probability not equal to one.

Bienvenüe and François (2003) examined the global convergence of adaptive and self-adaptive $(1, \lambda)$ -evolution strategies on the sphere. They showed that $(z_g)_{g \geq 1} = (\|x_g\|/\sigma_g)$ is a homogeneous Markov chain, that is, z_g only depends on z_{g-1} . This also confirms an early result obtained in Beyer (1996b) that the evolution of the mutation strength can be decoupled from the evolution of $\|x_g\|$. Furthermore, they showed that (x_g) converges or diverges log-linearly if the process has certain characteristics.

Auger (2005) followed this line of research. She analyzed a general model of an $(1, \lambda)$ -ES on the sphere. Auger proved that the induced Markov process fulfills the required conditions for log-linear convergence or divergence if the offspring number λ is chosen appropriately. However, her final results for the $(1, \lambda)$ -ES again depend on a Monte Carlo simulation, thus providing only a “probabilistic proof”.

Semenov (2002) and Semenov and Terkel (2003) examined the convergence and the convergence velocity of evolution strategies using the theory of supermartingales. Because of the complicated nature of the underlying stochastic process, the authors did not succeed in a rigorous mathematical treatment of the stochastic process. Similar to the Markov chain approach, the authors had to resort to Monte Carlo simulations in order to show that the necessary conditions are fulfilled. In Semenov (2002) and Semenov and Terkel (2003), the $(1, \lambda)$ -ES was considered. Offspring are generated according to

$$\begin{aligned}\sigma_{g,l} &= \sigma_g e^{\vartheta_{g,l}} \\ x_{g,l} &= x_g + \sigma_{g,l} \zeta_{g,l}\end{aligned}\tag{128}$$

The fitness function considered is given by $f(x) = -|x|$. The random variables $\vartheta_{g,l}$ and $\zeta_{g,l}$ are uniformly distributed with $\vartheta_{g,l}$ assuming values in $[-2, 2]$ whereas $\zeta_{g,l}$ is defined on $[-1, 1]$. For this problem, it could be shown that the object variable and the mutation strength

converge almost surely to zero – provided that there are at least three offspring. Additionally, the convergence velocity of the mutation strength and the distance to the optimizer is bounded from above by a function of the form $\exp(-ag)$, which holds asymptotically almost surely.

Another viewpoint is to consider the evolutionary algorithm as a randomized algorithm and to conduct runtime analyses. The goal is to obtain upper and lower bounds for the runtime, bypassing the dynamical processes.

Concerning continuous search spaces, so far results for the $(1 + \lambda)$ -ES, the $(\mu + 1)$ -ES, and the $(1, \lambda)$ -ES have been reported (see, e.g., Jägersküpper 2003, 2006b, 2007; Jägersküpper and Witt 2005). Some of the Jägersküpper (2006a) results are reproduced here:

- The $(1 + 1)$ -ES performs with overwhelming probability $\mathcal{O}(N)$ steps to halve the approximation error in the search space.
- The $(1 + \lambda)$ -ES as well as the $(1, \lambda)$ -ES get along with $\mathcal{O}(N/\sqrt{\ln(1 + \lambda)})$ steps with overwhelming probability—when the 1/5-rule is based on the number of successful mutations.
- The $(1 + \lambda)$ -ES using a modified 1/5-rule, which is based on the number of successful steps, is proved to be indeed capable of getting along with $\mathcal{O}(N/\sqrt{\ln(1 + \lambda)})$ steps with overwhelming probability, which is asymptotically optimal.
- The $(\mu + 1)$ -ES using Gaussian mutations adapted by the 1/5-rule needs $\mathcal{O}(\mu N)$ steps with overwhelming probability to halve the approximation error in the search space, which is also asymptotically optimal. (An *overwhelming probability* is defined as follows: An event occurs with overwhelming probability with respect to N if the probability of nonoccurrence is exponentially small in N (see Jägersküpper 2006a, p. 15).)

The analyzed fitness functions are the sphere and positive definite quadratic forms. The analyses also considered the adaptation mechanism of the mutation strength. So far, the 1/5th-rule could be analyzed. Up to now, no results have been obtained considering self-adaptation or the cumulative step-size adaptation.

One general drawback of the approach is that the constants hidden in the \mathcal{O} -notation usually cannot be quantified.

So far, it can be stated that exact provable results can be obtained using runtime analysis or the theory of stochastic processes. However, this goes along with a coarser image of the dynamics. As a result, questions regarding the optimal population sizing or the influence of the mutation strength cannot be answered. In contrast, the progress rate theory and the dynamical systems approach can be used to obtain analytical results and to derive answers for these questions. These, however, are usually based on models of the real evolutionary processes and are valid as long as the assumptions made in the derivation hold. Each approach aims to obtain a specific type of result. Therefore, the different methodologies should be seen as complementary and not as conflictive approaches allowing for a gradually improving understanding of the convergence and optimization behavior of evolutionary algorithms.

4 Conclusions

This chapter presented an overview over the progress rate and dynamical systems approach mainly applied to the analysis of evolution strategies in real-valued search spaces. The approach aims to provide quantitative analyses of evolutionary algorithms. To this end, local progress measures, that is, expected changes of important quantities from one generation

to the next, are introduced and analyzed. The results can be used to investigate the performance of different algorithms and its dependencies on the strategy parameter settings.

While the local progress measures may be regarded as the “microscopic forces” driving the EA as a dynamical system, the “macroscopic behavior” appears as the consequence of these quantities: The (self-)adaptive behavior of the EA is modeled as a dynamical system. The step-size adaptation mechanisms considered include mutative self-adaptation and the cumulative step-size adaptation which lies at the core of the covariance matrix adaptation. As a result, one gains insights into the functioning of the adaptation methods.

So far, the approach was mainly applied to evolution strategies. Further applications include real-coded genetic algorithms (Deb and Beyer 1999). However, the analysis techniques developed bear the potential to also gain insights into other natural computing paradigms, such as estimation of distribution algorithms (EDAs) and particle swarm optimization (PSO) algorithms.

5 The Progress Coefficients

For the readers’ convenience, the definition of the progress coefficients are listed below:

$$d_{1,\lambda}^{(k)} = \frac{\lambda}{\sqrt{2\pi}} \int_{-\infty}^{\infty} t^k e^{-\frac{t^2}{2}} \Phi(t)^{\lambda-1} dt \quad (129)$$

$$d_{1+\lambda}^{(k)}(x) = \frac{\lambda}{\sqrt{2\pi}} \int_x^{\infty} t^k e^{-\frac{t^2}{2}} \Phi(t)^{\lambda-1} dt \quad (130)$$

$$e_{\mu,\lambda}^{\alpha,\beta} = \frac{\lambda - \mu}{\sqrt{2\pi}^{\alpha+1}} \binom{\lambda}{\mu} \int_0^{\infty} t^{\beta} e^{-\frac{\alpha+1}{2}t^2} \Phi(t)^{\lambda-\mu-1} (1 - \Phi(t))^{\mu-\alpha} dt \quad (131)$$

$$c_{\mu,\lambda} = \frac{e_{\mu,\lambda}^{1,0} - \gamma_{\mu,\lambda}(1)e_{\mu,\lambda}^{1,1}}{\sqrt{1 - \frac{\mu-1}{\mu} [1 + e_{\mu,\lambda}^{1,1} - e_{\mu,\lambda}^{2,0} - 2\gamma_{\mu,\lambda}(1)(e_{\mu,\lambda}^{1,0} + e_{\mu,\lambda}^{1,2} - e_{\mu,\lambda}^{2,1})]}} \quad (132)$$

$$\gamma_{\mu,\lambda}(1) = \frac{e_{\mu,\lambda}^{1,0} - e_{\mu,\lambda}^{1,2} + 3e_{\mu,\lambda}^{2,1} - 2e_{\mu,\lambda}^{3,0}}{\frac{6\mu^2}{(\mu-1)(\mu-2)} - (6 + 3e_{\mu,\lambda}^{1,1} + 3e_{\mu,\lambda}^{1,3} - 6e_{\mu,\lambda}^{2,0} - 9e_{\mu,\lambda}^{2,2} + 6e_{\mu,\lambda}^{3,1})}. \quad (133)$$

The progress coefficient $c_{1,\lambda}$ is a special case of the progress coefficients $d_{1,\lambda}^{(k)}$ with $c_{1,\lambda} := d_{1,\lambda}^{(1)}$. The progress coefficient $c_{\mu/\mu,\lambda}$ is given as $c_{\mu/\mu,\lambda} = e_{\mu,\lambda}^{1,0}$.

Abstract

When applying evolutionary algorithms to the task of optimization it is important to have a clear understanding of their capabilities and limitations. By analyzing the optimization time of various variants of evolutionary algorithms for classes of concrete optimization problems, important insights can be gained about what makes problems easy or hard for these heuristics. Still more important than the derivation of such specific results is the development of methods that facilitate rigorous analysis and enable researchers to derive such results for new variants of evolutionary algorithms and more complex problems. The development of such methods and analytical tools is a significant and very active area of research. An overview of important methods and their foundations is presented together with exemplary applications. This enables one to apply these methods to concrete problems and participate in the theoretical foundation of evolutionary computing.

1 Introduction and Motivation

Evolutionary algorithms form a large and loosely defined class of algorithms, they can be and are used for many different purposes. Even though it can be argued that they are not really suited for optimization in the strong sense (De Jong 1992), optimization remains one of the main fields of application. There they compete with other optimization methods and can be classified as randomized optimization heuristics, while in the more general sense the label randomized search heuristic is more appropriate. (It can be argued that it would be more appropriate to speak of probabilistic heuristics since heuristics is not dealt with where randomization is introduced later but with heuristics where randomization is a central concept. However, since the notion of randomized algorithms is well established, this notion is adopted here, too.) When the performance of evolutionary algorithms is to be assessed in the context of optimization, it makes most sense to consider evolutionary algorithms as randomized *algorithms*, adopting the perspective that is common in the community concerned with the design and analysis of (randomized) algorithms (Cormen et al. 2001; Mitzenmacher and Upfal 2005; Motwani and Raghavan 1995). This implies that we perform rigorous analysis and present strictly proven results based on no unproven assumptions or simplifications. While such a rigorous approach makes it difficult to obtain results for complex evolutionary algorithms and complex optimization problems, it has several advantages that in summation make it much more attractive than a purely experimental approach or heuristic analyses based on reasonable yet unproven assumptions.

The most prominent and important advantage of the rigorous analytical approach is that it provides foundations, a firm ground of knowledge that can serve as a trustworthy basis for design and analysis of evolutionary algorithms. In most cases, the proofs of analytical results provide a level of insight and give leverage to understand the working principles of evolutionary algorithms that is difficult if not impossible to obtain in other ways. It advances common beliefs about evolutionary algorithms to proven facts and knowledge, advancing the field to a well-founded science. The results derived with the methods presented here come with a degree of generality that is impossible to achieve with experiments alone. Moreover, the methods themselves turn out to be applicable to a wide range of evolutionary algorithms and many different fitness functions. Another important aspect that is dealt with briefly is oriented toward complexity theory, that is, the derivation of fundamental lower bounds that hold for

all algorithms operating within the considered scenario. This reveals fundamental limitations and can in practice save a lot of time since no effort is wasted for provably impossible tasks. Finally, a completely different aspect of equal importance is the usefulness of rigorously proven results in teaching. By learning analytical tools and methods for the analysis of evolutionary algorithms, students can develop a deep understanding and the ability to design and analyze their own algorithms in their own contexts.

It can be remarked that computational complexity of evolutionary algorithms can be taken to mean something entirely different, namely, aspects of the efficient implementation of evolutionary algorithms. While it is true that for some modules of evolutionary algorithms there are implementations known that are considerably more efficient than the obvious ones this is not at all the focus of this chapter. (One example is implementing standard bit mutations where each of n bits flips with probability $1/n$ by randomly determining the position of the next bit to be flipped. This decreases the (expected) number of random experiments from n to just 1.) While in concrete cases efficient implementations can decrease the run time considerably, in general, evolutionary algorithms are rather easy and straightforward to implement. In practical applications, often most time is spent in the evaluation of a complex fitness function so that the computational effort spent on the evolutionary algorithm's modules becomes negligible. This motivates that the analysis can be simplified by considering the number of evaluations of the fitness functions as an appropriate measure for the actual run time. This is more accurate than the number of generations, another measure that is often used, where the effect of the population size on the run time cannot be assessed. One has to be cautious, however, when dealing with complex evolutionary algorithms or hybridizations of evolutionary algorithms where the computational effort of the algorithm itself, apart from evaluations of the fitness function, becomes considerable or even dominant.

In the next section, we give a brief outline of the kind of evolutionary algorithms we consider and we describe the perspective adopted for analysis. Fundamental limitations that are inherent to the specific scenario that usually governs the application of evolutionary algorithms are discussed in [Sect. 3](#). There are two ways of finding and describing such limits that are fundamentally different, namely, “no free lunch” arguments and black-box complexity. A brief introduction to both concepts will be given. [Section 4](#) is devoted to the description of methods for the analysis of evolutionary algorithms. Clearly, this section contains the most important and hopefully useful parts of this chapter. Finally, this chapter concludes with a summary in [Sect. 5](#).

2 Evolutionary Algorithms

While there is a large amount of different variants of evolutionary algorithms with new and related paradigms such as particle swarm optimization or ant colony emerging, here we restrict ourselves to simplified and rather basic algorithms. This restriction facilitates the analysis and allows for a clearer identification of causes for the effects that are observed. Yet, it is not too restrictive: it turns out that the methods, which are developed with a specific and quite restricted evolutionary algorithm in mind, can often be generalized and extended to more complex evolutionary algorithms.

The most basic evolutionary algorithm considered is the so-called $(1 + 1)$ EA. Its extreme simplicity makes it attractive for formal analysis, hence it shares important typical properties with much more complex evolutionary algorithms. Here we present it without any stopping

criterion as this subject is typically not dealt with in the context of computational complexity of evolutionary algorithms.

Algorithm 1 (the $(1 + 1)$ EA)

1. Initialization
 $t := 0$

Choose $x_t \in \{0, 1\}^n$ uniformly at random.

2. Repeat forever
3. Mutation

Create $y := x_t$. Independently for each $i \in \{1, 2, \dots, n\}$, flip the bit $y[i]$ with probability $1/n$.

4. Selection

If $f(y) \geq f(x_t)$ then $x_{t+1} := y$ else $x_t := y$.

 $t := t + 1$

The mutation operator employed in line 3 of the $(1 + 1)$ EA (Algorithm 1) is called standard bit mutation with mutation probability $1/n$. While $1/n$ is the most recommended choice, it is known that it can be far from optimal for some fitness functions (Jansen and Wegener 2000). When this mutation operator is replaced by a local operator that flips exactly one bit, we obtain an algorithm that is known as *randomized local search* (RLS). While being close to the $(1+1)$ EA we consider RLS not to be an evolutionary algorithm since evolutionary algorithms are supposed to be able to perform a global search in the search space and randomized local search, by definition, is restricted to a local search. Since the $(1 + 1)$ EA with mutation probability $1/n$ flips on average one bit in each mutation one may

Algorithm 2 (the $(\mu + \lambda)$ EA)

1. Initialization
 $t := 0$

Choose $x_t^{(1)}, x_t^{(2)}, \dots, x_t^{(\mu)} \in \{0, 1\}^n$ independently uniformly at random.

2. Repeat forever
3. For $i \in \{1, 2, \dots, \lambda\}$ **do**
4. Selection

Select $z \in \{x_t^{(1)}, x_t^{(2)}, \dots, x_t^{(\mu)}\}$ uniformly at random.

5. Crossover

With probability p_c

 $z' := z$

Select $z'' \in \{x_t^{(1)}, x_t^{(2)}, \dots, x_t^{(\mu)}\}$ uniformly at random.

 $z := \text{crossover}(z', z'')$
6. Mutation

Create $y^{(i)} := z$. Independently for each $j \in \{1, 2, \dots, n\}$, flip the bit $y^{(i)}[j]$ with probability $1/n$.

7. Selection

Sort $x_t^{(1)}, x_t^{(2)}, \dots, x_t^{(\mu)}, y^{(1)}, y^{(2)}, \dots, y^{(\lambda)}$ with respect to fitness in decreasing order, in case of equal fitness sort offspring y before parents x . Let the first μ points be the sequence $x_{t+1}^{(1)}, x_{t+1}^{(2)}, \dots, x_{t+1}^{(\mu)}$.

speculate that the two algorithms behave similarly. It is known that this is indeed the case for many problems but that they differ in extreme ways on other problems and that it is difficult to give a precise description of problems where the two algorithms provably perform similarly (Doerr et al. 2008).

In general, evolutionary algorithms make use of a larger population size and produce more than one offspring per generation. A still very simple evolutionary algorithm that has both properties is described. Since the population size is larger than one, it can also make use of crossover.

It can be seen that the $(1 + 1)$ EA is the special case of the $(\mu + \lambda)$ EA that we obtain by setting $\mu = \lambda = 1$. As crossover operator, any operator acting on binary strings may be used. Uniform crossover will be considered. It is also possible to consider the $(\mu + \lambda)$ EA without crossover, that is, set the probability for crossover to 0, $p_c = 0$.

Finally, a third kind of evolutionary algorithm called (μ, λ) EA is introduced. It is similar to the $(\mu + \lambda)$ EA but employs a different selection at the end of each generation. The new population is selected from the offspring alone, the old generation is discarded in any case. Clearly, this implies that

$$\max \left\{ x_t^{(i)} \mid i \in \{1, 2, \dots, \mu\} \right\}$$

may decrease with increasing t . A formal description is given just as was done for the other algorithms. Note that $\lambda \geq \mu$ is needed here.

Algorithm 3 (the (μ, λ) EA)

1. Initialization

$t := 0$

Choose $x_t^{(1)}, x_t^{(2)}, \dots, x_t^{(\mu)} \in \{0, 1\}^n$ independently uniformly at random.

2. Repeat forever

3. For $i \in \{1, 2, \dots, \lambda\}$ do

4. Selection

Select $z \in \{x_t^{(1)}, x_t^{(2)}, \dots, x_t^{(\mu)}\}$ uniformly at random.

5. Crossover

With probability p_c

$z' := z$

Select $z'' \in \{x_t^{(1)}, x_t^{(2)}, \dots, x_t^{(\mu)}\}$ uniformly at random.

$z := \text{crossover}(z', z'')$

6. Mutation

Create $y^{(i)} := z$. Independently for each $j \in \{1, 2, \dots, n\}$,

flip the bit $y^{(i)}[j]$ with probability $1/n$.

7. Selection

Sort $y^{(1)}, y^{(2)}, \dots, y^{(\lambda)}$ with respect to fitness in decreasing order.

Let the first μ points be the sequence $x_{t+1}^{(1)}, x_{t+1}^{(2)}, \dots, x_{t+1}^{(\mu)}$.

$t := t + 1$

Since in our description of evolutionary algorithms they never stop it is not obvious how we want to measure their computational complexity. We decide to consider the first point of time (measured by the number of evaluations of the fitness function) when a global optimum is sampled. We call this the *optimization time*. Note that it is usually not

difficult to change this into other notions of achieving a goal like approximation. For the $(1+1)$ EA, the optimization time on a fitness function $f: \{0, 1\}^n \rightarrow \mathbb{R}$ is given by the following equation.

$$T_{(1+1) \text{ EA}, f} = \min\{t \mid f(x_t) = \max\{f(x') \mid x' \in \{0, 1\}^n\}\}$$

For the $(\mu + \lambda)$ EA, we are slightly less accurate when defining the optimization time. We define it based on the number of generations (but still close to the actual number of f -evaluations) in the following way.

$$T_{(\mu+\lambda) \text{ EA}, f} = \min\left\{\mu + \lambda t \mid \max\left\{f\left(x_t^{(i)}\right) \mid i \in \{1, \dots, \mu\}\right\} = \max\{f(x) \mid x \in \{0, 1\}^n\}\right\}$$

For the (μ, λ) EA we use the same definition, $T_{(\mu, \lambda) \text{ EA}, f} = T_{(\mu+\lambda) \text{ EA}, f}$.

Clearly, $T_{A,f}$ is a random variable and we are mostly interested in its expectation $E(T_{A,f})$. In cases where this expected value is misleading due to exceptionally large values that occur only with small probabilities other properties are of interest. In particular, bounds on $\text{Prob}(T_{A,f} \leq t_u(n))$ and $\text{Prob}(T_{A,f} \geq t_l(n))$ for some upper bound t_u and some lower bound t_l are often of interest. One can consider an algorithm to be efficient if either $E(T_{(1+1) \text{ EA}, f})$ is polynomially bounded from above or $\text{Prob}(T_{A,f} \leq t_u(n)) \geq 1/p(n)$ holds for some polynomials $t_u(n)$ and $p(n)$. The reason for this rather generous notion of efficiency can be found in restarts: If one knows that $\text{Prob}(T_{A,f} \leq t_u(n)) \geq 1/p(n)$ holds for some evolutionary algorithm A , one can turn it into an evolutionary algorithm with polynomial expected optimization time at most $t_u(n)p(n)$ by stopping A after $t_u(n)$ fitness evaluations and restarting it.

In addition to considering simple evolutionary algorithms, the analysis is further simplified by not analyzing the optimization time with arbitrary precision but by restricting ourselves to an asymptotic analysis taking into account the dominating factors. One can make use of the well-known notions for the description of the order of growth of functions (see, e.g., Cormen et al. 2001) and perform analysis for a growing dimension of the search space n . Thus, the dimension of the search space n plays the same role as the length of the input in the analysis of problem-specific algorithms.

3 Fundamental Limits

Evolutionary algorithms are considered in the context of optimizing some unknown fitness function $f: S \rightarrow R$ where S is some finite search space and R typically is a subset of \mathbb{R} . Since S is finite it usually does not hurt to assume that R is finite, too. When looking for fundamental limits on the performance of evolutionary algorithms (and all other algorithms working in the same scenario) one has to be careful about what exactly the algorithm can make use of. It is assumed that the algorithm designer knows that the algorithm is going to be applied to some unknown function $f \in \mathcal{F} \subseteq \{g: S \rightarrow R\}$. So, any problem-specific knowledge the algorithm designer may have is in the framework expressed in this knowledge about the set of potential fitness functions \mathcal{F} . An algorithm is required to find some optimal point $s \in S$, that is, some $s \in S$ with $f(s) = \max\{f(x) \mid x \in S\}$. One can assume that the algorithm can make any use of the fact that the concrete fitness function f belongs to \mathcal{F} , $f \in \mathcal{F}$, but has no other way of obtaining knowledge about the concrete fitness function f but to query the function value $f(x)$ for arbitrary $x \in S$. The number of such queries (we call f -evaluations) are counted until an optimum is found for the first time. Note that we do not expect the algorithm to know or to

notice that it found an optimum. This is the scenario that we consider and call *black-box optimization*. We call an algorithm A a *black-box algorithm* for \mathcal{F} if for each function $f \in \mathcal{F}$ it finds an optimum of f within at most t f -evaluations with probability converging to 1 with t going to infinity, $\forall f \in \mathcal{F} : \lim_{t \rightarrow \infty} \text{Prob}(T_{A,f} \leq t) = 1$.

Adopting the usual worst-case perspective of computer science, one is interested in the best performance any algorithm can achieve for such a set of potential fitness functions \mathcal{F} where performance is taken to be the worst-case performance. Formally, one can define for a class of functions \mathcal{F} and a black-box algorithm for \mathcal{F} the *worst case expected optimization time*

$$T_{A,\mathcal{F}} = \max \{ E(T_{A,f}) \mid f \in \mathcal{F} \}$$

Finally, one can define for $\mathcal{F} \subseteq \{f : S \rightarrow R\}$ the *black-box complexity* $B_{\mathcal{F}}$ of \mathcal{F} :

$$B_{\mathcal{F}} = \min \{ T_{A,\mathcal{F}} \mid A \text{ is a black-box algorithm for } \mathcal{F} \}$$

It is not difficult to see that restricting the attention to f -evaluations alone can lead to cases where NP-hard function classes \mathcal{F} have only polynomial black-box complexity (Droste et al. 2006): if a polynomial number of f -evaluations is sufficient to reconstruct the concrete problem instance at hand an optimal solution can be computed (in exponential time) without any further f -evaluations. This seeming weakness is more than compensated by the fact that in contrast to classical complexity theory one is able to derive absolute lower bounds that are not based on any complexity theoretical assumption like $P \neq NP$.

Another noteworthy consequence from the definition is that for any class of functions \mathcal{F} we have $B_{\mathcal{F}} \leq |\mathcal{F}|$: a black-box algorithm knows about all $f \in \mathcal{F}$, this includes knowledge about the global optima. Thus, it can sample for each function one of its global optima one by one sampling an optimum of the unknown objective function $f \in \mathcal{F}$ after at most $|\mathcal{F}|$ steps. Moreover, we have

$$\mathcal{F} \subseteq \mathcal{F}' \Rightarrow B_{\mathcal{F}} \leq B_{\mathcal{F}'}$$

since for the subset \mathcal{F} the maximum in the definition of $T_{A,\mathcal{F}}$ is taken over a subset of functions.

Attention is restricted to deterministic black-box algorithms for a moment. Such algorithms can be described as a tree: The first point in the search space $x \in S$ they sample is the root of the tree. The second point the algorithm decides to sample is in general based on its f -value $f(x)$ so that there are up to $|R|$ possible second points. We represent this in the tree by attaching each second point as child to the root. We mark the corresponding edge with the f -value that led to this choice. Clearly, this way the root can become a node of degree at most $|R|$. Continuing this way by adding the third points the algorithm samples (depending on the first two points together with their function values) to the appropriate node we see that any deterministic black-box algorithm can be described as an $|R|$ -ary tree. If we are interested in optimal black-box algorithms, it is safe to assume that on each path from the root to a leaf each point from S is encountered at most once. Thus, the trees have finite size. If necessary, one can enlarge the trees such that each path from the root to a leaf contains exactly $|S|$ nodes. If the criterion is not changed for assessing the performance of an algorithm, this formal change does not change its performance and may make a formal treatment simpler.

Considering deterministic black-box algorithms as trees we recognize that due to their finite size and finite possible markings at the nodes and edges there is only a finite number

of such algorithms. In such cases, we describe any randomized black-box algorithm as a probability distribution over the deterministic black-box algorithms. From an algorithmic perspective, the idea is to modify randomized black-box algorithms in a way that they begin with making a sufficiently large number of random coin tosses, storing the outcomes in memory. After that, they work deterministically and every time the original randomized algorithm needed to make a random decision the modified version acts deterministically using the stored outcome of the random experiment.

3.1 “No Free Lunch”

For a fixed set of functions \mathcal{F} , in general $T_{A,\mathcal{F}}$ depends on the black-box algorithm A under consideration. There are, however, classes of functions, where this value is equal regardless of the choice of A – provided that we consider only distinct f -evaluations or, equivalently, black-box algorithms that do not revisit any point in the search space. Thinking of constant fitness functions this is clearly not surprising at all. But it is quite remarkable that this also holds for the class of all functions $\mathcal{F} = \{f : S \rightarrow R\}$. When this was first published (Wolpert and Macready 1997), using the colorful label “no free lunch theorem,” it caused enormous discussions about its scope and meaning. If on average over all problems all algorithms perform equal, what sense does it make to design any specific randomized search heuristic? The result can even be strengthened. It is not necessary that one averages only over constant functions or over all functions. The same result can be proven if the set of functions \mathcal{F} has the property to be closed under permutations of the search space. For a function $f: S \rightarrow R$ we can define the function $\sigma f: S \rightarrow R$ by $\sigma f(x) = f(\sigma^{-1}(x))$ for a permutation σ of S . A class of functions \mathcal{F} is called *closed under permutations* of the search space if $f \in \mathcal{F}$ implies $\sigma f \in \mathcal{F}$ for all functions $f \in \mathcal{F}$ and all permutations σ . Moreover, it can be shown that being closed under permutations is not only a sufficient but also a necessary condition for a set \mathcal{F} to allow for a “no free lunch” result. Note that it is not necessary to consider the average over the class of functions \mathcal{F} . One can make precise statements over the existence of “no free lunch” results for probability distributions over \mathcal{F} different from the uniform distribution leading to the most general “no free lunch theorem” known (Igel and Toussaint 2004). Since the generalization is not too surprising, one can stick to the simpler result (Schumacher et al. 2001). In order to formulate the result precisely, the notion of a *performance measure* is needed.

Remember that any randomized black-box algorithm can be described as a probability distribution over the set of all deterministic black-box algorithms. Moreover, remember that any deterministic black-box algorithm can be described as an $|R|$ -ary tree where each path from the root to a leaf contains exactly $|S|$ nodes. When one such deterministic black-box algorithm A and some function $f \in \mathcal{F}$ are fixed, this defines a path in the tree that one can call a *trace* $T(A, f) = ((x_1, f(x_1)), (x_2, f(x_2)), \dots, (x_{|S|}, f(x_{|S|})))$. This trace can be projected onto a vector of function values $V(A, f) = (f(x_1), f(x_2), \dots, f(x_{|S|}))$. If it is agreed that reasonable performance measures should only depend on the function values and not on the search points themselves then one can give a formal definition of a performance measure as a function mapping such vectors of function values to \mathbb{R} . Clearly, important performance measures, in particular the performance measure one can consider (the first point of time when a global maximum is found), can be defined in this way. Using this formal definition of a performance measure one can obtain the following result that is cited without a proof.

Theorem 1 (NFL Theorem (Schumacher et al. 2001)) *Let S, R be two finite sets. On average over all functions $f \in \mathcal{F} \subseteq \{g: S \rightarrow R\}$ all black-box algorithms perform equal for all performance measures $M: \{V|V = V(A, h)\} \rightarrow \mathbb{R}$ if and only if the set of functions \mathcal{F} is closed under permutations of the search space.*

While this result has the obvious consequence that there is no way one can develop meaningful algorithms for function classes \mathcal{F} that are closed under permutations, it is not so clear what the relevance of this result is. We mention that it is unusual for a class of functions to be closed under permutations. The fraction of classes where this is the case is exponentially small (Igel and Toussaint 2003). Moreover, classes of functions that are defined via some nontrivial notion of a neighborhood cannot be closed under permutations since neighborhoods are not preserved under permutations of the search space. On the other hand, it is not difficult to see that each black-box algorithm that performs well on a specific function performs very poorly on an exponentially large number of similar functions with probability very close to one (Droste et al. 2002b).

3.2 Black-Box Complexity

Much more interesting than the fundamental but in their relevance severely limited “no free lunch” results are concrete results on the black-box complexity $B_{\mathcal{F}}$ for some relevant class of functions \mathcal{F} . One can obtain upper bounds on $B_{\mathcal{F}}$ by proving that some specific black-box algorithms optimizes on average each function $f \in \mathcal{F}$ within some bounded number of f -evaluations. Lower bounds, however, are much more difficult to obtain. They require a formal proof that no algorithm at all is able to optimize all functions from \mathcal{F} with less than a certain number of f -evaluations. If one sticks to this assumption that S and R are finite sets, though, Yao’s minimax principle is a very useful tool to prove such lower bounds.

Theorem 2 (Yao’s Minimax Principle (Motwani and Raghavan 1995; Yao 1977)) *If a problem consists of a finite set of instances of a fixed size and allows a finite set of deterministic algorithms, the minimal worst-case instance expected optimization time of a randomized algorithm is bounded below for each probability distribution on the instances by the expected optimization time of an optimal deterministic algorithm.*

Yao’s minimax principle simplifies the proofs of lower bounds in two ways: First, there is no need to analyze a randomized algorithm but we can restrict our attention to deterministic algorithms. This, typically, is much simpler. Second, one is free to define a distribution over the class of functions \mathcal{F} any way one likes. Two concrete examples will be considered to see how such results can be derived. To this end, two example functions and a general way of creating a class of functions based on a single fitness function are discussed.

Definition 1 Let $n \in \mathbb{N}$ be given. The function $\text{ONEMAX}: \{0, 1\}^n \rightarrow \mathbb{R}$ is defined by $\text{OneMAX}(x) = \sum_{i=1}^n x[i]$. The function $\text{NEEDLE}: \{0, 1\}^n \rightarrow \mathbb{R}$ is defined by $\text{NEEDLE}(x) = \prod_{i=1}^n x[i]$.

For any function $f: \{0, 1\}^n \rightarrow \mathbb{R}$ and any $a \in \{0, 1\}^n$ let $f_a: \{0, 1\}^n \rightarrow \mathbb{R}$ be defined by $f_a(x) = f(x \oplus a)$, where $x \oplus a$ denotes the bit-wise exclusive or of x and a . For any function $f: \{0, 1\}^n \rightarrow \mathbb{R}$ let $f^* := \{f_a | a \in \{0, 1\}^n\}$.

The very well-known example function ONEMAX yields as function value the number of ones in the bit string. Its generalization ONEMAX_a can be described as maximizing the Hamming distance to the bit-wise complement of the global optimum \bar{a} , where the fitness value exactly equals this Hamming distance. Clearly, ONEMAX is rather easy to optimize since it gives clear hints into the direction of the unique global optimum. On the other, the example function NEEDLE is a flat plateau of fitness 0 with a single peek at the all ones bit string 1^n . Its generalization NEEDLE_a has this unique global optimum at \bar{a} . Since NEEDLE_a gives no hints at all with respect to the global optimum, it is rather difficult to optimize.

It is remarked that NEEDLE^* is closed under permutations of the search space. It follows from the NFL theorem (Theorem 1) that all algorithms that do not revisit any points make the same number of f -evaluations on NEEDLE^* . We consider a deterministic algorithm that enumerates the search space $\{0, 1\}^n$ in some fixed order. Clearly, for each $i \in \{1, 2, \dots, 2^n\}$, there is exactly one function NEEDLE_a that is optimized by this algorithm with the i th f -evaluation. Thus, the average number of f -evaluations this algorithm (and due to \blacktriangleright Theorem 1 any algorithm) makes on NEEDLE^* equals

$$\sum_{i=1}^{2^n} \frac{i}{2^n} = \frac{2^n(2^n + 1)}{2 \cdot 2^n} = 2^{n-1} + \frac{1}{2}$$

and we obtain $B_{\mathcal{F}} = 2^{n-1} + \frac{1}{2}$. Nevertheless, the lower bound will be derived in the proof of the next theorem to see a very simple application of Yao's minimax principle (\blacktriangleright Theorem 2).

Theorem 3 (Droste et al. 2006) $B_{\text{NEEDLE}^*} = 2^{n-1} + 1/2$. $B_{\text{ONEMAX}^*} = \Omega(n/\log n)$

Proof The upper bound for B_{NEEDLE^*} follows from the analysis of the deterministic algorithm enumerating the search space $\{0, 1\}^n$. For the lower bound, we use the uniform distribution over NEEDLE^* and consider a deterministic black-box algorithm A for NEEDLE^* . Clearly, such an algorithm is equivalent to a tree with at least 2^n nodes since otherwise there is some $x \in \{0, 1\}^n$ that is not a label of any node in this tree. Any function that has this x as its unique global optimum cannot be optimized by A . Since x is the unique global optimum of $\text{NEEDLE}_{\bar{x}}$, we see that we have at least 2^n nodes as claimed. Each node in the tree of an optimal black-box algorithm has at most one child. The only two possible function values are 0 and 1. After making an f -evaluation for some x with function value 1 the algorithm terminates since the global optimum is found. Thus, the tree is actually a list of 2^n nodes. Clearly, the average number of function evaluations made by this algorithm equals

$$\sum_{i=1}^{2^n} \frac{i}{2^n} = \frac{2^n(2^n + 1)}{2 \cdot 2^n} = 2^{n-1} + \frac{1}{2}$$

and the lower bound follows.

For ONEMAX^* one can argue in a similar way, again using the uniform distribution over the class of functions under consideration. Any black-box algorithm for ONEMAX^* needs to contain at least 2^n nodes since otherwise there is some function ONEMAX_a that cannot be optimized by this algorithm. Now there are $n+1$ different function values for ONEMAX_a . After sampling a point with function value n any optimal deterministic black-box algorithm for

ONEMAX* can terminate. Thus, the degree of each node in the tree of such an algorithm is bounded above by n . Since an n -ary tree of height h contains at most

$$\sum_{i=0}^h n^i = n^{h+1} - 1$$

nodes we have $n^{h+1} - 1$ and $h = \Omega(n/\log n)$ follows. Since the average height of this tree is still $\Omega(n/\log n)$, $\Omega(n/\log n)$ is obtained as lower bound on B_{ONEMAX^*} .

Results on black-box complexity are not restricted to results for example functions and classes of functions obtained by generalizing such example functions. It is possible to derive nontrivial lower bounds on the black-box complexity of combinatorial optimization problems such as sorting and shortest paths. Moreover, for the class of unimodal problems an exponential lower bound of 2^{n^ε} for any positive constant $\varepsilon < 1$ is known (Droste et al. 2006).

4 Methods for the Analysis of Evolutionary Algorithms

The analysis of evolutionary algorithms is not so much concerned with the derivation of general lower bounds on the difficulty of problems as in black-box complexity but with proving concrete bounds on the (expected) optimization time of specific evolutionary algorithms for specific problems. While at the end of the day one is interested in results for one's own evolutionary algorithm on one's own specific problem or, from a broader perspective, in results on classes of evolutionary algorithms on relevant practical problems, it is worthwhile to start with very simple evolutionary algorithms on very simple example functions. The aim of this section is not to present the most advanced results obtained by clever applications of the most advanced methods. Here we aim at presenting the most important and useful methods in an accessible way following a hands-on kind of approach. The goal is to enable the reader of this section to apply these methods himself or herself and participate in the development of more advanced results and methods.

4.1 Fitness-Based Partitions

We begin with a very simple and basic method for the derivation of upper bounds on the expected optimization time. In spite of its simplicity, this method, called the method of fitness-based partitions, is very helpful and delivers strong bounds in many cases. Consider the $(1 + 1)$ EA (Algorithm 1) on some arbitrary fitness function $f: \{0, 1\}^n \rightarrow \mathbb{R}$. Due to the strict selection employed, the fitness value $f(x_t)$ is increasing with t , though not strictly, of course. Clearly, $E(T_{(1+1)\text{EA},f})$ equals the expected number of f -evaluations until the function value of the current search point x_t is increased to the maximum value for the first time. This together with the increasing nature of $f(x_t)$ leads one to the idea to structure the optimization of f by the $(1 + 1)$ EA in the following way. The search space is partitioned into disjoint sets of points with similar fitness values. We obtain an upper bound on $E(T_{(1+1)\text{EA},f})$ by summing up the average waiting times for leaving these sets. This idea is made more precise in the following definition and theorem.

Definition 2 Let $f: \{0, 1\}^n \rightarrow \mathbb{R}$ be some fitness function. L_0, L_1, \dots, L_k (for $k \in \mathbb{N}$) is called an f -based partition if the following properties hold.

1. $L_0 \cup L_1 \cup \dots \cup L_k = \{0, 1\}^n$
2. $\forall i < j \in \{0, 1, \dots, k\}: \forall x \in L_i, y \in L_j: f(x) < f(y)$
3. $L_k = \{x \in \{0, 1\}^n \mid f(x) = \max\{f(y) \mid y \in \{0, 1\}^n\}\}$

Due to the strict selection, if the $(1 + 1)$ EA leaves some set L_i it can only reach a point in some set L_j with $j > i$. Moreover, with reaching L_k a global optimum is found. These observations lead directly to the following theorem.

Theorem 4 *For $f: \{0, 1\}^n \rightarrow \mathbb{R}$ be some fitness function. Let L_0, L_1, \dots, L_k be some f -based partition. The probability of leaving L_i is defined as*

$$s_i := \min \left\{ \sum_{j=i+1}^k \sum_{y \in L_j} \left(\frac{1}{n}\right)^{H(x,y)} \left(1 - \frac{1}{n}\right)^{n-H(x,y)} \mid x \in L_i \right\}$$

where $H(x, y)$ denotes the Hamming distance of $x, y \in \{0, 1\}^n$

For the expected optimization time of the $(1 + 1)$ EA on f , the following holds:

$$\mathbb{E}(T_{(1+1) \text{ EA}, f}) \leq \sum_{i=0}^{k-1} \frac{1}{s_i}$$

Proof We observe that for any $x \in L_i$

$$\sum_{j=i+1}^k \sum_{y \in L_j} \left(\frac{1}{n}\right)^{H(x,y)} \left(1 - \frac{1}{n}\right)^{n-H(x,y)}$$

equals the probability to mutate $x \in L_i$ to some $y \in L_j$ with $j > i$. Thus, $f(y) > f(x)$ holds and such an event implies that the $(1 + 1)$ EA leaves L_i . Thus, s_i is a lower bound on the actual probability to leave the current set L_i by means of the next mutation. The expected waiting time for such an event is geometrically distributed with expectation $1/s_i$. Since each fitness layer needs to be left at most once

$$\mathbb{E}(T_{(1+1) \text{ EA}, f}) \leq \sum_{i=0}^{k-1} \frac{1}{s_i}$$

follows.

This method will be applied to the analysis of OneMax. Note that since the $(1 + 1)$ EA is completely symmetric with respect to 0- and 1-bits, the same result holds for any OneMax_a . We use the trivial f -based partition, namely, defining

$$L_i = \{x \in \{0, 1\}^n \mid \text{ONEMAX}(x) = i\}, i \in \{0, 1, \dots, n\}$$

to have one fitness layer for each of the $n + 1$ fitness values. It is observed that in order to leave L_i , it suffices to flip exactly one of the $n - i$ 0-bits in one mutation. Thus,

$$s_i \geq \binom{n-i}{1} \frac{1}{n} \left(1 - \frac{1}{n}\right)^{n-1} \geq \frac{n-i}{en}$$

follows and we obtain

$$\mathbb{E}(T_{(1+1) \text{ EA}, \text{OneMAX}}) \leq \sum_{i=0}^{n-1} \frac{en}{n-i} = en \sum_{i=1}^n \frac{1}{i} = O(n \log n)$$

as an upper bound. In comparison with the lower bound obtained by means of black-box complexity, it can be seen that this upper bound is off by a factor of at most $O(\log^2 n)$. It will be seen in [Sect. 4.2](#) that it is even tight.

We consider the function $\text{BinVal}: \{0, 1\}^n \rightarrow \mathbb{R}$ defined by

$$\text{BINVAL}(x) = \sum_{i=1}^n x[i] 2^{n-i-1}$$

We observe that $x \in \{0, 1\}^n$ yields as function value the integer that has x as its binary representation. Using the trivial f -based partition, namely

$$L_i = \{x \in \{0, 1\}^n \mid \text{BINVAL}(x) = i\}, i \in \{0, 1, \dots, 2^n - 1\}$$

we obtain 2^n fitness layers. Since it is obvious that at least one generation is needed to leave each layer, the best one can hope for is $2^n - 1$ as upper bound. We learn that a large number of fitness layers cannot be used if small upper bounds are to be proved.

We try to be a bit less naive and define

$$L_i = \left\{ x \in \{0, 1\}^n \setminus \bigcup_{j=0}^{i-1} L_j \mid \text{BINVAL}(x) < \sum_{j=0}^i 2^{n-1-j} \right\}, i \in \{0, 1, \dots, n\}$$

as f -based partition for BINVAL . We observe that L_i contains all $x \in \{0, 1\}^n$ that start with a sequence of i consecutive 1-bits followed by a 0-bit, so L_0 contains exactly all $x \in \{0, 1\}^n$ where the leftmost bit is 0 and $L_n = \{1^n\}$. Thus, for each L_i with $i < n$, it suffices to flip the leftmost 0-bit in order to leave L_i . This implies

$$s_i \geq \frac{1}{n} \left(1 - \frac{1}{n}\right)^{n-1} \geq \frac{1}{en}$$

as lower bound on s_i and we obtain

$$\mathbb{E}(T_{(1+1) \text{ EA}, \text{BINVAL}}) \leq \sum_{i=0}^{n-1} en = en^2 = O(n^2)$$

as upper bound for the expected optimization time of the $(1 + 1)$ EA on BINVAL . While being much improved over $2^n - 1$ it will be seen in [Sect. 4.4](#) that this is still not tight.

Fitness-based partitions do also work for families of functions with similar structure. To see an example, we consider $\text{JUMP}_k: \{0, 1\}^n \rightarrow \mathbb{R}$ (Droste et al. 2002a) with

$$\text{JUMP}_k(x) = \begin{cases} n - \text{OneMax}(x) & \text{if } n - k < \text{OneMax}(x) < n \\ k + \text{OneMax}(x) & \text{otherwise} \end{cases}$$

where $k \in \{1, 2, \dots, n\}$ is a parameter. These n different fitness functions all have the same main properties. The unique global optimum is the all one string 1^n , all points with exactly $n - k$ 1-bits are local optima (except for $k = 1$, since $\text{JUMP}_1 = 1 + \text{OneMax}$ and there is no local optimum that is not also a global one). For $x \in \{0, 1\}^n$ with less than $n - k$ 1-bits the function

equals $k + \text{ONEMAX}(x)$ so in that region, the local optima can be found in time $O(n \log n)$. There a direct mutation to the global optimum is necessary; such a mutation flips exactly all k remaining 0-bits. An upper bound on $E(T_{(1+1) \text{ EA}, \text{JUMP}_k})$ is obtained using the trivial f -based partition where each fitness value gets its own fitness layer L_i by

$$L_i = \{x \in \{0, 1\}^n \mid \text{JUMP}_k(x) = i\}, i \in \{1, 2, \dots, n\}$$

and $L_{n+1} = \{1^n\}$. For all $i < k$ we have $n - k < \text{ONEMAX}(x) < n$ for all $x \in L_i$. Thus, for these i it suffices to flip one of the $n - i$ 1-bits in a mutation to leave L_i . For all i with $k \leq i < n$ the situation is similar to **ONEMAX**, it suffices to flip one of the $k + n - i$ 0-bits to leave L_i . Finally, for L_n , it is necessary to flip exactly the k remaining 0-bits. These insights yield

$$s_i \geq \begin{cases} \binom{n-i}{1} \frac{1}{n} \left(1 - \frac{1}{n}\right)^{n-1} \geq \frac{n-i}{en} & \text{for } i < k \\ \binom{n-i+k}{1} \frac{1}{n} \left(1 - \frac{1}{n}\right)^{n-1} \geq \frac{n-i+k}{en} & \text{for } k \leq i < n \\ \left(\frac{1}{n}\right)^k \left(1 - \frac{1}{n}\right)^{n-k} \geq \frac{1}{en^k} & \text{for } k = n \end{cases}$$

leading to

$$E(T_{(1+1) \text{ EA}, \text{JUMP}_k}) \leq \sum_{i=1}^{k-1} \frac{en}{n-i} + \sum_{i=k}^n \frac{en}{n-i+k} + en^k = O(n \log n + n^k)$$

as upper bound on the expected optimization time.

We have already seen for **BinVal** that different f -based partitions can lead to different upper bounds on $E(T_{(1+1) \text{ EA}, f})$ for the same fitness function f . In some situations this may turn out to be useful. We consider the class of functions **LONGPATH** $_k$: $\{0, 1\}^n \rightarrow \mathbb{R}$ (Horn et al. 1994) with parameter $k \in \mathbb{N}$, $k > 1$ and $(n-1)/k \in \mathbb{N}$, given by

$$\text{LONGPATH}_k(x) = \begin{cases} n^2 + i & \text{for } x = x^{(i)} \\ n^2 - n \sum_{i=1}^k x[i] - \sum_{i=k+1}^n x[i] & \text{otherwise} \end{cases}$$

based on a path $P_k^n = (x^{(1)}, x^{(2)}, \dots, x^{(l(k,n))})$ with $x^{(i)} \in \{0, 1\}^n$ and $H(x^{(i)}, x^{(i+1)}) = 1$ for all i . The path P_k^n is recursively defined by $P_1^1 = (0, 1)$ for $n = 1$ and

$$P_k^n = \left(0^k x^{(1)}, 0^k x^{(2)}, \dots, 0^k x^{(l(k,n-k))}, 0^{k-1} 1 x^{(l(k,n-k))}, 0^{k-2} 11 x^{(l(k,n-k))}, \dots, \right. \\ \left. 1^k x^{(l(k,n-k))}, 1^k x^{(l(k,n-k)-1)}, \dots, 1^k x^{(1)} \right)$$

for $n \in \mathbb{N}$ where $x^{(i)} \in \{0, 1\}^{n-k}$ is the i th point in the path P_k^{n-k} . The path P_k^n is called the long- k path of dimension n , it has length $l(k, n) = (k+1)2^{(n-1)/k} - k + 1$ and the following interesting property. For each $x^{(i)} \in P_k^n$ with at least s successors on the path we have that $H(x^{(i)}, x^{(i+j)}) = j$ for all $j \in \{1, 2, \dots, \min\{s, k-1\}\}$ and no other successor of $x^{(i)}$ on the path has Hamming distance j to $x^{(i)}$ (Rudolph 1997).

Clearly, **LONGPATH** $_k$ does not have any local optima. Either a point is the unique global optimum or it has a Hamming neighbor with strictly larger function value. Thus, it is possible to optimize **LONGPATH** $_k$ by means of single-bit mutations. On the other hand, due to its recursive definition, the long k -path of dimension n consists of k segments where for each path point in any segment, it suffices to flip at most k specific bits to leave the current segment.

Thus, there are two different f -based partitions that align with the properties of LONGPATH_k . The trivial one has one fitness layer for each fitness value. Since the mutations of single bits are sufficient to leave a fitness layer, this yields $E(T_{(1+1) \text{ EA}, \text{LONGPATH}_k}) = O(n|P_k^n|)$ as upper bound. The other f -based partition uses the segments of the long k -path as fitness layers leading to $E(T_{(1+1) \text{ EA}, \text{LONGPATH}_k}) = O(n^{k+1}/k)$ as upper bound. Since both upper bounds are valid we have the following result.

Theorem 5 (Rudolph 1997) $E(T_{(1+1) \text{ EA}, \text{LONGPATH}_k}) = O(\min\{n|P_k^n|, n^{k+1}/k\})$

As a final example for the wide applicability of the method of fitness-based partitions the class of linear functions is considered. A fitness function $f: \{0, 1\}^n \rightarrow \mathbb{R}$ is called *linear* if there exist weights $x_0, x_1, \dots, x_n \in \mathbb{R}$ such that $f(x) = w_0 + \sum_{i=1}^n x[i]w_i$ holds. We observe that ONEMAX as well as BINVAL are linear functions.

Since the $(1+1)$ EA is completely symmetric with respect to the roles of 0-bits and 1-bits one can change any linear function with some weights $w_i < 0$ to another linear function with no negative weights simply by replacing w_i by $-w_i$. This changes the roles of 0 and 1 at the i th position and does not influence the optimization time in any way. Moreover, one can assume $w_0 = 0$ since a constant summand has no influence on the selection employed in the $(1+1)$ EA. Since the $(1+1)$ EA is also completely symmetric with respect to bit positions, one can reorder the bits such that $w_1 \geq w_2 \geq \dots \geq w_n$ holds. Finally, if one is concerned with upper bounds on the expected optimization time, it can be assumed that even $w_1 \geq w_2 \geq \dots \geq w_n > 0$ holds, since $w_i = 0$ implies that the i th bit has no influence on the function value. Clearly, this doubles the number of global optima and can only decrease the expected optimization time in comparison to the case where $w_i \neq 0$ holds.

Now, considering any linear function $f(x) = \sum_{i=1}^n w_i x[i]$ with $w_1 \geq w_2 \geq \dots \geq w_n > 0$ one defines the following f -based partition:

$$L_i = \left\{ x \in \{0, 1\}^n \mid \sum_{j=1}^{i-1} w_j x[j] \leq f(x) < \sum_{j=1}^i w_j x[j] \right\}, i \in \{1, 2, \dots, n\}$$

and $L_{n+1} = \{1^n\}$. It is observed that now the situation is similar to the situation for BINVAL . For any $x \in L_i$ there is at least one bit among the leftmost i bits such that flipping this bits leads to an offspring $y \in L_j$ with $j > i$. This yields $s_i \geq (1/n)(1 - 1/n)^{n-1} \geq 1/(en)$ and we obtain

$$E(T_{(1+1) \text{ EA}, f}) \leq \sum_{i=1}^n en = O(n^2)$$

as upper bound. Note that this upper bound holds for any linear function f .

The method of fitness-based partitions is not necessarily restricted to the simple $(1+1)$ EA, but it is tightly linked to the strict plus-selection that does not accept any decrease in function values. It is not too difficult to generalize it to other evolutionary algorithms with such a selection. For example, it can be shown that for the $(1+\lambda)$ EA, that is, the $(\mu+\lambda)$ EA with population size $\mu = 1$, the expected optimization time on ONEMAX is bounded above by $E(T_{1+\lambda \text{ EA}, \text{ONEMAX}}) = O(n \log n + n\lambda)$ using the method of fitness-based partitions (Jansen et al. 2005). But it does not work for the (μ, λ) EA due to the missing monotonicity in fitness of the current best member of the population.

4.2 General Lower Bound

In order to assess the strength of an upper bound on $E(T_{A,f})$, a lower bound is needed for comparison. One way of obtaining lower bounds is resorting to fundamental limits. This, however, will not lead to strong lower bounds since “no free lunch” results do not apply to function classes of practical interest and black-box complexity most often yields relatively weak lower bounds since it takes into account the performance of optimal algorithms, not the specific evolutionary algorithm one is dealing with. In order to obtain stronger lower bounds on $E(T_{A,f})$ one needs to take into account specific properties of evolutionary algorithm A .

We consider an evolutionary algorithm A that uses standard bit mutations as the only way of creating new offspring. This holds for the $(1+1)$ EA and the $(\mu+\lambda)$ -EA without crossover. If A has a population of size $\mu > n \log n$ it makes $\Omega(n \log n)$ f -evaluations already in the initialization. It can be claimed that if the fitness function has a unique global optimum $x^* \in \{0, 1\}^n$, we have $E(T_{A,f}) = \Omega(n \log n)$ in any case, that is, for $\mu \leq n \log n$, too (Jansen et al. 2005).

We consider some $x \in \{0, 1\}^n$ from the initial population, that is, chosen uniformly at random. Each bit in x differs from the corresponding bit in the unique global optimum x^* with probability $1/2$. We can introduce random variables X_i with $i \in \{1, 2, \dots, n\}$, one for each bit, that assumes the value 1 if $x[i] \neq x^*[i]$ and the value 0 otherwise. Clearly, the expected Hamming distance between x and x^* equals $E(H(x, x^*)) = \sum_{i=1}^n X_i = n/2$. Since the random variables X_i are independent, one is in a situation where Chernoff bounds can be applied (Motwani and Raghavan 1995). We have a random variable $X = \sum_{i=1}^n X_i$ with $0 < \text{Prob}(X_i = 1) < 1$ for all $i \in \{1, 2, \dots, n\}$. Chernoff bounds yield strong bounds on the probability that X deviates considerably from its expected value. For example, for δ with $0 < \delta < 1$

$$\text{Prob}(X \geq (1 + \delta)E(X)) = e^{-E(X)\delta^2/3}$$

$$\text{Prob}(X \leq (1 - \delta)E(X)) = e^{-E(X)\delta^2/2}$$

hold. In this situation, we have that with probability $1 - e^{-\Omega(n)}$ the Hamming distance of x and x^* is bounded below by $n/3$. With a population of size $\mu \leq n \log n$ this holds for each member of the population. We get a bound on the probability that any member of the population has a Hamming distance of less than $n/3$ to the unique global optimum x^* by taking the union bound, that is, by summing up the probabilities for each member of the initial population. Thus, with probability $1 - \sum_{i=1}^{\mu} e^{-\Omega(n)} = 1 - e^{-\Omega(n)}$, each member of the initial population has Hamming distance at least $n/3$ to x^* . One can denote this event as B and have $\text{Prob}(B) = 1 - e^{-\Omega(n)}$.

If one wants to reach x^* in this situation within at most t f -evaluations, there has to be at least one member of the initial population where all those differing bits flip at least once within at most t mutations. Remember that the number of differing bits is bounded below by $n/3$. The probability for this event can be estimated in a very direct way. A single bit flips with probability $1/n$, thus it does not flip at all in t mutations with probability $(1 - 1/n)^t$. One can see that it flips at least once within these t mutations with probability $1 - (1 - 1/n)^t$. Since the bits are independent we have that with probability at most $(1 - (1 - 1/n)^t)^{n/3}$ the at

least $n/3$ bits differing from x^* are all flipped at least once in these t mutations. Thus, finally, one can bound the probability that among those at least $n/3$ bits there is at least one that was never flipped in t mutations from below by $1 - (1 - (1 - 1/n)^t)^{n/3}$. We consider $t = (n-1) \ln n$ generations and see that $(1 - 1/n)^{(n-1) \ln n} \geq e^{-\ln n} = 1/n$ holds. Thus, in $t = (n-1) \ln n$ generations the probability that there is one bit that is needed to flip in order to reach x^* is not flipped at all is bounded below by $1 - (1 - 1/n)^{n/3} \geq 1 - e^{-1/3} = \Omega(1)$. We denote this event as C and have $\text{Prob } C = \Omega(1)$. For the optimization time we thus have

$$\begin{aligned} E(T_{A,f}) &\geq E(T_{A,f} | B \wedge C) \text{ Prob}(B \wedge C) = E(T_{A,f} | B \wedge C) \text{ Prob}(B) \text{ Prob}(C) \\ &= (n-1) \ln(n) \left(1 - e^{-\Omega(n)}\right) \Omega(1) = \Omega(n \log n) \end{aligned}$$

as claimed. It is not difficult to see that the proof can be generalized to fitness functions where the number of global optima is larger than 1 but polynomially bounded. It can be remarked that this proof is similar to the classical result on the coupon collector's problem (Mitzenmacher and Upfal 2005; Motwani and Raghavan 1995).

Clearly, this general lower bound $E(T_{A,f}) = \Omega(n \log n)$ that holds for any mutation-based evolutionary algorithm and any fitness function $f: \{0, 1\}^n \rightarrow \mathbb{R}$ is still rather general and as an immediate consequence rather weak. Nevertheless, it proves that the upper bound on ONEMAX is in fact asymptotically tight and we have $E(T_{(1+1) \text{ EA}, \text{ONEMAX}_a}) = \Theta(n \log n)$ for all $a \in \{0, 1\}^n$.

4.3 Expected Multiplicative Distance Decrease

We return to the often simpler task of proving upper bounds on the expected optimization time. The idea of fitness-based partitions is to measure the progress of $(1 + 1)$ EA by means of the increase in fitness values. To achieve this, the fitness values are grouped in appropriate layers. Considering BINVAL as the example, we have already seen that finding an appropriate grouping can make the difference between a good upper bound and a completely useless upper bound. While this method has the advantage that it is easy to apply and often yields very useful and sometimes even tight upper bounds, it has the intrinsic disadvantage that one needs to define in advance how the algorithm under consideration will most likely increase the function values. This ordering is in some sense implicit in the definition of the fitness layers. One can see this by considering BINVAL. The definition of L_i made it necessary to have the bits in the current bit string flip from left to right. Clearly, the real random process under consideration is less strict: any 0-bits can be flipped to increase the function value. It may well be the case that due to this greater degree of freedom, the real random process that governs the $(1 + 1)$ EA on BINVAL is faster in finding the optimum than the upper bound of $O(n^2)$ predicts.

We reconsider the main idea – measuring the progress the algorithm makes by means of an increase in function value – and capture it in a more general form. To be concrete, attention should be again restricted to the $(1 + 1)$ EA and it should be remarked that generalizations to other evolutionary algorithms like the $(1 + \lambda)$ EA are again not too difficult.

Consider the $(1 + 1)$ EA optimizing some fitness function $f: \{0, 1\}^n \rightarrow \mathbb{Z}$ with $f_{\text{opt}} = \max\{f(x) | x \in \{0, 1\}^n\}$. Note that the assumption that the function values are integers will be important in the following. When the current search point is x_t , we know that a global

optimum is reached if the function value is increased by $f_{\text{opt}} - f(x_t)$. If, for any $x_t \in \{0, 1\}^n$, one is able to describe a sequence of at most l operations that can all be applied to x_t and that when applied simultaneously lead to the global optimum, then each of these operations causes an average increase of function value of at least $(f_{\text{opt}} - f(x_t))/l$. In different terms, each operation decreases the distance to the maximal fitness value $f_{\text{opt}} - f(x_t)$ on average by a factor of at least $1 - 1/l$. Since different potential points $x_t \in \{0, 1\}^n$ are dealt with, it does not really make sense to talk about $f(x_t)$; the average increase in function value $(f_{\text{opt}} - f(x_t))/l$ clearly depends on the x_t under consideration. Thus, we consider $f_{\text{max}} = \max\{f_{\text{opt}} - f(x) \mid x \in \{0, 1\}^n\}$. Now we have the distance to the maximal function value after t such operations is decreased in expectation by a factor of at least $(1 - 1/l)^t$. Since the function values are integers, we know that the global optimum is reached if the difference is decreased to less than 1. Thus, if $(1 - 1/l)^t f_{\text{max}} < 1$ holds, we know that in expectation the optimum is reached. So, a number of $l \ln f_{\text{max}}$ such local operations is on average sufficient to reach the optimum. If it is additionally assumed that the expected waiting time for each such local operation is bounded above by w we obtain

$$\mathbb{E}(T_{(1+1) \text{ EA}, f}) = O(wl \ln f_{\text{max}})$$

as upper bound on the expected optimization time.

This method of the expected multiplicative distance decrease (Neumann and Wegener 2004) is applied to the class of linear functions with integer weights. Consider some $f: \{0, 1\}^n \rightarrow \mathbb{Z}$ with $f(x) = w_0 + \sum_{i=1}^n w_i x[i]$ with all $w_i \in \mathbb{Z}$. As we did when using the method of fitness-based partitions, we assume without loss of generality that $w_0 = 0$ and $w_1 \geq w_2 \geq w_3 \geq \dots \geq w_n > 0$ holds since one wants to derive an upper bound on $\mathbb{E}(T_{(1+1) \text{ EA}, f})$. Remember that we had $\mathbb{E}(T_{(1+1) \text{ EA}, f}) = O(n^2)$ using fitness-based partitions.

Due to the assumptions on f , the unique global optimum is 1^* and we have

$$f_{\text{max}} = \max\{f_{\text{opt}} - f(x) \mid x \in \{0, 1\}^n\} = \sum_{i=1}^n w_i \leq nw_{\text{max}}$$

where $w_{\text{max}} = \max\{w_i \mid i \in \{1, 2, \dots, n\}\}$ denotes the maximal weight of a single bit. For each $x \in \{0, 1\}^n$ we consider the at most n mutations that flip single bits for positions i where $x[i] = 0$ holds. Clearly, applying these up to n mutations simultaneously leads to the unique global optimum 1^n . Moreover, the probability to have a mutation flipping a single bit equals

$$\binom{n}{1} \frac{1}{n} \left(1 - \frac{1}{n}\right)^{n-1} = \left(\frac{1}{n}\right)^{n-1} > e^{-1}$$

so we have $w < e$ in the notation. Since $l = n$ we have

$$\mathbb{E}(T_{(1+1) \text{ EA}, f}) = O(wl \ln f_{\text{max}}) = O(n \ln(nw_{\text{max}}))$$

for any linear functions with integer weights. For **BINVAL**, we have $w_{\text{max}} = 2^{n-1}$ and $\mathbb{E}(T_{(1+1) \text{ EA}, f}) = O(n^2)$ follows. This is no improvement over the bound of the same size obtained using f -based partitions. But this result is more powerful. If one restricts oneself to linear functions with polynomially bounded integer weights, one can obtain $\mathbb{E}(T_{(1+1) \text{ EA}, f}) = O(n \log n)$, which is asymptotically tight since it matches the general lower bound $\Omega(n \log n)$.

While being more flexible than the method of fitness-based partitions, the method of the expected multiplicative distance decrease has the inherent disadvantage that the upper bounds one can obtain directly depend on the size of the function values. Since for example functions there are no bounds on the size of the function values, one may be tempted to believe that at least for some example functions, one cannot obtain any useful result at all using this method. This, however, is too pessimistic. It turns out that function values can be unnecessarily large when considering evolutionary algorithms or other randomized search heuristics where selection depends only on the ordering of the function values and not on the function values themselves. Another way to say this is the following. Given a fitness function $f: \{0, 1\}^n \rightarrow \mathbb{Z}$ with arbitrary function values, it is possible to come up with another fitness function $f': \{0, 1\}^n \rightarrow \mathbb{Z}$ such that the $(1 + 1)$ EA behaves the same on f and f' but the function values of f' are limited in size (Reichel and Skutella 2009). This way, much tighter bounds can be obtained, not only for example functions but also for combinatorial optimization problems.

4.4 Drift Analysis for Upper Bounds

The idea of both methods, fitness-based partitions as well as the method of the expected multiplicative distance decrease, is to measure the progress of the evolutionary algorithm A in some way. When using fitness-based partitions this progress has to be achieved in a pre-defined way that is implicit in the definition of the fitness layers. When using the method of the expected multiplicative distance decrease, the progress can be obtained by operations in any way but it is always measured in function values. We gain even more flexibility if we allow for different measures of progress. Consider some evolutionary algorithm A where Z denotes the set of all possible populations of A . We call a function $d: Z \rightarrow \mathbb{R}_0^+$ a *distance measure* if $d(P) = 0$ holds if and only if the population $P \in Z$ contains a point with maximal function value. Calling a unary operator a distance measure appears to be strange at first sight. However, what is really measured is the distance to the set of global optima. Thus, we can omit the obligatory second part in distance measuring because it is fixed for a fixed fitness function f . Note that this notion of distance is very weak, in particular, d need not be a metric. Again, we concentrate on the $(1 + 1)$ EA in order to simplify the considerations. It has to be remarked, though, that the method taken into consideration is not at all restricted to such simple evolutionary algorithms and that it can be easily applied to much more complex evolutionary algorithms.

For the $(1 + 1)$ EA we have $Z = \{0, 1\}^n$ since the current population consists of a single search point $x_t \in \{0, 1\}^n$. Clearly, we have $T_{(1+1) \text{ EA}, f} = \min\{t \mid d(x_t) = 0\}$ for any fitness function f . We consider the maximum distance M and want to bound the average time until initial distance that is at most M is decreased to 0. Clearly, $M = \max\{d(x) \mid x \in Z\}$ holds. We concentrate on a single generation and consider the decrease in distance in a single generation, that is, $D_t = d(x_{t-1}) - d(x_t)$. Note that D_t is a random variable that may take negative values with positive probability, actually indicating an increase in distance. One is interested in the expected decrease in distance in a single generation, $E(D_t \mid T_{(1+1) \text{ EA}, f} > t)$, and call this *drift*. Since one wants to derive an upper bound on the expected optimization time one can assume a pessimistic point of view and consider the worst-case drift Δ , that is, the smallest drift possible, $\Delta = \min\{E(D_t \mid T_{(1+1) \text{ EA}, f} > t) \mid t \in \mathbb{N}\}$. Even if this worst-case drift Δ is strictly positive, one can prove the drift theorem $E(T_{(1+1) \text{ EA}, f}) \leq M/\Delta$ (He and Yao 2004),

here for the $(1+1)$ EA. The result is intuitively plausible. If one wants to overcome a distance of at most M and can travel at a speed of at least Δ , the average travel time is bounded above by M/Δ . Since the proof will turn out to be helpful when looking for a similar method for lower bounds, the theorem is stated together with its proof here. Again, we restrict ourselves to the $(1+1)$ EA even though much more general results can be proved with essentially the same proof.

Theorem 6 (Drift Theorem for the $(1+1)$ EA (He and Yao 2004)) *Consider the $(1+1)$ EA on some function $f: \{0, 1\}^n \rightarrow \mathbb{R}$ and some distance measure $d: \{0, 1\}^n \rightarrow \mathbb{R}_0^+$ with $d(x) = 0 \Leftrightarrow f(x) = \max\{f(y) \mid y \in \{0, 1\}^n\}$. Let $M = \max\{d(x) \mid x \in \{0, 1\}^n\}$, $D_t = d(x_{t-1}) - d(x_t)$, and $\Delta = \min\{\mathbb{E}(D_t \mid T_{(1+1)\text{EA},f} > t) \mid t \in \mathbb{N}\}$.*

$$\Delta > 0 \Rightarrow \mathbb{E}(T_{(1+1)\text{EA},f}) \leq M/\Delta$$

Proof In order to simplify notation we define $T := T_{(1+1)\text{EA},f}$. If we consider $\sum_{t=1}^T D_t$ we see that

$$\sum_{i=1}^T D_i = \sum_{t=1}^T d(x_{t-1}) - d(x_t) = d(x_0) - d(x_T) = d(x_0)$$

holds since most of the summands cancel out and we have $d(x_T) = 0$ by assumption on d and definition of T . Since M is an upper bound on $d(x)$ for all $x \in \{0, 1\}^n$, we have $M \geq d(x_0)$ and

$$M \geq \sum_{i=1}^T D_i$$

follows. Since M is not a random variable, we have $M = \mathbb{E}(M)$. By the definition of the expected value and the law of total probability, we get

$$M \geq \mathbb{E}\left(\sum_{i=1}^T D_i\right) = \sum_{t=1}^{\infty} \text{Prob}(T = t) \mathbb{E}\left(\sum_{i=1}^T D_i \mid T = t\right)$$

Making use of the linearity of the expectation and changing the ordering in the sums, we get

$$\sum_{t=1}^{\infty} \text{Prob}(T = t) \mathbb{E}\left(\sum_{i=1}^T D_i \mid T = t\right) = \sum_{t=1}^{\infty} \sum_{i=1}^T \text{Prob}(T = t) \mathbb{E}(D_i \mid T = t)$$

Making use of the total law of probability a second time and reordering again, we get

$$\begin{aligned} & \sum_{i=1}^{\infty} \sum_{t=i}^{\infty} \text{Prob}(T = t) \mathbb{E}(D_i \mid T = t) \\ &= \sum_{i=1}^{\infty} \sum_{t=i}^{\infty} \text{Prob}(T \geq i) \text{Prob}(T = t \mid T \geq i) \mathbb{E}(D_i \mid T = t \wedge T \geq i) \\ &= \sum_{i=1}^{\infty} \text{Prob}(T \geq i) \sum_{t=i}^{\infty} \text{Prob}(T = t \mid T \geq i) \mathbb{E}(D_i \mid T = t \wedge T \geq i) \\ &= \sum_{i=1}^{\infty} \text{Prob}(T \geq i) \sum_{t=1}^{\infty} \text{Prob}(T = t \mid T \geq i) \mathbb{E}(D_i \mid T = t \wedge T \geq i) \end{aligned}$$

where the last equation makes use of the fact that $\text{Prob}(T = t \mid T \geq i) = 0$ for $t < i$ holds.

Another application of the law of total probability (this time in the reverse direction) yields

$$\begin{aligned} \sum_{i=1}^{\infty} \text{Prob } (T \geq i) \sum_{t=1}^{\infty} \text{Prob } (T = t \mid T \geq i) E(D_i \mid T = t \wedge T \geq i) \\ = \sum_{i=1}^{\infty} \text{Prob } (T \geq i) E(D_i \mid T \geq i) \end{aligned}$$

Clearly, $\Delta \leq E(D_i \mid T \geq i)$ holds, so we have

$$\sum_{i=1}^{\infty} \text{Prob } (T \geq i) E(D_i \mid T \geq i) \geq \Delta \sum_{i=1}^{\infty} \text{Prob } (T \geq i) = \Delta E(T)$$

by the definition of the expectation. Putting things together we observe that we proved $M \geq \Delta E(T)$ and $E(T) \leq M/\Delta$ follows for $\Delta > 0$.

One of the advantages of the drift theorem is that it allows for the definition of almost arbitrary distance measures. It was known that the expected optimization time of the (1+1) EA on linear functions is $O(n \log n)$ (Droste et al. 2002a) (different from the bound $O(n^2)$ that was proven here using f -based partitions) before the method of drift analysis was introduced to the field of evolutionary computation, but the proof is long, tedious, and difficult to follow. Applying drift analysis, the same result can be shown in a much simpler way making use of an appropriate distance measure.

As usual, we consider a linear function $f: \{0, 1\}^n \rightarrow \mathbb{R}$ with $f(x) = \sum_{i=1}^n w_i x[i]$ where $w_1 \geq w_2 \geq \dots \geq w_n > 0$ holds. Clearly, the bits with smaller index have at least the potential to be more important than the other bits. In one extreme case, **BinVal** is an example, any bit has a weight w_i that is so large that it dominates all bits to its right, that is, $w_i > \sum_{j=i+1}^n w_j$. In the other extreme case, **OneMax** is an example, all weights are equal. We try to prove an upper bound for all these cases simultaneously by defining a distance measure (similar to a potential function) that in some way expresses the greater importance of bits that are closer to the left of the bit string. We define (He and Yao 2004)

$$d(x) = \ln \left(1 + 2 \sum_{i=1}^{n/2} (1 - x[i]) + \sum_{i=(n/2)+1}^n (1 - x[i]) \right)$$

making bits in the left half twice as important as bits in the right half. It can be observed that

$$\begin{aligned} M &= \max \left\{ \ln \left(1 + 2 \sum_{i=1}^{n/2} (1 - x[i]) + \sum_{i=(n/2)+1}^n (1 - x[i]) \right) \mid x \in \{0, 1\}^n \right\} \\ &= \ln \left(1 + n + \frac{n}{2} \right) = \Theta(\log n) \end{aligned}$$

holds. For an upper bound, one needs now a lower bound on

$$E(D_t \mid T_{(1+1) \text{ EA}, f} > t) = E(d(x_{t-1}) - d(x_t) \mid T_{(1+1) \text{ EA}, f} > t)$$

It is easy to observe that this expectation is minimal either for $x_{t-1} = 011 \dots 1 = 01^{n-1}$ or $x_{t-1} = 11 \dots 1011 \dots 1 = 1^{n/2} 01^{(n/2)-1}$. One can skip the still somewhat tedious calculations

for these two cases and remark that $\Omega(1/n)$ can be proved as the lower bound in both cases. So, we have $\Delta = \Omega(1/n)$ and $M = \Theta(\log n)$ and this leads to

$$E(T_{(1+1) EA,f}) = \frac{M}{\Delta} = \frac{\Theta(\log n)}{\Omega(1/n)} = O(n \log n)$$

as claimed.

Another advantage of this method is that it is not a problem if the distance is not monotonically decreased during the run. It completely suffices if the expected decrease in distance, that is, the drift, is positive. This can be illustrated with a small example that makes use of the (μ, λ) EA (Algorithm 3).

Consider the $(1, n)$ EA, that is, the (μ, λ) EA with $\mu = 1$ and $\lambda = n$ on the function LEADINGONES: $\{0, 1\}^n \rightarrow \mathbb{R}$ that is defined by $\text{LEADINGONES}(x) = \sum_{i=1}^n \prod_{j=1}^i x[j]$. The function value

$\text{LEADINGONES}(x)$ equals the number of consecutive 1-bits in x counting from left to right. A simple application of fitness-based partitions yields $E(T_{(1+1)EA,LEADINGONES}) = O(n^2)$ (Droste et al. 2002a) and $E(T_{(1+\lambda) EA,LEADINGONES}) = O(n^2 + n\lambda)$ (Jansen et al. 2005). For the $(1, \lambda)$ EA, however, this method cannot be applied. With drift analysis, however, an upper bound can be derived with ease.

We define $d(x) = n - \text{LEADINGONES}(x)$ as distance and observe that $M = n$ holds. Applying the drift theorem, as presented in Theorem 6, yields an upper bound on the number of expected *generations* the evolutionary algorithm needs to locate an optimum. For the $(1 + 1)$ EA this simply equals the number of f -evaluations. For the $(1, \lambda)$ EA, this number needs to be multiplied by λ in order to get the expected number of f -evaluations. For the estimation of $E(d(x_{t-1}) - d(x_t) | T > t)$ the following two simple observations are made. If among the $\lambda = n$ mutations generating offspring there is at least one where exactly the left most 0-bit is flipped, the distance is decreased by exactly 1. Since such a mutation has probability $(1/n)(1 - 1/n)^{n-1} \geq 1/(en)$ we have that this happens with probability at least $1 - (1 - (1/(en)))^n = \Omega(1)$. Second, the distance can only increase if in one generation there is no mutation that does not change a bit at all. This holds since such a mutation simply creates a copy of its parent. In this case, the parent belongs to the offspring and the fitness of the parent in the next generation cannot be worse. Such an event happens with probability at most $(1 - (1 - 1/n))^n \leq (1 - 1/e)^n = e^{-\Theta(n)}$. Moreover, in this case, the distance cannot increase by more than n . Together this yields

$$\begin{aligned} E(d(x_{t-1}) - d(x_t) | T > t) &\geq 1 \cdot \left(1 - \left(1 - \left(\frac{1}{en}\right)\right)\right) - n \cdot \left(\left(1 - \frac{1}{n}\right)^n\right)^n \\ &\geq 1 \cdot \Omega(1) - n \cdot e^{-\Theta(n)} = \Omega(1) \end{aligned}$$

and proves that $\Delta = \Omega(1)$ holds. Thus, we have $E(T_{(1, n) EA, LEADINGONES}) = O(n)^2$.

4.5 Drift Analysis for Lower Bounds

It would be nice to have such a general and powerful method like drift analysis for lower bounds, too. We reconsider the proof of Theorem 6 and observe that this is not so hard to have. In the calculations in this proof, almost all steps are exact equalities, only at two places

we made estimations and use of bounds. One is $\Delta \leq E(D_i | T \geq i)$ and this stems from the definition of Δ :

$$\Delta = \min\{E(D_t | T_{(1+1) EA,f} > t) | t \in \mathbb{N}\}$$

Clearly, for a lower bound on the expected optimization time we need a different definition that takes into account the maximal drift, not the minimal as for the upper bound. Thus, we replace Δ by

$$\Delta_l = \max\{E(D_t | T_{(1+1) EA,f} > t) | t \in \mathbb{N}\}$$

and have $\Delta_l \geq E(D_i | T \geq i)$ as needed.

The second place one can make use of a bound is $M \geq \sum_{i=1}^T D_i$. This, again is true due to the definition of M

$$M = \max \{d(x) | x \in \{0, 1\}^n\}$$

Clearly, one could again replace M by $M_l = \min \{d(x) | x \in \{0, 1\}^n\}$, but this, unfortunately, is pointless: $M_l = 0$ holds and only the trivial bound $E(T_{A,f}) \geq 0$ can be achieved. Reconsidering the proof of (❷ [Theorem 6](#)) a bit closer, we observe that actually the first step reads

$$E(M) = M \geq E\left(\sum_{i=1}^T D_i\right)$$

and we see that $E(M)$ could be replaced by $E(d(P_0))$, the expected distance of the initial population P_0 . This yields $E(d(P_0)) = E\left(\sum_{i=1}^T D_i\right) \leq E(T_{A,f})\Delta_l$ and we obtain $E(T_{A,f}) \geq E(d(P_0))/\Delta_l$ as drift theorem for lower bounds.

We apply this lower bound technique at a simple example and derive a lower bound on $E(T_{(1+1) EA, LEADINGONES})$. Like for the upper bound for the $(1, n)$ EA on **LEADINGONES** we use the rather trivial distance measure

$$d(x) = n - \text{LEADINGONES}(x)$$

Now we need to bound the decrease in distance in one generation from above. To this end, it is observed that it is necessary that the leftmost 0-bit is flipped in a mutation to decrease d . This happens with probability $1/n$. In this case, clearly, the decrease can be bounded by n . This, however, does not yield a useful bound. It should be remembered that one only needs to bound the *expected* decrease and try to estimate this in a more careful way.

The decrease in distance stems from two sources. The leftmost 0-bits that is flipped decreases the distance by 1. Moreover, any consecutive bits right of this leftmost 0-bit that all happen to be 1-bits after the mutation decrease this distance further, it is decreased by the length of the sequence of consecutive 1-bits. One needs to estimate this random length.

The crucial observation for the estimation of the random length of this block of 1-bits is that all bits that are right of the leftmost 0-bit never had any influence on the selection. This is the case since the number of leading ones never decreases and the function value

$\text{LEADINGONES}(x) = \sum_{i=1}^n \prod_{j=1}^i x[j]$ does not depend on any bit right of the leftmost 0-bit. It is claimed that this implies that these bits are distributed according to the uniform distribution. This can be proved by induction on the number of steps. Clearly, it holds in the beginning

since this is the way the initial bit string x_0 is generated. For any $t > 0$ we have for an arbitrary $x \in \{0, 1\}^n$

$$\begin{aligned}\text{Prob } (x_t = x) &= \sum_{y \in \{0,1\}^n} \text{Prob } (x_{t-1} = y) \text{ Prob } (\text{mut}(y) = x) \\ &= 2^{-n} \sum_{y \in \{0,1\}^n} \text{Prob } (\text{mut}(y) = x)\end{aligned}$$

making use of the induction hypothesis. The crucial observation is that

$$\text{Prob } (\text{mut}(y) = x) = \text{Prob } (\text{mut}(x) = y)$$

holds for standard bit mutations. This is the only property of the mutation operator that is needed here. Note, however, that there are mutation operators known where this does not hold (Jansen and Sudholt 2010). Now we have

$$\begin{aligned}\text{Prob } (x_t = x) &= 2^{-n} \sum_{y \in \{0,1\}^n} \text{Prob } (\text{mut}(y) = x) \\ &= 2^{-n} \sum_{y \in \{0,1\}^n} \text{Prob } (\text{mut}(x) = y) = 2^{-n}\end{aligned}$$

and see that these bits are indeed uniformly distributed.

Thus, the expected decrease in distance in a single mutation is

$$\sum_{i=1}^n i \text{Prob } (\text{decrease distance by } i) \leq \sum_{i=1}^n i \left(\frac{1}{n}\right) \left(\frac{1}{2^{i-1}}\right) < \frac{1}{n} \sum_{i=1}^{\infty} \frac{i}{2^{i-1}} = \frac{4}{n}$$

and we have $\Delta_l < 4/n$.

Since $E(d(x_0))/\Delta_l = \Theta(nE(d(x_0)))$, all one has to do is to estimate the expected initial distance. Clearly,

$$E(d(x_0)) < n - \sum_{i=1}^n \frac{i}{2^i} = n - 2$$

and we have $E(T_{(1+1)} \text{ EA, LEADINGONES}) = \Theta(n^2)$. It can be seen that this implies that the upper bound on $E(T_{(1+1)} \text{ EA, LEADINGONES})$ derived by means of f -based partitions is indeed tight.

4.6 Typical Events

Sometimes, a statement about the expected optimization time can be made and proved based on a good understanding of the evolutionary algorithm and the fitness function. Such proofs tend to be *ad hoc* and difficult to generalize. Sometimes, however, there is a common element that is worth pointing out. Here, we consider situations where the optimization time is dominated by something that typically happens in a run of the evolutionary algorithm, we call this a typical event.

To make things more concrete, an example is considered. As usual, we use the $(1 + 1)$ EA and reconsider a fitness function where we already proved an upper bound on the expected optimization time, JUMP_k . Remember that using the method of fitness-based partitions, we were able to prove that

$$E(T_{(1+1) \text{ EA, JUMP}_k}) = O(n^k + n \log n)$$

holds. The dominating term n^k stems from the fact that in order to reach the unique global optimum starting in one of the local optima, a mutation of k specific bits is necessary. Such a mutation has probability $((1/n)^k(1 - 1/n)^{n-k})$ and leads to an expected waiting time of $\Theta(n^k)$. Remembering the structure of JUMP_k

$$\text{JUMP}_k(x) = \begin{cases} n - \text{ONEMAX}(x) & \text{if } n - k < \text{ONEMAX}(x) < n \\ k + \text{ONEMAX}(x) & \text{otherwise} \end{cases}$$

the following observations are made. If the current x_t contains at most $n - k$ 1-bits, in order to reach the global optimum by means of a direct mutation, such a mutation needs to flip exactly all 0-bits in x_t . In this case the expected optimization time is bounded below by $\Omega(n^k)$. Since for all $x \in \{0, 1\}^n$ with more than $n - k$ but less than n 1-bits the function value equals $n - \text{ONEMAX}(x)$ leading toward the local optima, we believe that it is quite likely that a local optimum will be reached.

We make this reasoning more concrete and define the typical event B that there exists some $t \in \mathbb{N}$, such that $\text{ONEMAX}(x_t) \leq n - k$ holds. It follows from the law of total probability that

$$E(T_{(1+1)\text{EA}, \text{JUMP}_k}) \geq \text{Prob}(B)E(T_{(1+1)\text{EA}, \text{JUMP}_k} \mid B)$$

holds. As already argued above, $E(T_{(1+1)\text{EA}, \text{JUMP}_k} \mid B) = \Omega(n^k)$ holds. Since $E(T_{(1+1)\text{EA}, \text{JUMP}_k}) = \Omega(n \log n)$ follows from the general lower bound (Sect. 4.2), it suffices to prove that $\text{Prob}(B) = \Omega(1)$ holds.

We make a case distinction on the value of k . For $k < n/3$ we have

$$\text{Prob}(\text{ONEMAX}(x_0) \leq n - k) = 1 - 2^{-\Omega(n)}$$

as can easily be shown using Chernoff bounds. Clearly, $\text{Prob}(B) = 1 - 2^{-\Omega(n)}$ follows in this case. For the case $k > (n/3)$ one can first observe that still

$$\text{Prob}(\text{ONEMAX}(x_0) \leq n - k) = 1 - 2^{-\Omega(n)}$$

holds. It can be seen that $\text{Prob}(B)$ is bounded below the probability that the unique global optimum is reached before a local optimum is reached. It can be observed that after an initialization with at most $(2/3)n$ 1-bits the global optimum can only be reached via a mutation of all 0-bits with at least $n/3$ 0-bits in each current x_t . Such a mutation has probability at most $1/n^{n/3}$. Since the function is similar to $-\text{ONEMAX}$ it can be concluded that some local optimum is reached in expectation within $O(n \log n)$ steps. More precisely, there is some constant c such that the expected time to reach a local optimum is bounded above by $cn \log n$. By Markov's inequality, it follows that with probability at least $1/2$, we reach a local optimum in at most $2cn \log n$ steps if the global optimum is not reached before. We consider $2cn^2 \log n$ steps as n independent trials to reach a local optimum, each consisting of $2cn \log n$ steps. It can be concluded that, given that the global optimum is not reached before, a local optimum is reached within $O(n^2 \log n)$ steps with probability $1 - 2^{-\Omega(n)}$. Since the probability to reach the optimum in a single mutation is bounded above by $1/n^{n/3}$, the probability to reach the optimum within $O(n^2 \log n)$ steps is bounded above by $O((n^2 \log n)/n^{n/3}) = 2^{-\Omega(n)}$. Together, we have $\text{Prob}(B) = 1 - 2^{-\Omega(n)}$ in this case, too. So we have

$$E(T_{(1+1)\text{EA}, \text{JUMP}_k}) = \Theta(n^k + n \log n)$$

and observe that the upper bound derived by means of f -based partitions is indeed tight.

4.7 Typical Runs

The situation described in the previous section was in some sense exceptionally simple. The optimization time is governed by one specific event that needs to occur: Some point x with at most $n - k$ 1-bits needs to become x_t before the global optimum is found. Often the situation is less clear but still there is a rather clear idea how an evolutionary algorithm may optimize a specific fitness function. Often, it is not even necessary that the evolutionary algorithm does in fact optimize this fitness function in this way. Proving that one specific way is possible within some number of f -evaluations and with some probability is often sufficient to get at least an upper bound on the expected optimization time. This can be made clear by again considering JUMP _{k} but now a more complex evolutionary algorithm. Attention is restricted to JUMP _{k} for relatively small values of k , $k = O(\log n)$.

We consider the $(\mu + \lambda)$ EA with $\lambda = 1$, $p_c > 0$ and uniform crossover. Note that this is the first time that an evolutionary algorithm with crossover is dealt with. It will be seen that this makes the analysis considerably more difficult. It is assumed that the population size μ is polynomially bounded from above and not too small. It is assumed $\mu \geq k \log^2 n$ holds. Since $k = O(\log n)$, this allows for relatively small population sizes. Finally, it is assumed that the probability for crossover p_c is rather small. A proof that works for $p_c \leq 1/(ckn)$ where $c > 0$ is a sufficiently large positive constant is discussed.

We start by describing what we consider to be a typical run of the $(\mu + 1)$ EA with uniform crossover. We do so by describing different *phases* and what one expects in these phases to happen. For each phase, we define entry conditions that need to be fulfilled at the beginning of each phase and exit conditions that define the end of each phase. Here, three phases are described. For the first phase, the entry condition is empty. This has the advantage that we can assume any time to start with phase 1. In particular, if anything goes wrong in any phase, we can assume the algorithm to be restarted. This would be different if we had entry conditions that assume that the current population is actually randomly distributed according to the uniform distribution. The exit condition of the first phase is that each member of the current population contains exactly $n - k$ 1-bits. This implies that the population contains only local optima.

The entry condition for the second phase is equal to the exit condition of the first phase. This is usually the case since the exit of one phase should be the entry to the next phase. The exit condition of the second phase is that still all members of the current population contain exactly $n - k$ 1-bits each; additionally, we demand that

$$\forall i \in \{1, 2, \dots, n\}: \sum_{j=1}^{\mu} 1 - x^{(j)}[i] \leq \mu/(4k) \quad (1)$$

holds where $x^{(j)}$ denotes the j th member of the current population. It is observed that \bullet Eq. 1 ensures that at each of the n position, the number of 0-bits summed over the complete population is bounded above by $\mu/(4k)$. Note that this is a relatively large upper bound. The complete population contains exactly μk 0-bits, since each member contains exactly k 0-bits in the second phase. Thus, if these bits were evenly distributed, one would expect to see $\mu k/n = O(\mu \log(n)/n)$ 0-bits at each position. The bound $\mu/(4k)$ is by a factor of $\Theta(n/k^2) = \Omega(n/\log^2 n)$ larger.

The entry condition for the third and final phase is the exit condition of the second case. Its exit condition is that an optimal search point is member of the current population.

In the first phase, the situation is similar to ONE MAX. It is not difficult to see that on average after $O(\mu \log n)$ f -evaluations the exit condition of phase 1 is met (Jansen and Wegener 2002). Moreover, by considering longer runs as restarts like we did in the previous section, one can obtain an upper bound of $p_1 \leq \varepsilon$ for the probability not to complete the first phase within $O(\mu \log n)$ steps for any positive constant ε .

The second phase is much more difficult to analyze. When the phase begins, each member of the population contains exactly k 0-bits. We have to prove that these 0-bits become somewhat distributed among the different positions. To this end, we consider some specific bit position, say the first. Let z denote the number of 0-bits at this position summed over the whole population. We want to show that $z \leq \mu/(4k)$ holds after some time.

Clearly, in one generation, this number of 0-bits z can change by at most by 1. Let A_z^+ resp. A_z^- be the event that (given z) the number of zeros (at position 1) increases resp. decreases in one round. One wants to estimate the probabilities of A_z^+ and A_z^- . Since one wants to prove an upper bound on the number of 0-bits, one needs an upper bound on $\text{Prob}(A_z^+)$ and a lower bound on $\text{Prob}(A_z^-)$. Since this seems to be rather complicated, one can consider six (classes of) events that have probabilities that one can estimate directly. From now on, the index z will be omitted to simplify the notation.

- B : crossover is chosen as operator, $\text{Prob}(B) = p_c$.
- C : an object with a one at position 1 is chosen for replacement, $\text{Prob}(C) = (\mu - z)/\mu$.
- D : an object with a zero at position 1 is chosen for mutation, $\text{Prob}(D) = z/\mu$.
- E : the bit at position 1 does not flip, $\text{Prob}(E) = 1 - 1/n$.
- F_i^+ : there are exactly i positions among the $(k-1)$ 0-positions $j \neq 1$ that flip and exactly i positions among the $(n-k)$ 1-positions that flip, $\text{Prob}(F_i^+) = \binom{k-1}{i} \binom{n-k}{i} (1/n)^{2i} (1 - 1/n)^{n-2i}$.
- G_i^+ : there are exactly i positions among the k 0-positions that flip and exactly $i-1$ positions among the $(n-k-1)$ 1-positions $j \neq 1$ that flip, $\text{Prob}(G_i^+) = \binom{k}{i} \binom{n-k-1}{i-1} (1/n)^{2i-1} (1 - 1/n)^{n-2i}$.

Using this event, one can observe that

$$A^+ \subseteq B \cup \left(\overline{B} \cap C \cap \left[\left(D \cap E \cap \bigcup_{0 \leq i \leq k-1} F_i^+ \right) \cup \left(\overline{D} \cap \overline{E} \cap \bigcup_{1 \leq i \leq k} G_i^+ \right) \right] \right)$$

holds. Similarly, we get

$$A^- \supseteq \overline{B} \cap \overline{C} \cap \left[\left(D \cap \overline{E} \cap \bigcup_{1 \leq i \leq k} F_i^- \right) \cup \left(\overline{D} \cap E \cap \bigcup_{0 \leq i \leq k} G_i^- \right) \right]$$

where

- F_i^- : there are exactly $i-1$ positions among the $(k-1)$ 0-positions $j \neq 1$ that flip and exactly i positions among the $(n-k)$ 1-positions that flip, $\text{Prob}(F_i^-) = \binom{k-1}{i-1} \binom{n-k}{i} (1/n)^{2i-1} (1 - 1/n)^{n-2i}$.

- G_i^- : there are exactly i positions among the k 0-positions that flip and exactly i positions among the $(n - k - 1)$ 1-positions $j \neq 1$ that flip, $\text{Prob}(G_i^-) = \binom{k}{i} \binom{n - k - 1}{i} (1/n)^{2i} (1 - 1/n)^{n-2i-1}$.

Since we are interested in the situation where the number of 0-bits is too large, we assume $z \geq \mu/(8k)$ in the following. It is tedious but not difficult to see that $\text{Prob}(A^-) - \text{Prob}(A^+) = \Omega(1/(nk))$ holds (Jansen and Wegener 2002). We consider the random walk defined by the random changes of z and prove that after $\Theta(\mu n^2 k^3)$ steps, the number of 0-bits at the current position is sufficiently decreased with probability $1 - O(1/n)$. By increasing the constant factor hidden in the number of generations $\Theta(\mu n^2 k^3)$ we can decrease the probability not to decrease the number of 0-bits. We obtain a bound on the probability that this happens at least one of the n positions by simply taking the union bound.

Unfortunately, this line of reasoning is valid only if $z \geq \mu/(8k)$ holds during the complete phase. If this is not the case, the probabilities $\text{Prob}(A^+)$ and $\text{Prob}(A^-)$ change. We cope with this additional difficulty in the following way. Consider the last time point of time when $z < \mu/(8k)$ holds. If at this point of time there are at most $\mu/(8k)$ generations left, the number of 0-bits can at most increase to $\mu/(8k) + \mu/(8k) = \mu/(4k)$, which is the bound that we wanted to prove. If there are more than $\mu/(8k)$ steps left, we can repeat the line of reasoning and now know that $z \geq \mu/(8k)$ holds all the time.

Finally, in the third phase, the probability that the global optimum is found is not too small. Note that this is the only phase where we actually take beneficial effects of uniform crossover into account. We can control the number of 0-bits at each position in a way that is similar to the second phase. We ensure that the number of 0-bits does not exceed $\mu/(2k)$ at each position. So we can concentrate on the creation of the global optimum. This is achieved if the following happens. We perform crossover (with probability p_c), we select two parents that do not share a 0-bit at any position (with some probability p), in uniform crossover the optimum 1^n is created (with probability $(1/2)^{2n}$), and this optimum is not destroyed by mutation (with probability $(1 - 1/n)^n$). We need to estimate the probability p of selecting two parents without a common 0-bit. After the first parent is selected, there are exactly k positions where the second parent may “collide” with this parent. Since at each position one has at most $\mu/(2k)$ 0-bits, the probability for this event is bounded below by $k \cdot (\mu/(2k))/\mu = 1/2$. Together, we have a probability of $\Omega(p_c 2^{-2k})$ to create the global optimum for each generation of the third phase. Combining the results for the different phases, we obtain $O(\mu n^2 k^3 + 2^{2k}/p_c)$ as upper bound on the expected optimization time.

5 Summary

Evolutionary algorithms can be described as randomized search heuristics that are often applied as randomized optimization heuristics. This motivates the investigation of their efficiency as is done for other optimization algorithms, too. Placing evolutionary algorithms in the context of design and analysis of randomized algorithms in this way makes the question of their computational complexity one of immense importance.

The aim of this chapter is to demonstrate that the analysis of the expected optimization time of evolutionary algorithms is something that can be done. More importantly, it aims at

demonstrating how it can be done. This encompasses rather general approaches like “no free lunch” theorems and results on the black-box complexity. For the latter, Yao’s minimax principle is introduced and its application is demonstrated in practical examples. On the other hand, concrete tools and methods for the analysis of evolutionary algorithms’ expected optimization times are discussed.

The method of fitness-based partitions is the conceptually simplest of the analytical tools introduced. It measures the progress of an evolutionary algorithm by means of fitness values in a predefined way. For a successful analysis, the definition of an appropriate grouping of fitness values into fitness layers is crucial. For many functions, tight upper bounds on the expected optimization time can be achieved this way. The method, however, is restricted to algorithms employing a kind of elitist selection, it cannot deal with decreases in function value.

The method of the expected multiplicative distance decrease also establishes upper bounds on the expected optimization time by measuring the progress of an evolutionary algorithm by means of fitness values. It does so, however, in a more flexible way. Instead of defining static fitness layers, one identifies ways of increasing the fitness in all situations. This yields an average multiplicative decrease of the difference between the current fitness and the fitness of an optimal solution that finally leads to an upper bound on the average time needed to decrease the difference to 0. This method is restricted to functions with integer function values. Since a finite search space is dealt with, this is not a fundamental limitation. Multiplication can turn rational function values into integer ones. More fundamental is that the proven bounds depend on the size of the function values. While this can be removed to some extent (Reichel and Skutella 2009), it often leads to bounds that are not asymptotically tight.

An even more flexible way of measuring the progress of an evolutionary algorithm is drift analysis. Here, progress can be measured in an almost arbitrary way. Moreover, it suffices to have bounds on the expected progress in a single generation for the proof of bounds on the expected optimization time. This allows for the analysis of algorithms that do not guarantee monotone progress as long as the expected progress is positive.

These three general methods for establishing upper bounds on the expected optimization time are complemented by lower bound techniques. There is a very general lower bound for all mutation-based algorithms of size $\Omega(n \log n)$ that holds for almost all fitness functions of practical interest. While being useful, it does not clearly establish a technique. The most powerful technique for proving lower bounds on the expected optimization time is drift analysis. The differences between the drift techniques for establishing upper and lower bounds are rather small, and drift analysis is equally flexible and powerful for both upper and lower bounds. We concentrated on proving upper and lower bounds for expected optimization times that are polynomial. For proving exponential lower bounds, better-suited drift theorems are available that allow us to establish strong negative results at ease (Oliveto and Witt 2008).

Basing analysis on either typical events or typical runs are not upper or lower bound techniques per se. Here, a lower bound proven with the method of typical events and an upper bound using the method of typical runs are presented. Both methods require a good idea of how the evolutionary algorithms actually works on the concrete fitness function under consideration. It is noteworthy that using the method of typical runs one could derive proven results for an evolutionary algorithm with crossover. However, it is not the case that the other methods do not allow for such results.

All methods using example functions that are in some sense artificial are introduced. This has the advantage that these fitness functions have a very clear structure. They can easily be used to demonstrate certain effects. Here they allowed for a clear presentation of the analytical

tools employed. Most methods described here most often have been developed using such example functions that facilitate the analysis. It is worth mentioning that the method of the expected multiplicative distance decrease is an exception. It was introduced not using any specific example function but for a combinatorial optimization problem, namely the minimum spanning tree problem (Neumann and Wegener 2004).

Clearly, these methods for the analysis of evolutionary algorithms are in no way restricted to the analysis of such example functions. They have been successfully applied to a large number of combinatorial optimization problems and a variety of different variants of evolutionary algorithms, see Oliveto et al. (2007) for an overview.

We concentrated on the presentation of analytical tools in a way that allows the reader to employ these methods for his or her own problems. This leads to a presentation using practical examples instead of presenting the methods in their most general form. Moreover, a complete overview of all methods ever employed in the analysis of evolutionary algorithms is not presented. Two methods not covered here worth mentioning are the method of delay sequences (Dietzfelbinger et al. 2003) that allows for very tight bounds and the method of family trees that facilitates the analysis of an evolutionary algorithm with a population size $\mu > 1$ (Witt 2006). Moreover, the various mathematical tools that are useful in the analysis of algorithms are not covered in detail, in particular the application of martingales is not discussed (Jansen and Sudholt 2010; Williams 1991).

While aiming at the analysis of evolutionary algorithms no method is actually restricted to this class of algorithms. It is possible to apply these methods to other randomized algorithms, successful examples include ant colony optimization (Doerr et al. 2007; Sudholt and Witt 2008a), memetic algorithms (Sudholt 2008), and particle swarm optimization (Sudholt and Witt 2008b; Witt 2009). We can be sure to see these methods presented here further applied to more algorithms and more problems and to see more powerful methods developed in the future.

Abstract

Since the state transitions of an evolutionary algorithm (EA) are of stochastic nature, the deterministic concept of the “convergence to the optimum” is not appropriate. In order to clarify the exact semantic of a phrase like “the EA converges to the global optimum” one has to, at first, establish the connection between EAs and stochastic processes before distinguishing between the various modes of stochastic convergence of stochastic processes. Subsequently, this powerful framework is applied to derive convergence results for EAs.

1 Introduction

Broadly speaking, the notion of “convergence” of an evolutionary algorithm (EA) simply means that the EA should approach some “limit” in the course of its evolutionary sequence of populations. Needless to say, this limit should represent something like the optimum of the optimization problem that one intends to solve. In this case, the “convergence” of an EA to a “limit” is a desirable property.

In order to endow the terms “convergence” and “limit” with a precise meaning in the context of EAs, it is necessary to embed EAs in the framework of “stochastic processes” (☞ Sect. 2) before the different modes of “stochastic convergence” and their basic results are introduced in ☞ Sect. 3. Subsequently, these basic results are applied, refined, and extended to EAs in ☞ Sect. 4, before ☞ Sect. 5 provides annotated pointers to the first results regarding the convergence theory of multi-objective EAs.

2 Stochastic Process Models of Evolutionary Algorithms

The analysis of the dynamic behavior of EAs benefits from the fact that it is always possible to establish a bijective mapping between an EA and a particular stochastic process. As a consequence, one can exploit the results and techniques of the well-founded theory of stochastic processes (Doob 1967).

Definition 1 Let $(X_t)_{t \in T}$ be a family of random variables (r.v.s) on a joint probability space (Ω, \mathcal{F}, P) with values in a set E of a measurable space (E, \mathcal{B}) and index set T . Then $(X_t)_{t \in T}$ is called a *stochastic process* with index set T . □

In general, there is no mathematical reason for restricting index set T to be a set of numerical values. But here the index set T is identical with \mathbb{N}_0 and the indices $t \in T$ will be interpreted as points of time.

Definition 2 A stochastic process $(X_t)_{t \in T}$ with index set $T = \mathbb{N}_0$ is called a *stochastic process with discrete time*. The image space E of $(X_t)_{t \in T}$ is called the *state space* of the process. The *transition probability*

$$P\{X_{t+1} \in A | X_t = x_t, X_{t-1} = x_{t-1}, \dots, X_1 = x_1, X_0 = x_0\} \quad (1)$$

describes the probability of the event of transitioning to some state in set $A \subseteq E$ in step $(t+1)$ subject to previous steps though the state space E . □

Evidently, random variable X_t will represent the population at generation $t \geq 0$ and the function in $\textcircled{1}$ Eq. 1 will indicate the likeliness that the population at generation $t + 1$ will be some $x \in A$ conditioned by all previous populations. Since the transition probability $\textcircled{1}$ Eq. 1 must somehow capture the stochastic nature of the genetic operators and selection methods, it is clear that the modeling of the transition probability function is the main task when establishing a link between EA and stochastic process. Due to combinatorial complexity, the more difficult this task becomes the larger is the set of preceding populations on which the transition probabilities are conditioned. Fortunately, the vast majority of EAs are designed in a manner that does not require the most general formulation of the stochastic process model, although there are tools and results supporting an analysis (Iosifescu and Grigorescu 1990). But typically, the genetic operators and selection methods only act on the current population of individuals without taking into account the genomes of the antecedent populations of individuals. In other words: The phylogenetic trees of the current individuals do not affect the future. As a consequence, the transition probabilities only depend on the current population. Stochastic processes with this property are endowed with an extensive theory (see, e.g., Iosifescu (1980), Seneta (1981), Nummelin (1984), and Meyn and Tweedie (1993)) and they bear their own name:

Definition 3 A stochastic process $(X_t)_{t \in T}$ with discrete time whose transition probability satisfies

$$\mathbb{P}\{X_{t+1} \in A | X_t = x_t, X_{t-1} = x_{t-1}, \dots, X_1 = x_1, X_0 = x_0\} = P_t\{X_{t+1} \in A | X_t = x_t\}$$

for all $t \geq 0$ is called a *Markov process with discrete time*. As for notation, often $P_t(x, A) := P_t\{X_{t+1} \in A | X_t = x\}$. If the transition probability of a Markov process with discrete time does not explicitly depend on the time parameter $t \geq 0$, that is,

$$\forall t \geq 0: P_t\{X_{t+1} = x | X_t = x_t\} = P\{X_{t+1} = x | X_t = x_t\},$$

then the Markov process is *time-homogeneous*, and *time-inhomogeneous* otherwise. A Markov process with countable state space is termed a *Markov chain*. \square

Since EAs work with discrete time, their stochastic models also use discrete time. Therefore, the phrase “with discrete time” will be left out hereinafter when talking about Markov processes and Markov chains. Next, suppose that an EA is deployed for solving the optimization problem

$$f(x) \rightarrow \min! \quad \text{subject to } x \in \mathcal{X} \tag{2}$$

where the objective function $f: \mathcal{X} \rightarrow \mathbb{R}$ is bounded from below. Now, solely, the type of the search space \mathcal{X} determines which type of Markov model and which part of Markov theory can be used.

2.1 Finite Search Space

If the search space \mathcal{X} is finite, so is the state space of the Markov chain. There are at least two approaches for modeling the state space. This will be exemplified by the binary search space $\mathcal{X} = \mathbb{B}^n$ with $\mathbb{B} = \{0, 1\}$.

2.1.1 Generic State Space Model

A straightforward generic model for the state space E of a Markov chain representing an EA with finite population size μ and search space $\mathcal{X} = \mathbb{B}^n$ is the μ -fold cartesian product $E = \mathcal{X}^\mu = (\mathbb{B}^n)^\mu = \mathbb{B}^{n \times \mu}$ that has been used in the early 1990s (see Eiben et al. (1991), Fogel (1994), Rudolph (1994b), and others). As a consequence, there are $|E| = 2^{n \times \mu}$ possible states and one needs $|E| \times |E|$ transition probabilities to characterize the stochastic effects caused by variation and selection operators. Evidently, these transition probabilities can be gathered in a square matrix $P = (p_{ij})$ of size $|E| \times |E|$, termed the *transition matrix*. Finally, one has to specify the *initial distribution* of the Markov chain to obtain a complete stochastic model of the EA. The initial distribution models the initialization of the EA.

The advantages of the generic state space model are that it also works for EAs with spatial structure and that it has a natural analogon for denumerable and innumerable search spaces.

2.1.2 Davis/Vose State Space Model

An alternative state space model was introduced independently by Davis (1991) and Vose (Nix and Vose 1992) also in the early 1990s. Its advantage is a smaller state space but its disadvantage is the fact that only panmictic EAs (every individual may mate with every other individual) without spatial structure can be modeled in this manner. Moreover, it has no analogon in case of innumerable search spaces.

Suppose that the position of the individuals in the population is of no importance and that the EA has a panmictic mating policy. Then, one only needs to know how many individuals of a certain type are present in the current population for deriving the transition probabilities. Since there are $|\mathcal{X}| = |\mathbb{B}^n| = 2^n$ possible individuals one needs a 2^n -tuple of nonnegative integers whose components count the number of occurrences of each type of individuals. Of course, the sum over all components must be exactly μ . As a consequence, the cardinality of the state space reduces to

$$|E| = \binom{2^n + \mu - 1}{\mu}$$

which is considerably smaller than the value $2^{n \times \mu}$ of the generic model. The transition matrix is of considerably smaller size as well.

Both approaches are thoroughly justified. But it is important to keep in mind that every EA that can be modeled by this approach can also be modeled in the generic setting whereas the converse is wrong in general. For example, see the efforts and insuperable difficulties in Muhammad et al. (1999) when trying to model a spatially structured EA with a Davis/Vose state space model.

2.2 Denumerable Search Space

An example of a denumerable but not finite search space is the integer search space $\mathcal{X} = \mathbb{Z}^n$. Apparently, this case has not been analyzed yet in the context of Markov chains although there exists a theory (see, e.g., part II in Seneta (1981)) using infinite-dimensional transition matrices. The reason might be due to the fact that in practice, the search space is almost

always equipped with box constraints leading to a finitely sized subset. Exceptions without box constraints are rare (see, e.g., Rudolph 1994c).

The generic state space model for a population of μ individuals is $E = \mathcal{X}^\mu = \mathbb{Z}^{n \times \mu}$ whereas the analogon of the Davis/Vose state space model $E = \{e \in \mathbb{N}_0^\infty : \sum_{i=1}^{\infty} e_i = \mu\}$ requires an infinite-dimensional tuple of nonnegative integers whose components count the number of occurrences of each type of individual and must add up to μ . Since this model has the same limitations as in the finite case and both models are now of infinite cardinality, it is quite obvious that there is no advantage of the Davis/Vose model in the denumerable case.

2.3 Innumerable Search Space

The typical representative for an innumerable search space is $\mathcal{X} = \mathbb{R}^n$. Here, only the generic state space model is expedient: $E = \mathcal{X}^\mu = \mathbb{R}^{n \times \mu}$. Since the probability to sample a specific point in \mathbb{R}^n from a continuous distribution is zero, the transition probabilities are specified by transition probability functions (in lieu of matrices) describing transitions from a state to a set of states with nonzero measure (see, e.g., Rudolph 1996).

3 Stochastic Convergence

The limit behavior of stochastic sequences requires a concept of convergence that captures the random nature of the sequence. This can be done in quite a different manner (Lukacs 1975). Here, only the most frequently used concepts are presented.

Definition 4 Let Z, Z_0, Z_1, \dots be random variables defined on a probability space $(\Omega, \mathcal{A}, \mathbb{P})$. The sequence $(Z_t : t \geq 0)$ is said

(a) to *converge completely* to random variable Z , denoted $Z_t \xrightarrow{c} Z$, if

$$\sum_{t=0}^{\infty} \mathbb{P}\{|Z_t - Z| > \varepsilon\} < \infty \text{ for every } \varepsilon > 0,$$

(b) to *converge with probability 1*, denoted $Z_t \xrightarrow{w.p.1} Z$, if

$$\mathbb{P}\left\{\lim_{t \rightarrow \infty} |Z_t - Z| = 0\right\} = 1,$$

(c) to *converge in probability* to Z , denoted $Z_t \xrightarrow{p} Z$, if

$$\lim_{t \rightarrow \infty} \mathbb{P}\{|Z_t - Z| > \varepsilon\} = 0 \text{ for every } \varepsilon > 0 \text{ and}$$

(d) to *converge in mean* to Z , denoted $Z_t \xrightarrow{m} Z$, if

$$\lim_{t \rightarrow \infty} \mathbb{E}[|Z_t - Z|] = 0. \quad \square$$

Basic relationships between these concepts of stochastic convergence are summarized in Theorem 1 below.

Theorem 1 (see Lukacs (1975), pp. 33–36 and 51–52) $Z_t \xrightarrow{c} Z \Rightarrow Z_t \xrightarrow{w.p.1} Z \Rightarrow Z_t \xrightarrow{p} Z$ and $Z_t \xrightarrow{m} Z \Rightarrow Z_t \xrightarrow{p} Z$. The converse is wrong in general. \square

Under additional conditions, some implications may be reversed. Here, the last implication is of special interest:

Theorem 2 (see Williams 1991, pp. 127–130) *If $|Z_t| \leq Y$ with $E[Y] < \infty$ for all $t \geq 0$ and $Z_t \xrightarrow{P} Z$ then also $Z_t \xrightarrow{m} Z$. \square*

Notice that the so-called *dominated convergence theorem* above also holds for the special case, where random variable Y is replaced by a finite constant $K \in (0, \infty)$. The example below is intended to provide a first impression about the differences between the modes of stochastic convergence introduced previously.

Example 1 (Modes of stochastic convergence) Let $(Z_t)_{t \geq 1}$ be a sequence of independent random variables. Depending on their probability distributions, the sequences converge to zero in different modes.

- $P\{Z_t = 0\} = 1 - \frac{1}{t}$ and $P\{Z_t = 1\} = \frac{1}{t}$

At first, one can confirm convergence to zero in probability since $P\{Z_t > \varepsilon\} = P\{Z_t = 1\} = \frac{1}{t} \rightarrow 0$ for $t \rightarrow \infty$. But there is no complete convergence since the probability mass does not move quickly enough to zero: $\sum_{t=1}^{\infty} P\{Z_t > \varepsilon\} = \sum_{t=1}^{\infty} P\{Z_t = 1\} = \sum_{t=1}^{\infty} \frac{1}{t} = \infty$. Note that $0 \leq Z_t \leq 1$ for all $t \geq 0$. Evidently, the sequence is bounded from above by constant $K = 1$. Thanks to $\textcircled{1}$ **Theorem 1**, one has convergence in mean.

- $P\{Z_t = 0\} = 1 - \frac{1}{t^2}$ and $P\{Z_t = 1\} = \frac{1}{t^2}$

As can be seen from $P\{Z_t > \varepsilon\} = P\{Z_t = 1\} = \frac{1}{t^2} \rightarrow 0$ for $t \rightarrow \infty$ the sequence converges to zero in probability. Here, the convergence is quick enough to guarantee even complete convergence: $\sum_{t=1}^{\infty} P\{Z_t > \varepsilon\} = \sum_{t=1}^{\infty} P\{Z_t = 1\} = \sum_{t=1}^{\infty} \frac{1}{t^2} < \infty$. For the same reasons as above, the sequence also converges in mean.

- $P\{Z_t = 0\} = 1 - \frac{1}{t}$ and $P\{Z_t = t\} = \frac{1}{t}$

This sequence also converges to zero in probability: $P\{Z_t > \varepsilon\} = P\{Z_t = t\} = \frac{1}{t} \rightarrow 0$ for $t \rightarrow \infty$. But the convergence is not quick enough to establish complete convergence: $\sum_{t=1}^{\infty} P\{Z_t > \varepsilon\} = \sum_{t=1}^{\infty} P\{Z_t = t\} = \sum_{t=1}^{\infty} \frac{1}{t} = \infty$. Note that the sequence is not bounded from above. Moreover, the fact that $E[Z_t] = 0 \cdot P\{Z_t = 0\} + t \cdot P\{Z_t = t\} = t \cdot \frac{1}{t} = 1$ for all $t \geq 1$ reveals that the sequence does not converge to zero in mean.

- $P\{Z_t = 0\} = 1 - \frac{1}{t^2}$ and $P\{Z_t = t\} = \frac{1}{t^2}$

Thanks to $P\{Z_t > \varepsilon\} = P\{Z_t = t\} = \frac{1}{t^2} \rightarrow 0$ for $t \rightarrow \infty$ one may confirm not only convergence in probability but also complete convergence: $\sum_{t=1}^{\infty} P\{Z_t > \varepsilon\} = \sum_{t=1}^{\infty} P\{Z_t = t\} = \sum_{t=1}^{\infty} \frac{1}{t^2} < \infty$. Although the sequence is not bounded from above, one can ensure convergence in mean via $E[Z_t] = 0 \cdot P\{Z_t = 0\} + t \cdot P\{Z_t = t\} = t \cdot \frac{1}{t^2} = \frac{1}{t} \rightarrow 0$ for $t \rightarrow \infty$.

- $P\{Z_t = 0\} = 1 - \frac{1}{t}$ and $P\{Z_t = t^2\} = \frac{1}{t}$

This sequence converges to zero in probability because of $P\{Z_t > \varepsilon\} = P\{Z_t = t^2\} = \frac{1}{t} \rightarrow 0$ for $t \rightarrow \infty$, but owing to $\sum_{t=1}^{\infty} P\{Z_t > \varepsilon\} = \sum_{t=1}^{\infty} P\{Z_t = t^2\} = \sum_{t=1}^{\infty} \frac{1}{t} = \infty$ and $E[Z_t] = 0 \cdot P\{Z_t = 0\} + t^2 \cdot P\{Z_t = t^2\} = t^2 \cdot \frac{1}{t} = t \rightarrow \infty$ for $t \rightarrow \infty$ there is neither complete convergence nor convergence in mean.

- $P\{Z_t = 0\} = 1 - \frac{1}{t^2}$ and $P\{Z_t = t^2\} = \frac{1}{t^2}$

Finally, this sequence converges to zero in probability owing to $P\{Z_t > \varepsilon\} = P\{Z_t = t^2\} = \frac{1}{t^2} \rightarrow 0$ for $t \rightarrow \infty$ and it actually converges completely to zero on account

Table 1

The modes of stochastic convergence that are realized by the random sequences of Example 1 depending on their probability distributions

Probability distribution		\xrightarrow{c}	\xrightarrow{p}	\xrightarrow{m}
$P\{Z_t = 0\} = 1 - \frac{1}{t}$	$P\{Z_t = 1\} = \frac{1}{t}$	-	+	+
$P\{Z_t = 0\} = 1 - \frac{1}{t^2}$	$P\{Z_t = 1\} = \frac{1}{t^2}$	+	+	+
$P\{Z_t = 0\} = 1 - \frac{1}{t}$	$P\{Z_t = t\} = \frac{1}{t}$	-	+	-
$P\{Z_t = 0\} = 1 - \frac{1}{t^2}$	$P\{Z_t = t\} = \frac{1}{t^2}$	+	+	+
$P\{Z_t = 0\} = 1 - \frac{1}{t}$	$P\{Z_t = t^2\} = \frac{1}{t}$	-	+	-
$P\{Z_t = 0\} = 1 - \frac{1}{t^2}$	$P\{Z_t = t^2\} = \frac{1}{t^2}$	-	+	+

of $\sum_{t=1}^{\infty} P\{Z_t > \varepsilon\} = \sum_{t=1}^{\infty} P\{Z_t = t^2\} = \sum_{t=1}^{\infty} \frac{1}{t^2} < \infty$. Convergence to zero in mean, however, cannot be attested: $E[Z_t] = 0 \cdot P\{Z_t = 0\} + t^2 \cdot P\{Z_t = t^2\} = t^2 \cdot \frac{1}{t^2} = 1$ for all $t \geq 1$. \square

• **Table 1** summarizes the results obtained from this example.

Stochastic processes with special properties can be useful devices in the analysis of the limit behavior of evolutionary algorithms.

Definition 5 Let (Ω, \mathcal{F}, P) be a probability space and $\mathcal{F}_0 \subseteq \mathcal{F}_1 \subseteq \dots \subseteq \mathcal{F}$ be an increasing family of sub- σ -algebras of \mathcal{F} and $\mathcal{F}_{\infty} := \sigma(\bigcup_t \mathcal{F}_t) \subseteq \mathcal{F}$. A stochastic process $(Z_t)_{t \geq 0}$ that is \mathcal{F}_t -measurable for each t is termed a *supermartingale* if

$$E[|Z_t|] < \infty \text{ and } E[Z_{t+1} | \mathcal{F}_t] \leq Z_t \text{ w.p.1}$$

for all $t \in \mathbb{N}_0$. \square

Nonnegative supermartingales, which means that additionally $Z_t \geq 0$ for all $t \geq 0$ have the following remarkable property:

Theorem 3 (see Neveu (1975, p. 26)) If $(Z_t)_{t \geq 0}$ is a nonnegative supermartingale then $Z_t \xrightarrow{w.p.1} Z < \infty$. \square

Although nonnegative supermartingales do converge to a finite limit with probability 1, nothing can be said about the limit itself unless additional conditions are imposed. The example below reveals that even a strict inequality, that is, $E[Z_{t+1} | \mathcal{F}_t] < Z_t$, does not necessarily imply a zero limit for nonnegative supermartingales.

Example 2 (Monotone decrease does not imply zero limit) Let $Z_t = 1 + 2^{-t} \cdot X_t^2 \geq 0$ for $t \geq 1$ where the sequence X_1, X_2, \dots consists of independent and identically distributed (i.i.d.) random variables with standard normal distribution $N(0, 1)$. Since $E[X_t^2] = 1$ for all $t \geq 1$ one has

$$E[E[Z_{t+1} | \mathcal{F}_t]] = 1 + 2^{-(t+1)} < E[Z_t] = 1 + 2^{-t}$$

for all $t \geq 1$ but $Z_t \xrightarrow{m} 1$ as $t \rightarrow \infty$. \square

For later purposes, it is of interest under which conditions the limit is the constant zero.

Theorem 4 (see Rudolph (1997a, p. 52)) *If $(Z_t)_{t \geq 0}$ is a nonnegative supermartingale satisfying*

$$\mathbb{E}[Z_{t+1} | \mathcal{F}_t] \leq c_t Z_t \text{ w.p.1}$$

for all $t \geq 0$ with $c_t \geq 0$ and

$$\sum_{t=1}^{\infty} \left(\prod_{k=0}^{t-1} c_k \right) < \infty \quad (3)$$

then $Z_t \xrightarrow{m} 0$ and $Z_t \xrightarrow{c} 0$.

It remains to provide some simple conditions that imply inequality (► Eq. 3).

Lemma 1 (see Rudolph (1997a, p. 53)) *The infinite series in (► Eq. 3) converges to a finite limit if*

- (a) $\limsup_{t \geq 0} c_t < 1$ or
- (b) $c_t \leq 1 - a/t$ for some $a > 1$ and almost all $t \geq 1$. □

The limit properties and stability of fixed points of deterministic dynamical systems can be analyzed via so-called Lyapunov functions. Bucy (1965) has shown that supermartingales play the role of Lyapunov functions in the stochastic setting. In fact, both concepts are closely related.

Theorem 5 (see Bucy (1965, pp. 153–154), and Bucy and Joseph (1968, pp. 83–84)) *Let $h: \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}^n$ be a continuous function with $h(0, \cdot) = 0$. Consider the stochastic dynamical system*

$$X_{t+1} = h(X_t, Y_t) \quad (4)$$

for $t \geq 0$ with $X_0 \in \mathbb{R}^n$ and where $(Y_t)_{t \geq 0}$ is a sequence of random vectors. If there exists a continuous nonnegative function $V: \mathbb{R}^n \rightarrow \mathbb{R}$ with the properties

- (a) $V(0) = 0$,
- (b) $V(x) \rightarrow \infty$ as $\|x\| \rightarrow \infty$,
- (c) $V(X_t)$ is a supermartingale along the motion of ► Eq. 4 and
- (d) there exists a continuous function $\gamma: \mathbb{R}_+ \rightarrow \mathbb{R}_+$ vanishing only at the origin and along the motion of ► Eq. 4 holds

$$\mathbb{E}[V(X_{t+1}) | \mathcal{F}_t] \leq V(X_t) - \gamma(\|X_t\|) \quad (5)$$

then $\|X_t\| \xrightarrow{w.p.1} 0$ as $t \rightarrow \infty$. □

In the theorem above, the function $V(\cdot)$ is a Lyapunov function. This result can be used to obtain a slightly weaker result than ► Theorem 4 without any effort: Set $Z_t = V(X_t)$ such that $(Z_t)_{t \geq 0}$ is a nonnegative supermartingale and choose $\gamma(z) = (1 - c)z$ with $c \in (0, 1)$. Then all conditions of ► Theorem 5 including ► Eq. 5 with

$$\mathbb{E}[Z_{t+1} | \mathcal{F}_t] \leq Z_t - \gamma(Z_t) = Z_t - (1 - c)Z_t = cZ_t$$

are fulfilled and one may conclude that $Z_t \xrightarrow{w.p.1} 0$ as $t \rightarrow \infty$.

4 Convergence Results for Evolutionary Algorithms

With the definitions of the previous section, one can assign a rigorous meaning to the notion of the convergence of an evolutionary algorithm.

Definition 6 Let $(X_t : t \geq 0)$ be the sequence of populations generated by some evolutionary algorithm and let $F_t^* = \min\{f(X_{t,1}), \dots, f(X_{t,\mu})\}$ denote the best objective function value of the population of size $\mu < \infty$ at generation $t \geq 0$. An evolutionary algorithm is said to *converge in mean (in probability, with probability 1, completely) to the global minimum* $f^* = \min\{f(x) : x \in \mathcal{X}\}$ of objective function $f: \mathcal{X} \rightarrow \mathbb{R}$ if the nonnegative random sequence $(Z_t : t \geq 0)$ with $Z_t = F_t^* - f^*$ converges in mean (in probability, with probability 1, completely) to zero. \square

The convergence results for evolutionary algorithms depend on the type of the transitions and the search space.

4.1 Time-Homogeneous Transitions

4.1.1 Finite State Space

If the state space is finite and the transition matrix does not depend on the iteration counter, then the limit behavior of the Markov chain and its associated EA solely depend on the structure of the transitions matrix: Let $p^{(0)}$ denote the initial distribution and P the transition matrix. The *state distribution* $p^{(t)}$ of the Markov chain at step $t \geq 0$ is given by $p^{(t)} = p^{(t-1)} \cdot P$ for $t \geq 1$ and $p^{(0)}$ for $t = 0$. The Chapman–Kolmogorov equations (see, e.g., Iosifescu 1980, p. 65) reveal that actually $p^{(t)} = p^{(0)} \cdot P^t$ for $t \geq 0$, where P^t denotes the t th power of transition matrix P . Clearly, the structural properties of P determine the shape of the limit matrix P^∞ , if any, for $t \rightarrow \infty$ and, therefore, also the limit behavior of the EA. In order to exploit these facts, some terminology is required first:

Definition 7 A square matrix $P: m \times m$ is called a *permutation matrix* if each row and each column contain exactly one 1 and $m - 1$ zeros. A matrix A is said to be *cogredient* to a matrix B if there exists a permutation matrix P , such that $A = P'BP$. A square matrix A is said to be *diagonal-positive* if $a_{ii} > 0$ for all diagonal elements and it is said to be *nonnegative (positive)*, denoted $A \geq 0$ (> 0), if $a_{ij} \geq 0$ (> 0) for each entry a_{ij} of A . A nonnegative matrix is called *reducible* if it is cogredient to a matrix of the form

$$\begin{pmatrix} C & 0 \\ R & T \end{pmatrix}$$

where C and T are square matrices. Otherwise, the matrix is called *irreducible*. An irreducible matrix is called *primitive* if there exists a finite constant $k \in \mathbb{N}$, such that its k th power is positive. A nonnegative matrix is said to be *stochastic* if all its row sums are 1. A stochastic matrix is termed *stable* if it has identical rows and it is called *column allowable* if each column contains at least one positive entry. \square

Theorem 6 (Iosifescu 1980, p. 95) *Each transition matrix of a homogeneous finite Markov chain is cogredient to one of the following normal forms:*

$$P_1 = \begin{pmatrix} C_1 & & & \\ & C_2 & & \\ & & \ddots & \\ & & & C_r \end{pmatrix} \quad \text{or} \quad P_2 = \begin{pmatrix} C_1 & & & \\ & C_2 & & \\ & & \ddots & \\ R_1 & R_2 & \cdots & R_r & T \end{pmatrix}$$

where submatrices C_1, \dots, C_r with $r \geq 1$ are irreducible and at least one of the submatrices R_i is nonzero. \square

Submatrix T in matrix P_2 above is associated with the *transient set* of the state space, whereas the matrices C_i are associated with the non-transient or *recurrent states*. Each matrix C_i represents a *recurrent set* of states that cannot be left once it is entered – as is evident from the structure of the normal forms above. In contrast, transient states can be visited several times but as soon as there is a transition to a recurrent state, the transient state will never be visited again. Thus, a transient state will be left forever with probability 1 after a finite number of iterations. Not surprisingly, recurrent and transient sets will play a different role in the limit behavior of a homogeneous finite Markov chain. Before presenting basic limit theorems, some terms have to be introduced:

Definition 8 Let P be the transition matrix of a homogeneous finite Markov chain. A distribution p on the states of the Markov chain is called a *stationary distribution* if $pP = p$ and a *limit distribution* if the limit $p = p^{(0)} \lim_{t \rightarrow \infty} P^t$ does exists. \square

Definition 9 Let $E = \mathcal{X}^\mu$ be the state space of a Markov chain representing some EA with population size $\mu \in \mathbb{N}$, finite search space \mathcal{X} and objective function $f: \mathcal{X} \rightarrow \mathbb{R}$ to be minimized. A state $x^* \in E$ is said to be *optimal* if there exists an $i = 1, \dots, \mu$ such that $f(x_i^*) = f^*$. The set E^* of all optimal states is termed the *optimal state set*. \square

Now some limit theorems may be stated:

Theorem 7 (Iosifescu 1980, p. 126; Seneta 1981, p. 127) *Let P be a reducible stochastic matrix, where $C: m \times m$ is a primitive stochastic matrix and $R, T \neq 0$. Then*

$$P^\infty = \lim_{k \rightarrow \infty} P^k = \lim_{k \rightarrow \infty} \begin{pmatrix} C^k & 0 \\ \sum_{i=0}^{k-1} T^i R C^{k-i} & T^k \end{pmatrix} = \begin{pmatrix} C^\infty & 0 \\ R_\infty & 0 \end{pmatrix}$$

is a stable stochastic matrix with $P^\infty = 1' p^{(\infty)}$, where $p^{(\infty)} = p^{(0)} P^\infty$ is unique regardless of the initial distribution, and $p^{(\infty)}$ satisfies: $p_i^{(\infty)} > 0$ for $1 \leq i \leq m$ and $p_i^{(\infty)} = 0$ for $m < i \leq n$. The rate of approach to the limit is geometric. \square

Thanks to this general result, it is a straightforward exercise to formulate general limit theorems for EAs: Suppose that the transition matrix for some EA is reducible and that all associated recurrent states are optimal states, that is, $E_r \subseteq E^*$. In this case

$$\mathbb{P}\{Z_t \leq \varepsilon\} = \mathbb{P}\{F_t^* - f^* \leq \varepsilon\} = \mathbb{P}\{X_t \in E^*\} \geq \mathbb{P}\{X_t \in E_r\} = \sum_{i \in E_r} p_i^{(t)}$$

holds for sufficiently small $\varepsilon > 0$. Since $\mathbb{P}\{Z_t > \varepsilon\} = 1 - \mathbb{P}\{Z_t \leq \varepsilon\}$ one obtains

$$\mathbb{P}\{Z_t > \varepsilon\} \leq 1 - \mathbb{P}\{X_t \in E_r\} = 1 - \sum_{i \in E_r} p_i^{(t)} \quad (6)$$

so that the limit of \bullet Eq. 6 is

$$\lim_{t \rightarrow \infty} \mathbb{P}\{Z_t > \varepsilon\} \leq 1 - \sum_{i \in E_r} p_i^{(\infty)} = 1 - 1 = 0 \quad (7)$$

which is the defining condition for convergence to the optimum in probability. Thanks to \bullet Theorem 7, it is known that $p_i^{(\infty)} > 0$ if and only if $i \in E_r$. Therefore, the sum in \bullet Eq. 7 accumulates to 1. Moreover, \bullet Theorem 7 states that the approach to the limit is geometric. Since a geometric series (of probabilities < 1) converges to a finite limit, one obtains the stronger mode of complete convergence to the optimum. Convergence in mean follows from \bullet Theorem 2 since $Z_t \xrightarrow{P} 0$ and the value of Z_t must be bounded in a finite state space. As a result, we have proven:

Theorem 8 (Rudolph 1997a, p. 119) *If the transition matrix of an EA is reducible and the set of recurrent states is a subset of the set E^* of optimal states, then the EA converges completely and in mean to the global optimum regardless of the initial distribution.* \square

The above theorem is formulated as a sufficient criterion. Actually, it is also a necessary criterion as shown in Agapie (1998a) and it also holds for stochastic processes more general than Markov chains (“random systems with complete connections”).

Theorem 9 (Necessary and sufficient condition; see Agapie (1998b, 2007)) *A time-homogeneous EA with finite state space converges completely and in mean to the global optimum if and only if all recurrent states are optimal or, equivalently, if and only if all nonoptimal states are transient.* \square

Another general result from Markov chain theory can be exploited for a different limit result regarding EAs.

Theorem 10 (Iosifescu 1980, p. 123; Seneta 1981, p. 119) *Let P be a primitive stochastic matrix. Then P^k converges as $k \rightarrow \infty$ to a positive stable stochastic matrix $P^\infty = 1' p^{(\infty)}$, where the limit distribution $p^{(\infty)} = p^{(0)} \cdot \lim_{k \rightarrow \infty} P^k = p^{(0)} P^\infty$ has nonzero entries and is unique regardless of the initial distribution. The rate of approach to the limit is geometric. Moreover, the limit distribution is identical with the unique stationary distribution and is given by the solution $p^{(\infty)}$ of the system of linear equations $p^{(\infty)} P = p^{(\infty)}$, $p^{(\infty)} 1' = 1$.* \square

The weakest version of stochastic convergence considered here is convergence in probability. If this mode of convergence cannot be verified, then all stronger modes are precluded automatically. Now, suppose that the transition matrix for some EA is primitive. Owing to \bullet Theorem 10, one obtains

$$\mathbb{P}\{Z_t > \varepsilon\} = 1 - \mathbb{P}\{X_t \in E^*\} = 1 - \sum_{i \in E^*} p_i^{(t)} \quad (8)$$

for sufficiently small $\varepsilon > 0$. Note that $E^* \subset E$ unless the objective function is constant. Therefore

$$\sum_{i \in E^*} p_i^{(\infty)} < 1 \quad \text{and finally} \quad \lim_{t \rightarrow \infty} \mathbb{P}\{Z_t > \varepsilon\} = 1 - \sum_{i \in E^*} p_i^{(\infty)} > 0$$

falsifying convergence in probability. Thus, we have proven:

Theorem 11 (Rudolph 1997a, p. 120) *If the transition matrix of an EA is primitive, then the EA does not converge in probability to the global optimum regardless of the initial distribution.* \square

At this point, it should be noted that the property of visiting an optimal state with probability one is a precondition for convergence but that the additional property of convergence itself does not automatically indicate any advantage with respect to finding the global solution. Since all practical implementations of EAs store the best solution they have ever seen, it suffices to visit some optimal state only once. Therefore, EAs with primitive transition matrix also can be useful optimization algorithms.

Theorem 12 (Rudolph 1997a, p. 120) *Let $(X_t)_{t \geq 0}$ be the sequence of populations generated by an EA with primitive transition matrix. Then the stochastic sequence $(V_t)_{t \geq 0}$ of best objective function values ever found defined by $V_t = \min\{F_\tau^*: \tau = 0, 1, \dots, t\}$ converges completely and in mean to the global optimum.* \square

As shown above, the convergence properties of EAs can be determined by a closer look at their transition matrices. Since the transition matrix can be decomposed into a product of intermediate transition matrices, each of them describing the probabilistic behavior of a single evolutionary operator (like crossover, mutation, and selection), it is sufficient to map each evolutionary operator on a transition matrix and to look at their products. For this purpose, the following result is useful.

Lemma 2 (Rudolph 1994b, p. 97; Agapie 1998a, p. 188) *Let I, D, C, P, A be stochastic matrices where I is irreducible, D is diagonal-positive, C column-allowable, P positive, and A arbitrary. Then the products*

- (a) *AP and PC are positive,*
- (b) *ID and DI are irreducible.*

\square

After initialization, the typical cycle of an EA consists of selection for reproduction (transition matrix R), recombination / crossover (transition matrix C), mutation (transition matrix M), and selection for survival (transition matrix S). As a consequence, the transition matrix P of the EA can be decomposed via $P = R \cdot C \cdot M \cdot S$.

For example, the transition matrix M of standard bit-flipping mutation on binary strings has the entries $m_{ij} = p_m^{\|\bar{i}-\bar{j}\|}(1 - p_m^{n\mu - \|\bar{i}-\bar{j}\|})$, where $\|\cdot\|$ denotes the Hamming norm on binary strings. The entries m_{ij} are all positive if the mutation probability p_m is greater than 0 and less than 1. In this case, transition matrix M for mutation is positive. Now, \bullet Lemma 2(a) reveals, that regardless of the structure of the ‘crossover matrix’ C , the product $C \cdot M$ is positive. The same \bullet Lemma 2(a) implies that no structure of the transition matrix of selection for reproduction R can avoid that the product $R \cdot C \cdot M$ is positive. Finally, \bullet Lemma 2(a) also

ensures that the entire transition matrix P is positive, if the transition matrix of selection for survival S is column allowable. Since every positive matrix is also primitive, one may invoke \bullet Theorem 11 to conclude that the EA will not converge to the optimum. Results of this type have been proven in Davis and Principe (1993) and Rudolph (1994b) for proportional survival selection: the corresponding transition matrix S is in fact column-allowable. The same result can be achieved for other popular selection operations.

Lemma 3 (Rudolph 1997a, p. 122) *If the selection operation chooses from offspring only then the associated transition matrix is column-allowable for proportional selection, q -ary tournament selection, q -fold binary tournament selection, and truncation selection.* \square

The structure of matrix S is decisive for convergence if the preceding operations are represented by a positive matrix. If the selection operation is made *elitist* then the product of all transition matrices becomes a reducible matrix as required by \bullet Theorem 8. A proof of this result specialized to proportional selection was sketched in Eiben et al. (1991) and rigorously elaborated in Suzuki (1993, 1995). Elitism can be realized by at least two different mechanisms:

1. Select from parents and offspring and ensure that the best individual is selected with probability 1.
2. Select from offspring only; if the best selected individual is worse than the best parent, then replace the worst selected individual with the best parent.

Selection operations that can be used for elitism of the first kind are stochastic universal sampling, q -fold binary tournament selection, and truncation selection. Selection operations with elitism of the second kind can use almost any selection method in the first phase since the reinjection of the best parent, if necessary, in the second phase guarantees convergence once an optimum has been found for the first time.

Theorem 13 (Rudolph 1997a, p. 125) *If the transition matrix for mutation is positive and the selection operation for survival is elitist, then the EA converges completely and in mean to the optimum regardless of the initial distribution.* \square

There are at least two reasons for nonconvergence: The optimum cannot be found with probability 1 or the optimum is as often lost as it is found. The second case can be eliminated by elitism. Then it remains to make sure that the optimum is found with probability 1.

Without elitism, the mutation operator usually causes loss of an optimum previously found. Therefore, early research (prior to 1990) recommended to switch off mutation. But this maneuver does not help, since an EA without mutation may converge to an arbitrary (possibly nonoptimal) uniform population (Fogel 1994) that cannot be altered by crossover / recombination and selection. Nevertheless, for special cases (Rudolph 2005), it is possible to specify the probability (< 1) of finding the optimum depending on the population and problem size.

But elitism is not a CONDITIO SINE QUA NON to achieve convergence to the optimum for Markovian optimization algorithms with time-homogeneous transition matrices and finite state space (Agapie 1998b) as demonstrated in the next example.

Example 3 (Convergence to optimum without elitism) The idea for the example is taken from Agapie (1998b). Consider the threshold accepting (TA) algorithm (Dueck and

Algorithm 1 Threshold accepting

```

initialize individual  $X_0 \in \mathbb{B}^n$ 
set  $t = 0$ 
repeat
     $Y_t = X_t \oplus B_t$ 
    if  $f(Y_t) \leq f(X_t) + T$  then
         $X_{t+1} = Y_t$ 
    else
         $X_{t+1} = X_t$ 
    end if
    increment  $t$ 

```

Scheuer 1990) as shown in [Algorithm 1](#), where B_0, B_1, \dots is an i.i.d. sequence of Bernoulli random vectors (i.e., each component is an independent Bernoulli random variable with parameter $0 < p_m < 1$), $T > 0$ is a positive threshold and \oplus denotes the bitwise exclusive-or operation. Notice that TA would be exactly an *elitist* (1+1)-EA if $T = 0$.

Evidently, TA can reach every point in the search space in one step, it accepts every improvement and also worse points, provided the difference does not exceed the threshold $T > 0$. Since worse points may be accepted, the method is not elitist. If this algorithm is applied to the minimization of the objective function

$$f(x) = \begin{cases} 0, & \text{if } x = 0 \\ 1 + \sum_{i=1}^n x_i, & \text{otherwise} \end{cases}$$

with threshold $T = 1$, then it is easily seen that TA may move to states with worse objective function value. TA may cycle freely through all states/solutions, but as soon as it hits the optimum at $x = 0$, then this state cannot be left since the difference in objective function values to all other solutions is larger than $T = 1$. Thus, only the optimal state 0 is recurrent whereas all other states are transient. Now, [Theorem 9](#) ensures convergence to the optimum without elitism. \square

The rigorous analysis in terms of Markov chain theory and the insight gained thereby has led to the conclusion that powerful sufficient conditions concerning properties and combinations of variation and selection operators can be derived already via simple basic probabilistic arguments (Rudolph 1998b) without using results from Markov chain theory: Let $(x_1, x_2, \dots, x_\mu) \in \mathcal{X}^\mu$ denote the population of μ parents. An offspring is produced as follows: At first, ρ parents are selected to serve as mates for the recombination process. This operation is denoted by

$$\text{mat} : \mathcal{X}^\mu \rightarrow \mathcal{X}^\rho$$

where $2 \leq \rho \leq \mu$. These individuals are then recombined by the procedure

$$\text{reco} : \mathcal{X}^\rho \rightarrow \mathcal{X}$$

yielding a preliminary offspring. Finally, a mutation via

$$\text{mut} : \mathcal{X} \rightarrow \mathcal{X}$$

yields the complete offspring. After all λ offspring have been produced in this manner, the selection procedure

$$\text{sel} : \mathcal{X}^k \rightarrow X^\mu$$

decides which offspring and possibly parents ($k \geq \mu$) will serve as the new parents in the next iteration. Thus, a single iteration of the evolutionary algorithm can be described as follows:

$$\forall i \in \{1, \dots, \lambda\} : x'_i = \text{mut}(\text{reco}(\text{mat}(x_1, \dots, x_\lambda)))$$

$$(y_1, \dots, y_\mu) = \begin{cases} \text{sel}(x_{\pi(1)}, \dots, x_{\pi(q)}, x'_1, \dots, x'_\lambda) & (\text{parents and offspring}) \\ \text{sel}(x'_1, \dots, x'_\lambda) & (\text{only offspring}) \end{cases}$$

where $1 \leq q \leq \mu$ and $\pi(1), \dots, \pi(\mu)$ is a permutation of the indices $1, \dots, n$ such that $f(x_{\pi(1)}) \leq f(x_{\pi(2)}) \leq \dots \leq f(x_{\pi(\mu)})$. This formulation includes selection methods that choose from the offspring and a subset of parents under the restriction that the best parent is a member of this subset.

After this operational description of evolutionary algorithms, one is in the position of defining some assumptions about the properties of the variation and selection operators:

- (A1) $\forall x \in (x_1, \dots, x_\mu) : P\{x \in \text{reco}(\text{mat}(x_1, \dots, x_\mu))\} \geq \delta_r > 0$.
- (A2) For every pair $x, y \in \mathcal{X}$ there exists a finite path x_1, x_2, \dots, x_τ of pairwise distinct points with $x_1 = x$ and $x_\tau = y$ such that $P\{x_{i+1} = \text{mut}(x_i)\} \geq \delta_m > 0$ for all $i = 1, \dots, \tau - 1$.
- (A2') For every pair $x, y \in \mathcal{X}$ holds $P\{y = \text{mut}(x)\} \geq \delta_m > 0$.
- (A3) $\forall x \in (x_1, \dots, x_k) : P\{x \in \text{sel}(x_1, \dots, x_k)\} \geq \delta_s > 0$.
- (A4) Let $v_k^*(x_1, \dots, x_k) = \max\{f(x_i) : i = 1, \dots, k\}$ denote the best fitness value within a population of k individuals ($k \geq \mu$). The selection method fulfills the condition

$$P\{v_\mu^*(\text{sel}(x_1, \dots, x_k)) = v_k^*(x_1, \dots, x_k)\} = 1.$$

Assumption (A₁) means that every parent may be selected for mating and is not altered by recombination with minimum probability $\delta_r > 0$. Assumption (A₂) ensures that every individual can be changed to an arbitrary other individual by a finite number of successive mutations, whereas assumption (A_{2'}) asserts the same but within a single mutation. Assumption (A₃) guarantees that every individual competing for survival may survive with minimum probability $\delta_s > 0$, whereas assumption (A₄) makes sure that the best individual among the competitors in the selection process will survive with probability one.

These assumptions lead to a nonzero lower bound $\delta_r \cdot \delta_m \cdot \delta_s > 0$ on the probability to move from some nonoptimal state to some other state on the finite path of length τ to the optimum. Repetitions of this argument lead to the lower bound $\delta = (\delta_r \cdot \delta_m \cdot \delta_s)^\tau > 0$ to reach an optimal state within τ iterations. Consequently, the probability that the optimal state has not been found after $t \geq \tau$ iterations is at most $(1 - \delta)^{\lfloor t/\tau \rfloor}$ converging to zero geometrically fast as $t \rightarrow \infty$. This proves complete and mean convergence to the optimum.

Theorem 14 (Rudolph 1998b) *If either assumption (A_{2'}) or the assumptions (A₁), (A₂), and (A₃) are valid then the evolutionary algorithm visits the global optimum after a finite number of iterations with probability one, regardless of the initialization. If assumption (A₄) is valid additionally and the selection method chooses from parents as well as offspring then the evolutionary algorithm converges completely and in mean to the global optimum regardless of the initialization.* \square

Finally, note that there are a number of general convergence conditions for EAs (see, e.g., He and Kang 1999 or He and Yu 2001) that are only of limited value since they are not further refined to properties of the variation and selection operations. It is not clear if such a refinement can lead to an extension of the results known currently.

4.1.2 Innumerable State Space

The convergence theory of probabilistic optimization methods resembling a $(1+1)$ -EA with $\mathcal{X} = \mathbb{R}^n$ and time-homogeneous transitions was established in Devroye (1976), Oppel and Hohenbichler (1978), Born (1978), Solis and Wets (1981), Pintér (1984), and others between the mid-1970s and mid-1980s. The proofs in each of these publications exploited the algorithms' property that the parent of the next generation cannot be worse than the current one, that is, it is guaranteed by the construction of the algorithms that the stochastic sequence $(Z_t : t \geq 0)$ is *monotonically* decreasing. As a consequence, $(Z_t : t \geq 0)$ is a nonnegative supermartingale that converges w.p.1 to a finite limit. Before summarizing the convergence results, some regularity conditions must be proclaimed: For all objective functions $f: \mathbb{R}^n \rightarrow \mathbb{R}$ holds

- (R₁) $f^* > -\infty$ and
- (R₂) the set $\mathcal{X}_\varepsilon^* = \bigcup_{x^* \in \mathcal{X}^*} \mathcal{V}_\varepsilon(x^*)$ has nonzero measure for all $\varepsilon > 0$,

where $\mathcal{V}_\varepsilon(x^*) = \{x \in \mathcal{X}: \|x - x^*\| \leq \varepsilon\}$ denotes the ε -vicinity around $x^* \in \mathcal{X}$. The first condition ensures the existence of an optimum whereas the second condition makes sure that at least one optimum is not an isolated point. The set $\mathcal{X}_\varepsilon^*$ is the set of ε -optimal solutions whereas $E_\varepsilon^* = \{x \in E \mid \exists i = 1, \dots, \mu : x_i \in \mathcal{X}_\varepsilon^*\}$ is the set of ε -optimal states.

Let $F^*(x) = \min\{f(x_1), f(x_2), \dots, f(x_\mu)\}$ denote the best objective function value in a state / population $x \in E$ consisting of μ individuals. Then the set $B(y) = \{x \in E : F^*(x) < F^*(y)\}$ is simply the set of states (populations) that contain an individual better than the best individual in population $y \in E$.

Theorem 15 (Rudolph 1997a, p. 201) *Let $X_0 \in E$ be the initial population of some elitist EA and let $P_c(x, A)$, $P_m(x, A)$ and $P_s(x, A)$ denote the transition probability functions of the crossover, mutation and selection operator, respectively, with $x \in E$ and $A \subseteq E$. If the conditions*

- (a) $\exists \delta_c > 0 : \forall x \in E : P_c(x, B(x)) \geq \delta_c$,
- (b) $\exists \delta_m > 0 : \forall x \in B(X_0) : P_m(x, E_\varepsilon^*) \geq \delta_m$ and
- (c) $\exists \delta_s > 0 : \forall x \in E : P_s(x, B(x)) \geq \delta_s$

hold simultaneously, then for every $\varepsilon > 0$, there exists a $\delta > 0$ such that $P_{cms}(x, A_\varepsilon) \geq \delta > 0$ for every $x \in B(X_0)$ and the EA converges completely and in mean to the optimum. \square

The next result refines \bullet Theorem 15 to specific variation and selection operators.

Theorem 16 (Rudolph 1997a, p. 204f) *A population-based EA with elitism that uses*

- (a) *multipoint, parametrized uniform, parametrized intermediate, averaging, gene pool, or parametrized intermediate gene pool recombination (with replacement);*

- (b) a mutation distribution with support \mathbb{R}^n and (possibly varying) positive definite covariance matrix whose spectrum stays in a fixed interval $[a, b] \subset \mathbb{R}_+$;
- (c) standard proportional, proportional SUS, q -ary tournament, q -fold binary tournament or top μ selection

converges completely and in mean to the global minimum of an objective function $f: \mathbb{R}^n \rightarrow \mathbb{R}$ from the set $\{f \in F : f(x) \rightarrow \infty \text{ as } \|x\| \rightarrow \infty\}$. \square

EAs with search space $\mathcal{X} = \mathbb{R}^n$ can converge to the optimum even without elitism – but only for special classes of problems (Rudolph 1994a, 1997b,a) (e.g., (L, Q) -convex functions) and where the mutation distribution is scaled proportionally to the length of the gradient at the current position. If this kind of information is available, then it is possible to apply general convergence results for supermartingales like \bullet Theorem 4, which is specialized to EAs below.

Theorem 17 (Rudolph 1997b) Let $(X_t : t \geq 0)$ be the sequence of populations generated by some evolutionary algorithm and let F_t^* denote the best objective function value of the population at generation $t \geq 0$. If $E[Z_t] < \infty$ and

$$E[Z_{t+1} | X_t, X_{t-1}, \dots, X_0] \leq c_t Z_t \quad w.p.1 \quad (9)$$

where $Z_t = F_t^* - f^*$ and $c_t \in [0, 1]$ for all $t \geq 0$ such that the infinite product of the c_t converges to zero, then the evolutionary algorithm converges in mean and with probability 1 to the global minimum of the objective function $f(\cdot)$. \square

Convergence properties of EAs applied to constrained “corridor model” function in the context of Markov chains can be found in Agapie and Agapie (2007).

4.2 Time-Inhomogeneous Transitions

4.2.1 Finite Search Space

Apparently, the development of EAs with time-inhomogeneous transitions was motivated by the observation that, owing to \bullet Theorem 11, many popular EAs do not converge but there existed many convergence proofs for the simulated annealing (SA) optimization algorithm (Hajek 1988; Aarts and Korst 1989; Haario and Saksman 1991) that is endowed with time-inhomogeneous transitions. As a consequence, the EAs were modified to meet the convergence conditions of the SA convergence theory (Davis 1991; Mahfoud and Goldberg 1992, 1995; Adler 1993). A more general point of view was the starting point in Suzuki (1998) and Schmitt et al. (1998) and Schmitt (2001, 2004). They exploited the theory of time-inhomogeneous Markov chains. Before summarizing their results, the case of elitist selection and time-dependent variation operators is considered.

Theorem 18 Let $(X_t)_{t \geq 0}$ be the stochastic sequence generated by an EA with elitist selection and a transition probability function $P_t(x, A)$ with $A \subseteq E$, that only describes the sequence of variation operations. If $P_t(x, E^*) \geq \delta_t$ for all $x \in E \setminus E^*$ and

$$\sum_{t=0}^{\infty} \delta_t = \infty$$

then the EA converges w.p.1 and in mean to the optimum as $t \rightarrow \infty$.

Proof Since the selection operation is elitist, it suffices to show that the probability of not transitioning to some optimal state in E^* converges to zero as $t \rightarrow \infty$. This probability can be bounded via

$$\mathbb{P}\{X_t \notin E^*\} \leq \prod_{k=1}^t (1 - \delta_k) \quad (10)$$

In order to prove that the product above converges to zero, the following equivalence (see \blacklozenge Sect. 2.3.1 in Rudolph (1999)) is useful:

$$\prod_{t=1}^{\infty} (1 - \delta_t) \rightarrow 0 \Leftrightarrow \sum_{t=1}^{\infty} \log\left(\frac{1}{1 - \delta_t}\right) \rightarrow \infty$$

From the series expansion of the logarithm, it is clear that

$$\log\left(\frac{1}{1 - z}\right) > z$$

for all $z \in (0,1)$. As a consequence, since

$$\sum_{t=1}^{\infty} \log\left(\frac{1}{1 - \delta_t}\right) > \sum_{t=1}^{\infty} \delta_t = \infty$$

is fulfilled by the precondition of the theorem, it has been proven that the product in \blacklozenge Eq. 10 converges to zero. This proves convergence in probability. Since selection is elitist, the associated sequence of best function values $(Z_t)_{t \geq 0}$ is a nonnegative supermartingale that converges w.p.1 to some finite limit. Since the limits of w.p.1 convergence and convergence in probability must be unique, one obtains w.p.1 convergence to the optimum. Moreover, elitism implies that $\mathbb{E}[Z_t] \leq \mathbb{E}[Z_0]$ for all $t \geq 0$, which in turn implies convergence in mean. \square

It remains to show how the preconditions of the theorem can be fulfilled. For example, use an arbitrary crossover operation and the usual bit-flipping mutation with time-variant mutation probability $p_m(t)$ with $p_m(t) \rightarrow 0$ as $t \rightarrow \infty$. It suffices to bound the probability that just one individual becomes optimal. Evidently, if $p_m(t) \leq 1/2$ then

$$\delta_t \geq \min\{p_m^h(t) \cdot (1 - p_m(t))^{n-h} : h = 0, 1, \dots, n\} = p_m^n(t)$$

The inequality below

$$\sum_{t=1}^{\infty} \delta_t \geq \sum_{t=1}^{\infty} p_m^n(t) = \infty$$

is fulfilled if, for example, $p_m(t) = (t + 1)^{-1/n}$. Thus, the mutation probability must not decrease too fast.

If elitism is dropped from the list of preconditions, then at least the selection operation must become time-dependent. The detailed studies in Schmitt et al. (1998) and Schmitt (2001, 2004) contain numerous results in this direction, which are dared to be summarized as follows:

Theorem 19 (Schmitt 2004) *An EA that uses*

- (a) *scaled mutations with $p_m(t) \sim t^{-\kappa_m/n}$ where $\kappa_m \in (0,1]$,*

- (b) gene-lottery or regular pair-wise crossover with $p_c(t) \sim p_m^{\kappa_c}(t)$ where $\kappa_c \in (0,1]$,
 (c) proportional selection using exponentiation $f^{g(t)}$ with $g(t) \sim \log(t+1)$

converges w.p.1 and in mean to the optimum. \square

4.2.2 Innumerable Search Space

Time-inhomogeneous transitions in innumerable search spaces have not been studied for EAs, apparently. If crossover is arbitrary, mutation is chosen as in [Theorem 16\(b\)](#), and selection is done as in simulated annealing, then the SA convergence theory can be applied directly ([Bélisle 1992](#)). Moreover, there is a simple analogon to the result with elitist selection in finite state space.

Corollary 1 (to [Theorem 18](#)) Let $(X_t)_{t \geq 0}$ be the stochastic sequence generated by an EA with elitist selection and a transition probability function $P_t(x,A)$ with $A \subseteq E$, that only describes the sequence of variation operations. If $P_t(x, E_e^*) \geq \delta_t$ for all $x \in E \setminus E_e^*$ and

$$\sum_{t=0}^{\infty} \delta_t = \infty$$

then the EA converges w.p.1 and in mean to the optimum as $t \rightarrow \infty$.

Proof Set $\mathcal{X} = \mathbb{R}^n$, $E = \mathbb{R}^{n \times \mu}$, replace E by E_e^* in the statement and proof of [Theorem 18](#). \square

4.3 Self-Adaptive Transitions

Self-adaptation in EAs may appear in various forms. Here, the focus is on the special case where each individual consists of the position in the search space $\mathcal{X} = \mathbb{R}^n$ and a number of (strategy) parameters that determine the shape of the mutation distribution.

In the simplest case, an individual might be described by the pair (x, σ) with $x \in \mathcal{X}$ and $\sigma > 0$. A mutation of an individual can be realized by $y = x + \sigma Z$ where Z is a standard multinormally distributed random vector. If σ is altered depending on the outcome y , then σ has been self-adapted. Evidently, in the context of Markov chains, this is the time-homogeneous case – but the state space becomes larger since the strategy parameters also must be represented in the state space. This fact makes the analysis considerably more complicated. Therefore, the presentation of results for self-adaptive transitions have been separated from the case with fixed, externally set strategy parameters (like mutation and crossover probability).

General results known by now are rare. One may apply [Theorem 16](#) to ensure convergence to the optimum for any kind of self-adaptive mutation mechanisms as long as it is guaranteed that the support is \mathbb{R}^n and that the eigenvalues of the covariance matrices stay in a fixed compact interval in \mathbb{R}_+ . In this case, one can derive a lower positive bound on the probability to hit \mathcal{X}_e^* in every iteration, which implies convergence to the optimum. The situation changes if the spectrum of the eigenvalues has no restrictions, that is, the smallest eigenvalue may approach zero and the largest eigenvalue may grow arbitrarily large. This may happen for Rechenberg's $\frac{1}{2}$ -rule. It has been shown ([Rudolph 1999, 2001b](#)) that the probability

to escape from local, non-global optima under the $\frac{1}{5}$ -rule is strictly less than 1. As a consequence, convergence to the optimum is not guaranteed. But if the objective function only has a single local and therefore global optimum, then the $\frac{1}{5}$ -rule leads to convergence w. p.1 where the approximation error is decreased geometrically fast (Jägersküpper 2006, 2007). If selection only accepts points whose objective function value is at least $\varepsilon > 0$ better than the parent, and if the $\frac{1}{5}$ -rule is changed such that the variance is increased for success probabilities far below $\frac{1}{5}$ (say, below $\frac{1}{20}$), then convergence to the optimum can be asserted (Greenwood and Zhu 2001).

In case of mutative self-adaptation of the variance of the mutation distributions, only unimodal or spherical objective functions have been analyzed. Whereas the proof in Semenov and Terkel (2003) via stochastic Lyapunov functions/supermartingales has a theoretical gap (a lemma is “proven” by experiments), the proof in Bienvenüe and Francois (2003) and Auger (2004) via Markov processes ensure convergence to the optimum for objective function $f(x) = x^2$ with $x \in \mathbb{R}$.

5 Further Reading and Open Questions

The previous section tacitly assumed that EAs are applied to optimization problems with a single objective function. But optimization under multiple objectives is the *de facto* standard for practical applications nowadays. Unfortunately, the convergence theory cannot easily be transferred from single- to multi-objective EAs. First, the solution in multi-objective optimization (via the *a posteriori* approach) is not a single point but a set of points (the Pareto set) whose objective function values (the Pareto front) are only partially ordered. Second, it is unclear how to assess the quality of the Pareto front approximation: all points should be close to the true Pareto front, the points should represent the entire Pareto front, and they should be “somehow uniformly distributed” over the Pareto front approximation. Early work (Rudolph 1998a, c) proved that at least a single individual approaches the Pareto front (convergence of the scalar Euclidean distance between point and set). Subsequent work (Hanne 1999; Rudolph and Agapie 2000; Rudolph 2001a) proved that the entire population approaches the Pareto front (convergence of the distance between sets). But nothing was shown with respect to the spread of the individuals and their distribution: it was possible that the entire population converges to a single point of the Pareto front. The problem was that the quality of an approximation is described by three objectives. As a consequence, achieving a good Pareto front approximation is itself a multi-objective problem with possibly incomparable approximations. A good compromise was a scalar measure termed *dominated hypervolume* or *S-metric* (Zitzler and Thiele 1998), as it rewards closeness to the Pareto front, it rewards a good spread, and it rewards a certain distributions of solutions (the more curved the Pareto front the more solutions). Although this scalar measure is appealing for formulating convergence results, it seems to be quite difficult to accomplish this goal. Moreover, it is quite likely that only those multi-objective EAs can reach an approximation with best S-metric value that deploy the S-metric indicator in the selection process for deciding which individuals should be integrated or discarded from the approximation. For such an EA, it was shown that it can converge to an approximation with best S-metric value if the true Pareto front is linear (Beume et al. 2009) but there are counter-examples for nonlinear Pareto fronts (Zitzler et al. 2008). Another approach was initiated in Schütze et al. (2007) by proving approximation properties of the Pareto archive of multi-objective EAs.

Summing up, the convergence theory for self-adaptive transitions and for multi-objective EAs is not complete yet. Challenging open questions that await answers are the convergence properties of model-assisted EAs, the covariance matrix adaptation evolution strategy (CMA-ES), and other related methods.

Abstract

This chapter provides an overview of the branch of evolutionary computation that is dedicated to solving optimization problems with multiple objective functions. On the one hand, it sketches the foundations of multiobjective optimization and discusses general approaches to deal with multiple optimization criteria. On the other hand, it summarizes algorithmic concepts that are employed when designing corresponding search methods and briefly comments on the issue of performance assessment. This chapter concludes with a summary of the main application areas of evolutionary multiobjective optimization, namely, learning/decision making and multiobjectivization.

1 Introduction

The term *evolutionary multiobjective optimization* – EMO for short – refers to the employment of evolutionary algorithms to search problems involving multiple optimization criteria. This type of problem arises naturally in practical applications, simply because there is usually no such thing as a ‘free lunch’: in embedded system design high performance comes along with high cost, in structural engineering the level of stability is related to the weight of the construction, and in machine learning the accuracy of a model needs to be traded off against the model complexity. There exist countless other examples, many of which are not restricted to a pair of counteracting criteria but a multitude of competing objectives. The design of a car, for instance, requires many aspects to be taken into account, be it driving characteristics, cost, environmental sustainability, or more subjective criteria such as comfort and appearance. One may argue that the multiobjective case represents the *normal* situation in reality, while the single-objective case is rather an exception.

Example 1 Consider the following knapsack problem, a classical combinatorial optimization problem. Given is a set $\{1, \dots, l\}$ of items and with each item i a corresponding weight $w_i \in \mathbb{R}^+$ and a corresponding profit $p_i \in \mathbb{R}^+$ is associated. The goal is to identify a subset S of the items that (i) maximizes the overall profit $f_p(S)$ and (ii) minimizes the overall weight $f_w(S)$ where

$$f_p(S) = \sum_{i \in S} p_i \quad (1)$$

$$f_w(S) = \sum_{i \in S} w_i \quad (2)$$

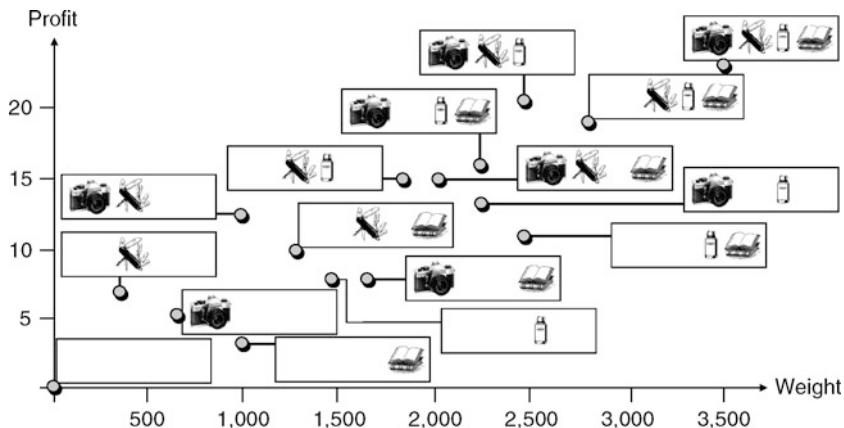

are the corresponding objective functions.  [Figure 1](#) illustrates a problem instance with four items.

It is obvious that with the knapsack problem, in general, both objectives cannot be achieved at the same time: maximum profit means all items need to be selected, minimum weight is obtained by choosing none of the items. In between these extremes, several compromise solutions may emerge, each of them representing a particular trade-off of profit versus weight. Classically, this problem is approached by transforming the weight objective into a constraint, that is,

$$\begin{aligned} & \text{argmax}_{S \subseteq \{1, \dots, l\}} f_p(S) \\ & \text{subject to} \quad f_w(S) \leq w_{\max} \end{aligned} \quad (3)$$

Fig. 1

Example of a knapsack problem instance with four items: (1) a camera with profit $p_1 = 5$ and weight $w_1 = 750$, (2) a pocket knife with profit $p_2 = 7$ and weight $w_2 = 300$, (3) a thermos flask with profit $p_3 = 8$ and weight $w_3 = 1,500$, and (4) a book with profit $p_4 = 3$ and weight $w_4 = 1,000$. All possible solutions are plotted with respect to their objective function values.

where w_{\max} is a fixed weight limit. This is one way to handle scenarios with multiple objectives, but various others exist.

The field of *Multiple Criteria Decision Making (MCDM)* explicitly addresses these issues and can be defined as (Steuer and Miettinen 2008)

- ▶ the study of methods and procedures by which concerns about multiple conflicting criteria can be formally incorporated into the management planning process.

In this sense, EMO can be regarded as a branch of MCDM (as well as it can be considered a branch of evolutionary computation) where evolutionary algorithms and other randomized search heuristics are the methods of choice. From a historical perspective, though, MCDM has been – until recently – mainly devoted to exact optimization techniques such as linear programming, while the first EMO studies pursued a specific MCDM approach, namely to find a *set* of suitable compromise solutions. Meanwhile, the boundaries between these communities have blurred, but still the large majority of papers dedicated to EMO is related to approximating the set of optimal compromise solutions, as will be detailed later.

This chapter is an attempt to summarize 25 years of EMO research from a unified point of view. The focus is on general concepts, and therefore the following overview does not lay claim to completeness, with respect to both specific research topics and publications in the field. Readers interested in a detailed discussion of specific algorithms, a complete historical overview, and an extensive collection of references may consult, for example, the textbooks by Deb (2001) and Coello Coello et al. (2007).

2 Fundamental Concepts

Before different ways on how to approach scenarios with multiple optimization criteria and how to design evolutionary algorithms for this purpose are discussed, some basic notions and reflections on multiobjective optimization will be presented in general.

2.1 Multiobjective Optimization Problems

Roughly speaking, optimization stands for the task of identifying within a set of solutions one solution that is best (or close to best). The set of potential solutions is denoted as *decision space*, in the following represented by the symbol X , and its elements are denoted as decision vectors – or simply solutions. Sometimes, the terms “decision space” and “search space” are used interchangeably, although here a subtle differentiation will be made: the search space is the space a concrete evolutionary algorithm operates on; it can be different from the decision space, which is part of the formal description of the optimization problem.

In order to define what “best” means, all solutions are evaluated by means of objective functions on the basis of which they can be compared. Without loss of generality, here it is assumed that an objective function f returns a real value, that is, $f: X \mapsto \mathbb{R}$, although the codomain could be any set. In single-objective optimization, there is just one objective function, while in the multiobjective case there are several ones, say f_1, \dots, f_n . These functions form a vector function $\mathbf{f} = (f_1, \dots, f_n)$ that assigns each decision vector a real vector, or *objective vector* in general. The objective vector contains the function values for all n objective functions and is an element of the so-called objective space Z , here $Z = \mathbb{R}^n$. Therefore, $\mathbf{f}: X \mapsto Z$ provides the mapping from the decision space to the objective space.

Finally, a binary relation \leqslant specifies an order on the objective space, which completes the formal description of the optimization problem. The minimum requirement for this relation is usually that it is a partial order, that is, reflexive, antisymmetric, and transitive. (A binary relation \leq over a set Y is (1) reflexive iff $a \leq a$ for all $a \in Y$, (2) antisymmetric iff $(a \leq b \wedge b \leq a) \Rightarrow (a = b)$ for all $a, b \in Y$, and (3) transitive iff $(a \leq b \wedge b \leq c) \Rightarrow (a \leq c)$ holds for all a, b , and c in Y .) In the single-objective case, usually the relations \leq (minimization) or \geq (maximization) are employed, in the multiobjective case, the choice is less obvious and will be discussed later in [Sect. 2.2](#). Now given \leqslant , two solutions $\mathbf{a}, \mathbf{b} \in X$ can be compared by first determining the objective vectors $\mathbf{f}(\mathbf{a}), \mathbf{f}(\mathbf{b})$ and then checking whether $\mathbf{f}(\mathbf{a}) \leqslant \mathbf{f}(\mathbf{b})$ or vice versa. The goal is to find a solution \mathbf{a} that is best, that is, there is no better solution; formally

$$\forall \mathbf{b} \in X : (\mathbf{f}(\mathbf{b}) \leqslant \mathbf{f}(\mathbf{a})) \Rightarrow (\mathbf{f}(\mathbf{a}) \leqslant \mathbf{f}(\mathbf{b})) \quad (4)$$

Furthermore, constraints may be involved, each of which can be regarded as a special case of an objective function in combination with a prespecified threshold. Fulfilling a constraint means the given threshold must not be exceeded; here it is assumed that a constraint is given by a constraint function $g: X \mapsto \mathbb{R}$, which needs to be equal to or less than 0 to be met. Several such constraint functions may be considered simultaneously, and a decision vector fulfilling the constraints is called a *feasible solution*; the entirety of the feasible solutions constitutes the *feasible set*. Hence, the optimization goal can be restated as finding the best among the feasible solutions.

Example 2 In the classical formulation of the knapsack problem according to [Eq. 3](#), the decision space is $X = \{0, 1\}^l$, the objective space is $Z = \mathbb{R}$, the objective function is $\mathbf{f} = (f_1)$ with $f_1(a_1, \dots, a_l) = \sum_{1 \leq i \leq l} a_i \cdot p_b$, the considered relation is \geq , and the weight is included using a constraint function $g(a_1, \dots, a_l) = (\sum_{1 \leq i \leq l} a_i \cdot w_i) - w_{\max}$ where w_{\max} is the weight limit. For the example in [Fig. 1](#), the feasible set is $X_f = \{(0, 0, 0, 0), (0, 1, 0, 0), (1, 0, 0, 0)\}$ when setting the weight limit to $w_{\max} = 800$.

In summary, a (multiobjective) optimization scenario can be described as follows:

- A *multiobjective optimization problem* is defined by a 5-tuple $(X, Z, \mathbf{f}, \mathbf{g}, \leq)$ where
 - X is the decision space,
 - $Z = \mathbb{R}^n$ is the objective space,
 - $\mathbf{f} = (f_1, \dots, f_n)$ is a vector-valued function consisting of n objective functions $f_i: X \mapsto \mathbb{R}$,
 - $\mathbf{g} = (g_1, \dots, g_m)$ is a vector-valued function consisting of m constraint functions $g_j: X \mapsto \mathbb{R}$, and
 - $\leq \subseteq Z \times Z$ is a binary relation on the objective space.

The goal is to identify a decision vector $\mathbf{a} \in X$ such that (i) for all $1 \leq i \leq m$ holds $g_i(\mathbf{a}) \leq 0$ and (ii) for all $\mathbf{b} \in X$ holds $\mathbf{f}(\mathbf{b}) \leq \mathbf{f}(\mathbf{a}) \Rightarrow \mathbf{f}(\mathbf{a}) \leq \mathbf{f}(\mathbf{b})$.

The question of how to define the relation \leq in a multiobjective context has remained open so far – it will be addressed next.

2.2 Preference Relations and Optimality

Consider the biobjective knapsack problem from ◉ [Example 1](#). Given two item sets S and T and the corresponding objective vectors (p_S, w_S) and (p_T, w_T) , when can S be said to be superior to T ? Clearly, if S is better in both objectives, that is, it provides higher profit at lower weight, then it can be called overall superior. Even if S is only better in one objective, while there is no difference in the other, for example, $p_S > p_T \wedge w_S = w_T$ then one may make the same statement. That means, in general, that a solution is better than another if the former is (1) not worse in any objective and (2) better in at least one objective. These considerations lead to a concept known as *(weak) Pareto dominance*.

- An objective vector $\mathbf{u} = (u_1, \dots, u_n)$ *weakly Pareto dominates* an objective vector $\mathbf{v} = (v_1, \dots, v_n)$, written as $\mathbf{u} \leq_{par} \mathbf{v}$, iff

$$\forall 1 \leq i \leq n : u_i \leq v_i \quad (5)$$

assuming without loss of generality that all objectives are to be minimized. Furthermore, iff

$$\mathbf{u} \leq_{par} \mathbf{v} \wedge \mathbf{v} \not\leq_{par} \mathbf{u} \quad (6)$$

then \mathbf{u} is said to *(Pareto) dominate* \mathbf{v} .

Using this concept, an objective vector is said to be better than another if the former weakly Pareto dominates the latter, while the latter does not weakly Pareto dominate the former. Pareto dominance represents the most commonly accepted notion of superiority in a multiobjective setting since it is a canonical generalization of the single-objective case. However, dominance may be defined in other ways as well, see ◉ [Fig. 2](#). One example is the so-called (additive) epsilon dominance (Helbig and Pateva 1994; Laumanns et al. 2002; Zitzler et al. 2003) defined as

$$\mathbf{u} \leq_{\varepsilon} \mathbf{v} : \Leftrightarrow \forall 1 \leq i \leq n : u_i \leq v_i + \varepsilon \quad (7)$$

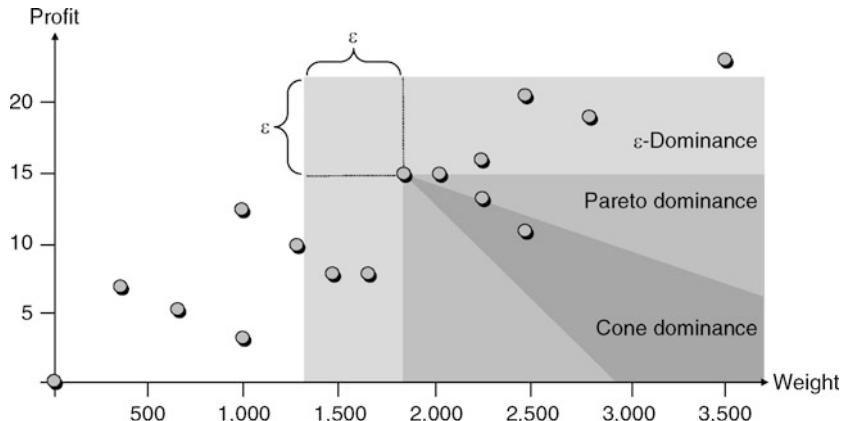

which is a relaxation of Pareto dominance using an additive term $\varepsilon \in \mathbb{R}$; another possibility is to use ordering cones (Miettinen 1999; Ehrgott 2005).

The dominance relation \leq structures the objective space and thereby implicitly induces a corresponding *preference relation* \preccurlyeq on the decision space with

$$\mathbf{a} \preccurlyeq \mathbf{b} : \Leftrightarrow \mathbf{f}(\mathbf{a}) \leq \mathbf{f}(\mathbf{b}) \quad (8)$$

Fig. 2

Illustration of three dominance concepts based on the example shown in [Fig. 1](#): Pareto dominance, epsilon dominance, and dominance using a pointed convex cone. The figure shows for a particular objective vector the area that is dominated in the objective space. Note that the considered knapsack problem is a mixed minimization/maximization problem and that, therefore, the definitions of the dominance relations change accordingly.

In this sense, the triple (f, Z, \leq) can be regarded as an indirect means to construct an order on X . In principle, there are also other ways to define this order and therefore the term preference relation will be used in a general notion:

- A *preference relation* $\preccurlyeq \subseteq X \times X$ is a binary relation on the decision space that is both reflexive and transitive, that is, \preccurlyeq is a preorder.

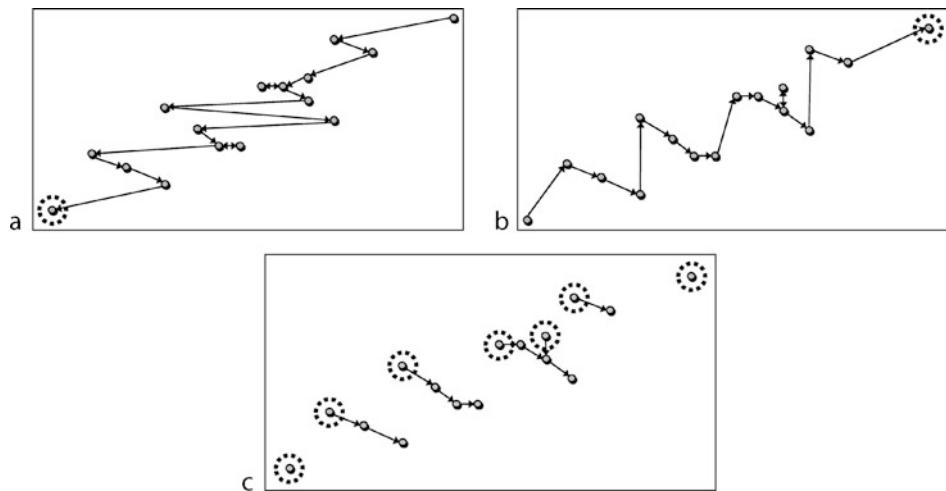

Note that there is an important difference between the relation $\leq \subseteq Z \times Z$ and the corresponding preference relation $\preccurlyeq \subseteq X \times X$. Since two different decision vectors may be mapped to the same objective vector, antisymmetry is not guaranteed, that is, from $\mathbf{a} \preccurlyeq \mathbf{b} \wedge \mathbf{b} \preccurlyeq \mathbf{a}$ it cannot be inferred that $\mathbf{a} = \mathbf{b}$. Hence, \preccurlyeq is usually only a preorder, while \leq is a partial order.

The above considerations hold for the single-objective as well as the multiobjective case. What is now the difference between these cases? To illustrate this, a graphical representation of a preference relation is helpful. The idea is to interpret the pair (X, \preccurlyeq) as a graph where X stands for the nodes and $\preccurlyeq \subseteq X \times X$ defines the edges: there is a directed edge from node $\mathbf{a} \in X$ to node $\mathbf{b} \in X$ iff $\mathbf{a} \preccurlyeq \mathbf{b}$. Such a graph will be denoted as a *relation graph*. For better visualization and to make the representation more compact, both reflexive edges and edges that can be inferred through the transitivity property will be omitted in the graphical rendering in the following.

Example 3 [Figure 3](#) depicts three relation graphs for the knapsack problem instance defined by [Fig. 1](#). For all graphs, weak Pareto dominance is the underlying dominance relation, but each time a different set of objectives is considered; the resulting preference relations are denoted as $\preccurlyeq_{par}^{f_w}$ (only weight is taken into account), $\preccurlyeq_{par}^{f_p}$ (only profit is taken into account), and $\preccurlyeq_{par}^{f_p, f_w}$ (biobjective case).

Fig. 3

Relation graphs for the knapsack problem considering (a) $(X, \preccurlyeq_{par}^{f_w})$, (b) $(X, \preccurlyeq_{par}^{f_p})$, and (c) $(X, \preccurlyeq_{par}^{f_p, f_w})$. The optimal solutions are marked by dotted circles.

As can be seen from Fig. 3, in the case of $n = 1$ (only a single objective is considered), the resulting graph represents a chain – a chain means that any two solutions $\mathbf{a}, \mathbf{b} \in X$ are *comparable*, that is, it holds either $\mathbf{a} \preccurlyeq \mathbf{b}$ or $\mathbf{b} \preccurlyeq \mathbf{a}$ (or both). In other words: the preference relation \preccurlyeq is a total preorder. (A relation $\leq \subseteq Y \times Y$ is total if for all $a, b \in Y$ holds $(a \leq b) \vee (b \leq a)$.) When $n > 1$, then there may be some solution pairs \mathbf{a}, \mathbf{b} for which neither $\mathbf{a} \preccurlyeq \mathbf{b}$ nor $\mathbf{b} \preccurlyeq \mathbf{a}$ holds, see Fig. 3c; in such a situation, \mathbf{a} and \mathbf{b} are denoted as *incomparable*. Among a set of incomparable solutions – a so-called *antichain* – no solution is preferable a priori unless further preference information is provided.

If several optimal solutions exist that are incomparable to each other, then multiple optima emerge in the objective space – a situation that is particular to multiobjective settings. In general, every solution for which no better solution exists is an optimal solution, cf. Sect. 2.1; in order theory, such a solution is denoted as a minimal element.

- The *minimal set* of a preordered set (Y, \leq) is defined as

$$\text{Min}(Y, \leq) := \{a \in Y \mid \forall b \in Y : b \leq a \Rightarrow a \leq b\} \quad (9)$$

The elements of $\text{Min}(Y, \leq)$ are denoted as *minimal elements*.

If we denote the situation $\mathbf{a} \preccurlyeq \mathbf{b} \wedge \mathbf{b} \not\preccurlyeq \mathbf{a}$ as “ \mathbf{a} dominates \mathbf{b} ,” then the minimal elements are those not dominated by others, that is, the *nondominated* ones. Whenever weak Pareto dominance is the underlying dominance relation, then the minimal elements of (X, \preccurlyeq_{par}) are called *Pareto optimal* and the entirety of the minimal elements is also known as *Pareto-optimal set*. The corresponding elements of the objective space are also called *Pareto-optimal*, while the set of Pareto-optimal objective vectors constitutes the *Pareto-optimal front*. The Pareto-optimal front may contain fewer elements than the Pareto-optimal set since decision vectors can be mapped to identical objective vectors.

In the example shown in Fig. 3, the Pareto-optimal sets for the single-objective scenarios (a) and (b) contain one solution, while in the biobjective setting (c) seven incomparable

solutions are included in the Pareto-optimal set. Note that, in principle, also in the case of a single objective, multiple Pareto optima may exist; however, they would not be incomparable and all Pareto-optimal solutions would be assigned the same objective function value. In the presence of multiple objectives, the Pareto-optimal set usually contains an antichain that reflects different trade-offs among the objectives.

2.3 Properties of the Pareto-Optimal Set

The Pareto-optimal set has different characteristics, each of which can have an impact on the optimization and the decision-making process. The most important aspects are the following:

Range: The ideal and the nadir objective vectors represent lower and upper bounds, respectively, on the objective function values of the Pareto-optimal set; knowledge of these points is not only helpful for decision making, but can also be important for interactive optimization procedures (Deb et al. 2006).

- ▶ Let X_p be the Pareto-optimal set of a multiobjective optimization problem. The *ideal point* $\underline{\mathbf{z}} = (\underline{z}_1, \dots, \underline{z}_n) \in \mathbb{R}^n$ of this problem is defined as

$$\underline{z}_i := \min_{\mathbf{a} \in X_p} f_i(\mathbf{a}) \quad (10)$$

and the *nadir point* $\bar{\mathbf{z}} = (\bar{z}_1, \dots, \bar{z}_n) \in \mathbb{R}^n$ is given by

$$\bar{z}_i := \max_{\mathbf{a} \in X_p} f_i(\mathbf{a}) \quad (11)$$

where all objectives are without loss of generality to be minimized.

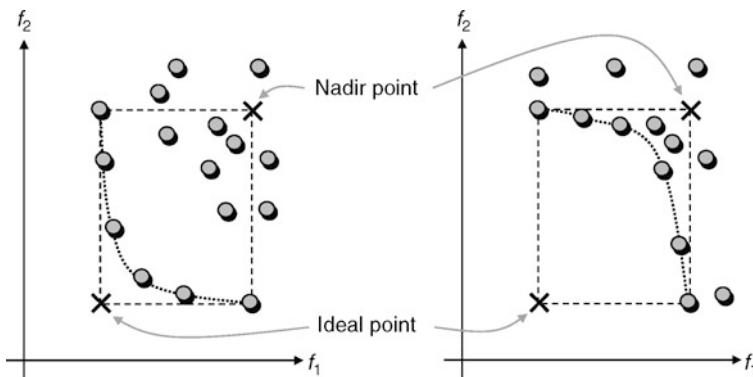

- [Figure 4](#) illustrates these concepts. If ideal point and nadir point are identical, then there is no conflict among the objectives and the Pareto-optimal front consists solely of the ideal point.

Shape: The image of the Pareto optima in the objective space can have different shapes that reflect how strongly objectives are in agreement or disagreement. For instance, the curvature of the front may be convex ([Fig. 4](#), left), concave ([Fig. 4](#), right), or contain convex and non-convex parts. If the decision space is continuous, then connectedness is another property that characterizes the front shape, see Ehrgott (2005). Roughly speaking, connectedness means that there are no gaps in the Pareto-optimal front; in the biobjective case, this implies that the Pareto-optimal objective vectors constitute a line. Pareto-optimal sets that are not contiguous in the objective space can cause difficulties with respect to both decision making and search.

Size: Whenever the underlying optimization problem is discrete, that is, the feasible set is finite as with the knapsack problem from [Example 1](#), the number of the Pareto-optimal solutions can become a crucial issue. If the size of the minimal set is rather small, one may aim at generating the entire Pareto-optimal set using appropriate optimization methods. The larger the set of Pareto optima becomes, the less feasible is this approach. If the number of Pareto-optimal solutions is even exponential in the input size, for example, exponential in the number of items with the knapsack problem, then the problem of identifying the Pareto-optimal set becomes intractable in general. This is the case with many multiobjective variants of combinatorial optimization problems like the multiobjective shortest path problem and the traveling salesperson problem (Ehrgott 2005).

Fig. 4

Two hypothetical minimization problems with two objectives each. The ideal points and the nadir points are identical, whereas the shapes of the Pareto-optimal fronts – visually emphasized by the auxiliary dotted lines – are different. The conflict between the objectives is weaker on the left side.

It is interesting to note that the size is related to the number of objectives involved. Winkler (1985) proved that the number of incomparable solution pairs increases, if further randomly generated objectives are added. Thereby, on the one hand the Pareto-optimal front may become larger and on the other hand the power of the dominance relation to guide the search may diminish – these are the main arguments that various researchers (Fonseca and Fleming 1995; Horn 1997; Deb 2001; Coello Coello et al. 2002; Fleming et al. 2005; Wagner et al. 2007), list in favor of the assumption that the search becomes harder the more objectives are involved. In the extreme case, when all solution pairs are incomparable, the Pareto-optimal set equals the decision space.

Computational complexity: The difficulty of combinatorial optimization problems can be expressed in terms of complexity classes. For instance, an NP-hard problem is assumed to be not solvable generally in polynomial time. In this context, it is remarkable that a polynomially solvable single-objective problem can become NP-hard when considering the multiobjective variant of it. One example is the shortest path problem: already in the bicriterion case it is, in general, not possible to identify *any* Pareto-optimal solution in polynomial time, while the extremes of the Pareto-optimal front can be computed efficiently, see Ehrhart (2005).

Several other properties could be listed here, for example, necessary and sufficient conditions for Pareto optimality. Optimality conditions are not discussed here, since the focus is on black-box optimization; the interested reader is referred to Miettinen (1999) instead.

3 Approaches to Multiobjective Optimization

In solving an optimization problem, one is interested in choosing the best solution for the application at hand. However, in the presence of multiple objectives the problem is usually underspecified. Whenever there is a conflict between the objectives and different trade-offs emerge, the choice of a Pareto-optimal decision vector is not arbitrary. Otherwise, it would be

sufficient to consider one of the objectives only and to generate an extreme point. It matters which Pareto-optimum is selected, and what is missing is the specification of this choice. But what is then the use of formulating a problem in terms of multiple optimization criteria?

The answer is that a multiobjective model can be regarded as an intermediate step. A *decision-making process* is necessary to add the information that is not contained in the model yet. To this end, a *decision maker*, a person or a group of persons responsible for the selection, expresses his or her preferences based on experience, expert knowledge, or further insights into the application. The preference information is then used to carry out a problem transformation that – usually – leads to a fully specified model where a total preorder on the decision space is induced. In principle, two types of problem transformations can be distinguished: (1) solution-oriented ones that leave the decision space unchanged, and (2) set-oriented ones where the approximation of the entire Pareto-optimal set is the focus.

3.1 Solution-Oriented Problem Transformations

Taking the sum of the objective function values is a commonly known method to reformulate a multiobjective problem in terms of a single objective problem. It is one example for handling multiple objectives by means of *scalarization* where a scalarizing function represents the new optimization criterion.

- ▶ A *scalarizing function* s is a function $s : Z \mapsto \mathbb{R}$ that maps each objective vector $(u_1, \dots, u_n) \in Z$ to a real value $s(u_1, \dots, u_n) \in \mathbb{R}$.

Typically, each scalarization relies on individual parameters by which the trade-off between the original objectives can be specified. The transformed problem is then given by $(X, \mathbb{R}, s \circ f, g, \leq)$, assuming that the scalarizing function is to be minimized. Three selected functions will be briefly presented here, more detailed discussions and other techniques can be found in Miettinen (1999) and Ehrgott (2005).

Weighted Sum Method: The scalarizing function is given by

$$s_W(u_1, \dots, u_n) := \sum_{1 \leq i \leq n} w_i u_i \quad (12)$$

where $w_1, \dots, w_n \in \mathbb{R}^+$ are the scalarization parameters that assign each objective a positive weight; typically, the weights sum up to 1. If all weights are greater than 0, then each optimal solution of the transformed problem is also a Pareto-optimal solution of the original multiobjective problem. The opposite does not hold in general, that is, in certain cases, there exists no weight combination such that a specific Pareto-optimal solution is also an optimal solution of the transformed problem (Ehrgott 2005).

Tchebycheff Method: This technique considers the distance to a reference point $(z_1, \dots, z_k) \in Z$ using an l_∞ -norm

$$s_T(u_1, \dots, u_n) := \max_{1 \leq i \leq n} w_i (u_i - z_i) \quad (13)$$

where $w_1, \dots, w_n \in \mathbb{R}^+$ are the weights as before with $\sum_{1 \leq i \leq n} w_i = 1$. Here, for every Pareto-optimal solution a corresponding weight combination exists, but not all minimal elements of the transformed problem are Pareto-optimal in the common sense. The reference point stands for an objective vector that the decision maker would like to achieve and that may represent an ideal choice.

ϵ -Constraint Method: Here, one of the objective functions is selected for optimization, without loss of generality the last, leading to the scalarizing function

$$s_C(u_1, \dots, u_n) := u_n \quad (14)$$

while the remaining objectives are converted into constraints, that is, $n - 1$ additional constraints $g_{m+i}(\mathbf{a}) = f_i(\mathbf{a}) - \varepsilon_i$ for $1 \leq i < n$ are created where $\varepsilon_i \in \mathbb{R}$ represents the threshold for the i th objective. (The constraints are added to the existing ones, that is, $\mathbf{g} = (g_1, \dots, g_m, g_{m+1}, \dots, g_{m+n-1})$.) The optimal solution to an ϵ -constraint problem is not necessarily Pareto-optimal with respect to the original problem, but any Pareto-optimal solution can be found by solving multiple ϵ -constraint transformations (Miettinen 1999; Laumanns et al. 2006).

Besides scalarization techniques, another possibility to totally order the decision space is to exchange the relation \leqslant of the multiobjective problem $(X, Z, \mathbf{f}, \mathbf{g}, \leqslant)$ under consideration. A lexicographic order \leqslant_{lex} , for instance, is a total order that encodes a ranking of the objectives

$$(u_1, \dots, u_n) \leqslant_{lex} (v_1, \dots, v_n) : \Leftrightarrow \exists 1 \leq i \leq n : (\forall 1 \leq j \leq i : u_j = v_j) \wedge (i = n \vee u_{i+1} < v_{i+1}) \quad (15)$$

with $(u_1, \dots, u_n), (v_1, \dots, v_n) \in \mathbb{R}^n$. The principle is that the objectives are considered one by one according to the ranking: the first objective where the objective values differ between two solutions decides which solution is better. Note that by renumbering the objectives, different rankings can be generated.

Independently of how exactly a solution-oriented problem transformation is carried out, the general idea is to refine the preference relation \preccurlyeq on the decision space such that all incomparable solutions become comparable, respectively, that \preccurlyeq becomes total. When considering the relation graph for (X, \preccurlyeq) , this mainly means that edges are inserted until a complete chain emerges; the edges represent additional knowledge or preferences that are specified by weights, constraint thresholds, objective rankings, etc., as sketched above. The resulting chain again should be a preference relation, \preccurlyeq_{ref} which should, to a certain extent, preserve the original preference relation. This can be formulated as follows:

- A relation $\preccurlyeq_{ref} \subseteq Y \times Y$ is a *refinement* of another relation $\preccurlyeq \subseteq Y \times Y$ iff

$$\forall a, b \in Y : a \preccurlyeq b \wedge b \not\preccurlyeq a \Rightarrow a \leqslant_{ref} b \wedge b \not\leqslant_{ref} a \quad (16)$$

and iff

$$\forall a, b \in Y : a \preccurlyeq b \wedge b \not\preccurlyeq a \Rightarrow a \leqslant_{ref} b \quad (17)$$

then \leqslant_{ref} is a *weak refinement* of \preccurlyeq .

For instance, the preference relations induced by the weighted sum approach, the Tchebycheff method, and lexicographic ordering are refinements of the Pareto dominance relation \preccurlyeq_{par} . That means if a $\mathbf{a} \in X$ dominates $\mathbf{b} \in X$, then \mathbf{a} is also better than \mathbf{b} with respect to the scalarizing function – in other words: dominance is preserved after the problem transformation. The ϵ -constraint method only represents a weak refinement of \preccurlyeq_{par} ; this guarantees that dominance is not violated, that is, whenever \mathbf{a} dominates \mathbf{b} , then \mathbf{a} is not worse than \mathbf{b} regarding the chosen objective. Other terms like (weak) *compatibility* (Hansen and Jaszkiewicz 1998), (weak) *Pareto compliance* (Zitzler et al. 2008a), or (strict) *monotonicity* (Miettinen 1999) are used as well in the literature to denote a (weak) refinement.

3.2 Set-Oriented Problem Transformations

Often, it is difficult to provide the preference information necessary for a solution-oriented problem transformation. Instead of specifying in advance which Pareto optimum is sought, an alternative is to generate the Pareto-optimal set and make a decision afterward on the basis of this knowledge. Since with most applications the identification of all Pareto-optimal solutions is infeasible, one is rather interested in approximating the Pareto-optimal set, that is, finding a suitable *set* of compromise solutions. In this case, one deals with a set problem where the decision space consists of all possible sets of solutions.

- ▶ For a multiobjective optimization problem $(X, Z, \mathbf{f}, \mathbf{g}, \leq)$, the associated *set problem* is given by $(\Psi, \Omega, F, \mathbf{G}, \leq)$ where
 - $\Psi = 2^X$ is the space of decision vector sets, that is, the powerset of X ,
 - $\Omega = 2^Z$ is the space of objective vector sets, that is, the powerset of Z ,
 - F is the extension of \mathbf{f} to sets, that is, $F(A) := \{\mathbf{f}(\mathbf{a}) : \mathbf{a} \in A\}$ for $A \in \Psi$,
 - $\mathbf{G} = (G_1, \dots, G_m)$ is the extension of \mathbf{g} to sets, that is, $G_i(A) := \max \{g_i(\mathbf{a}) : \mathbf{a} \in A\}$ for $1 \leq i \leq m$ and $A \in \Psi$, and
 - \leq extends \leq to sets where $A \leq B : \Leftrightarrow \forall \mathbf{b} \in B \exists \mathbf{a} \in A : \mathbf{a} \leq \mathbf{b}$.

The dominance relation \leq on sets represents a natural extension of a dominance relation \leq on solutions. It induces a corresponding *set preference relation* \preccurlyeq on the space Ψ of solution sets and therefore the terms comparability, incomparability, etc., also apply here. In the case of \preccurlyeq_{par} and the corresponding set preference relation \preccurlyeq_{par} , a solution set is also denoted as *Pareto set approximation*, and an optimal Pareto set approximation is one that contains for each Pareto-optimal objective vector a corresponding decision vector.

Example 4 Consider the knapsack problem and the four solution sets depicted in [Fig. 5](#): both A and B dominate C , D is incomparable to A , B , and C , and A and B are *indifferent*, that is, $A \preccurlyeq B \wedge B \preccurlyeq A$, with respect to Pareto dominance. Although A contains only Pareto-optimal solutions, it does not represent an optimal Pareto set approximation as the entire Pareto-optimal front is not covered.

It is important to note that the set problem resulting from the transformation is still underspecified – similarly to the original multiobjective problem – as usually incomparable Pareto set approximations exist. Again, preference information is required to impose a total preorder on Ψ ; however, the preferences are weaker and easier to specify than the ones needed for solution-oriented problem transformations. This is also the motivation for making the problem more complex by considering sets instead of single solutions (the size of Ψ is exponential in the size of X).

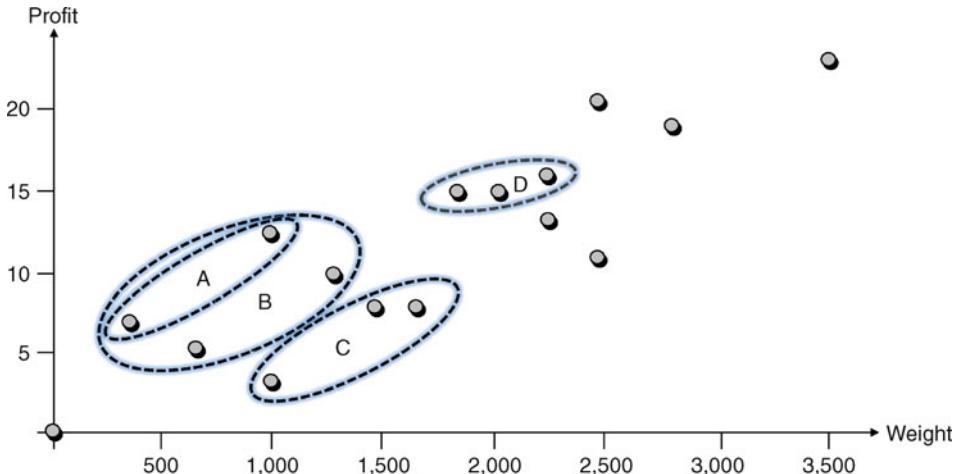

A common way to define a total preorder on Pareto set approximation relies on *quality indicators* – also denoted as performance measures or performance metrics – which represent functions that assign a tuple of solution sets a real value. Most popular are unary quality indicators:

- ▶ A (unary) *quality indicator* I is a function $I : \Psi \mapsto \mathbb{R}$ that assigns a Pareto set approximation a real value.

According to this definition, a unary quality indicator I can be regarded as a set quality measure or an objective function on solution sets. Therefore, it can be used to transform the

Fig. 5

Four Pareto set approximations for the knapsack problem instance from [Fig. 1](#).

set problem $(\Psi, \Omega, F, G, \leq)$ into a single-objective problem $(\Psi, \mathbb{R}, I, G, \leq)$ assuming that the indicator values are to be minimized.

Various quality indicators have been proposed in the literature, see Hansen and Jaszkiewicz (1998), Knowles and Corne (2002), and Zitzler et al. (2003); three selected unary indicators are briefly discussed here:

Hypervolume indicator: The *hypervolume indicator* I_H (Zitzler and Thiele 1998) gives the volume of the portion of the objective space that is weakly dominated by a specific Pareto set approximation. It can be formally defined as

$$I_H(A) := \lambda(H(A, R)) \quad (18)$$

where $R \subseteq Z$ is a given reference set of objective vectors,

$$H(A, R) := \{z \in Z : \exists \mathbf{a} \in A \exists \mathbf{r} \in R : \mathbf{f}(\mathbf{a}) \leq \mathbf{z} \leq \mathbf{r}\} \quad (19)$$

denotes the set of objective vectors that are enclosed by the front $F(A)$ given by A and the reference set R , and λ is the Lebesgue measure with $\lambda(H(A, R)) = \int_{\mathbb{R}^n} \mathbf{1}_{H(A,R)}(z) dz$ and $\mathbf{1}_{H(A,R)}$ being the characteristic function of $H(A, R)$. The hypervolume indicator is to be maximized. In [Fig. 6](#) on the left, the gray shaded area represents the set $H(A, R)$.

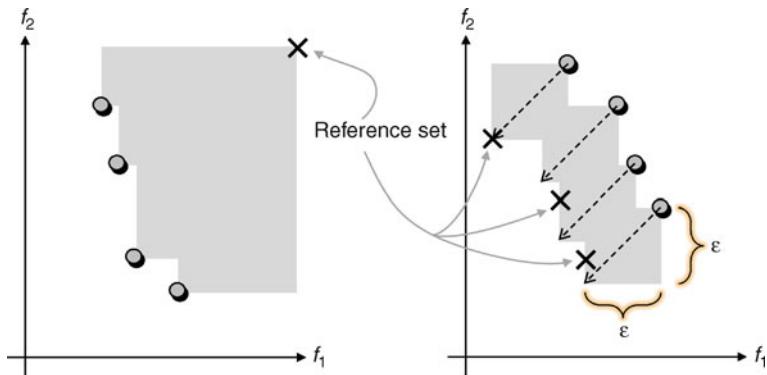

Epsilon indicator: The *epsilon indicator* I_ε (Zitzler et al. 2003) measures the objective-wise distance to a given reference set in the objective space; it is based on the concept of epsilon dominance

$$I_\varepsilon(A) := \inf_{\varepsilon} F(A) \leq_\varepsilon R \quad (20)$$

where \leq_ε is the natural extension of epsilon dominance from [Eq. 7](#) to solution sets with $A \leq_\varepsilon B : \Leftrightarrow \forall \mathbf{b} \in B \exists \mathbf{a} \in A : \mathbf{a} \leq_\varepsilon \mathbf{b}$. In other words, it provides the minimum ε such that the reference set is weakly Pareto dominated as illustrated in [Fig. 6](#) on the right; the smaller the value, the better the solution set.

Fig. 6

Illustration of the hypervolume indicator (left) and the (additive) epsilon indicator (right) for a minimization problems with two objectives each.

R indicators: The *R indicators* proposed in Hansen and Jaszkiewicz (1998) can be used to assess Pareto set approximations on the basis of scalarizing functions. The following quality indicator I_{RT} relies on the Tchebycheff method and requires multiple scalarizing functions $s_T^{(1)}, \dots, s_T^{(l)}$, each using a different combination of weights and the same reference point (z_1, \dots, z_n)

$$I_{RT}(A) := \frac{1}{l} \sum_{1 \leq i \leq l} \min_{\mathbf{a} \in A} s_T^{(i)}(\mathbf{a}) \quad (21)$$

It assumes the scalarizing functions to be minimized and simply takes the average over the best values per scalarizing function, which is to be minimized as well.

Often, it is beneficial to use a combination of quality indicators instead of a single indicator. One possibility is to define a sequence of indicators (I_1, \dots, I_l) and to apply a lexicographic order \leq_{lex} on \mathbb{R}^l , see Zitzler et al. (2008b). Thereby, the set problem $(\Psi, \Omega, F, G, \leq)$ is further transformed into the optimization problem $(\Psi, \mathbb{R}^l, (I_1, \dots, I_l), G, \leq_{lex})$. Such a hierarchy of indicators is especially useful for search as will be discussed in the next section.

Finally, note that the same considerations as with scalarizing functions apply to quality indicators: the induced set preference relation should be in accordance with the original set preference relation \leq . The relation \leq_H associated with the hypervolume indicator refines the set Pareto dominance relation \leq_{par} , while the relations \leq_ε and \leq_{RT} associated with I_ε and I_{RT} , respectively, only weakly refine \leq_{par} .

4 Search Algorithm Design

When designing a search algorithm for a multiobjective optimization problem, one either has to deal with a solution-oriented scenario or a set-oriented scenario – depending on the type of problem transformation chosen. In the first case, usually a single-objective problem emerges and the standard components of a black-box search method can be used. The latter case

requires specialized methods and by far most of the studies in the area of evolutionary multiobjective optimization focus on approximating the Pareto-optimal set. Therefore, in the following, a set-oriented problem transformation will be assumed and the corresponding algorithmic concepts that have been developed for this purpose will be discussed.

Note that the presentation focuses on evolutionary algorithms, although also other natural computing methods such as ant colony optimization and particle swarm optimization have been successfully applied to multiobjective scenarios. The general concepts are more or less the same, but the latter techniques may employ specialized procedures tailored to the algorithmic framework used.

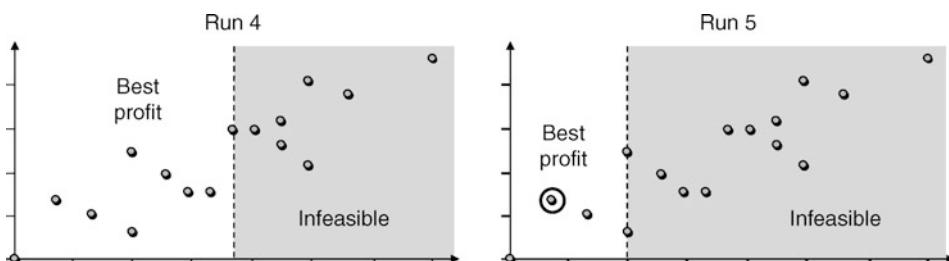

4.1 Types of Algorithms

One can distinguish between two types of search strategies to identify a suitable set of compromise solutions: the algorithms of the first category perform multiple single-objective runs, while the methods of the second category require only a single run. As to the multiple runs approach, consider, for example, the I_{RT} quality indicator from [Eq. 21](#) in combination with l Tchebycheff scalarizing functions $s_T^{(1)}, \dots, s_T^{(l)}$. For each scalarizing function $s_T^{(i)}$, a separate optimization run is carried out where the objective function f is $f = s_T^{(i)}$, that is, overall l runs are performed. Afterward, the best solutions found per run are combined to form a Pareto set approximation. A similar strategy can be devised on the basis of the ε -constraint method. First, the thresholds ε_i for the constraints that represent converted objective functions are set to ∞ , which means only the chosen objective is optimized. The best solution found is used to adapt the constraints, so that it falls into the infeasible region, and the next optimization run is carried out. This process is iterated until the feasible set equals the empty set. As before, the union of the best solutions per run form the approximation of the Pareto-optimal set. While for $n = 2$ this scheme is simple to implement as depicted in [Fig. 7](#), it becomes much more complex, if the number of optimization criteria is arbitrary, see Laumanns et al. ([2006](#)).

Most multiobjective evolutionary algorithms proposed in the literature are of the second type. Here, the population as a whole represents a Pareto set approximation and therefore a single run is sufficient. Taking this line of thought further, the successive application of mating selection, variation, and environmental selection aims at generating a new, better Pareto set

Fig. 7

Visualization of the multiple run strategy to approximate the Pareto-optimal set using the ε -constraint method. The figure shows for the knapsack problem and for two successive runs the current weight constraint and the best solution found.

approximation and therefore can be regarded as a multi-stage mutation operator on solution sets. From this perspective, a common multiobjective evolutionary algorithm implements a single-objective (1, 1)-strategy on solution sets with a clever mutation operator; this applies to almost all search strategies currently available. The idea of operating on a population of solution sets, that is, employing an evolutionary algorithm where each individual is a Pareto set approximation on its own and where possibly solution sets are recombined, has not gained much attention yet (end of 2008): there only exists a preliminary study (Bader et al. 2009) that fully addresses this issue, while some papers in the context of parallelism partially exploit this idea (Poloni 1995; Baita et al. 1995; Lee and Hajela 1996; Aherne et al. 1997; Sawai and Adachi 2000; Branke et al. 2004b; Mezmaz et al. 2006; Coello Coello et al. 2007). Thus, the potential of this multi-solution set strategy still needs to be explored.

4.2 Basic Algorithmic Concepts

The main difference between a single-objective evolutionary optimizer and a multiobjective one approximating the Pareto-optimal set lies in fitness assignment and selection, while variation has been treated similarly (and therefore is not discussed in the following). (Note that most recently (March 2009), specific set variation operators have been proposed (Bader et al. 2009; Voß et al. 2009).) The key question is how a better Pareto set approximation can be generated from the current population in a randomized fashion – independently of whether the search algorithm works with a single or multiple solution sets.

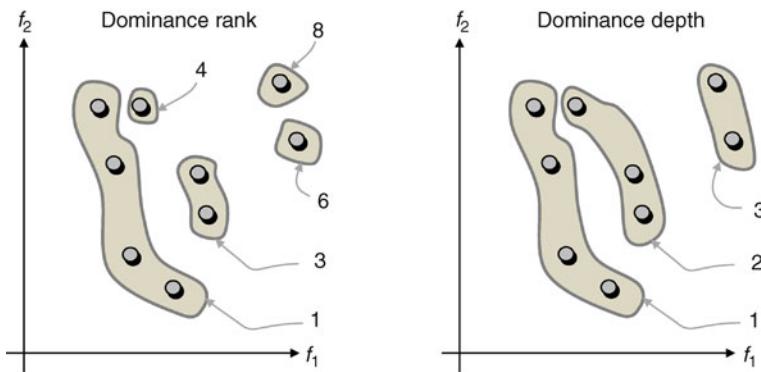

4.2.1 Fitness Assignment

One issue is to quantify the usefulness of a particular individual with regard to the entire population. The general idea behind most prevalent concepts is to assign fitness values respectively to rank the individuals according to the loss in quality of the Pareto set approximation that can be accounted to the removal of a particular individual. More specifically, the fitness of an individual $\mathbf{a} \in X$ is determined by taking the difference between the quality of the entire population P and the quality of the population without \mathbf{a} , for example, $fit_{\mathbf{a}} = I(P) - I(P \setminus \{\mathbf{a}\})$ where P is a multiset of decision vectors and I a unary quality indicator used for optimization. (Note that for reasons of simplicity, here individuals and decision vectors are not distinguished, although in practice usually a representation is required to encode decision vectors appropriately.)

A difficulty that arises is the fact that the set preference relation or the quality indicator used are usually insensitive to dominated population members. That means the quality of the population solely depends on the nondominated individuals. The consequence is that all dominated individuals are assigned a fitness of 0 when employing the above principle. For instance, the hypervolume indicator, which has become a popular measure for fitness assignment, does not change its value when dominated solutions are added to or removed from the solution set. The standard solution to this problem is to partition the population into nonoverlapping dominance classes that are organized in a hierarchy. Each class contains only mutually nondominating solutions, and the fitness values are then computed per dominance class. Furthermore, the individuals in the first class are considered superior to the second class, which in turn is better than the third class and so forth.

Fig. 8

Two different partitionings into dominance classes for a biobjective minimization problem. The numbers refer to the hierarchy of the dominance classes.

There exist different ways to create such a partitioning, Fig. 8 illustrates two popular schemes. The method of *dominance rank* (Fonseca and Fleming 1993) counts for each individual the number of population members that dominate it; this number gives the so-called dominance rank. All individuals with dominance rank 0 form the first dominance class, the second class consists of individuals with dominance rank 1, and so forth. Another method originally proposed in Goldberg (1989) and for the first time integrated in a multiobjective evolutionary algorithm by Deb and colleagues (Srinivas and Deb 1994; Deb et al. 2002a) uses the *dominance depth* – a strategy also known as nondominated sorting. Here, the minimal elements of the population form the first dominance class, that is, $\text{Min}(P, \leq_{\text{par}})$; the next class is represented by the minimal elements of the remaining population members, that is, $\text{Min}(P \setminus \text{Min}(P, \leq_{\text{par}}), \leq_{\text{par}})$, and the other classes are defined accordingly. Partitioning in terms of dominance depth has in comparison to dominance rank the additional property that classes with lower numbers dominate classes with higher numbers in the hierarchy.

As mentioned above, the fitness values, respectively, the ranking within each dominance class are determined using the underlying set measure or set preference relation. Density-based measures that resemble niching techniques like fitness sharing in single-objective evolutionary computation have been the most popular, particularly in the first decade of EMO. This approach usually relies on Euclidean distance in the objective space: it first computes the distances between all population members and on this basis then estimates the density around each individual. One example is the k th nearest neighbor method where k is a prespecified constant which is often set to 2. Here, the distance to the k th closest individual is taken as the density estimate for each population member and the individuals in each dominance class are then ranked in descending order of the density estimates (Zitzler et al. 2002). Many other techniques exist (Fonseca and Fleming 1993; Knowles and Corne 2000b; Deb et al. 2002a). All these techniques can be regarded as implementations of a specific quality indicator, I_D , which is based on Euclidean distance in the objective space. However, the problem with this type of indicator is that, in general, it does not represent a proper preorder as transitivity is violated (Knowles and Corne 2002; Zitzler et al. 2003, 2008b). This theoretical consideration can also be observed in practice: Euclidean distance-based multiobjective evolutionary algorithms tend to exhibit cyclic behavior, which means they do not progress after a certain point in time

(Laumanns et al. 2002). This can cause problems especially with applications involving many objective functions (Wagner et al. 2007).

The alternative to density-based fitness assignment is to directly use set preference relations or quality indicators that are preorders and (weak) refinements. In particular, the hypervolume indicator has been employed in this context since it provides a refinement of weak Pareto dominance and hence allows a fine-grained ranking of the individuals. Several hypervolume-based algorithms have been proposed (Emmerich et al. 2005; Igel et al. 2007; Zitzler et al. 2007) that all rely on the same principle: the population is first partitioned into dominance classes based on dominance depth and then for each dominance class the individuals are ranked according to their contribution to the overall hypervolume of the class. Precisely, the hypervolume contribution h_a of an individual a with respect to its dominance class A is given by

$$h_a = I_H(A) - I_H(A \setminus \{a\}) \quad (22)$$

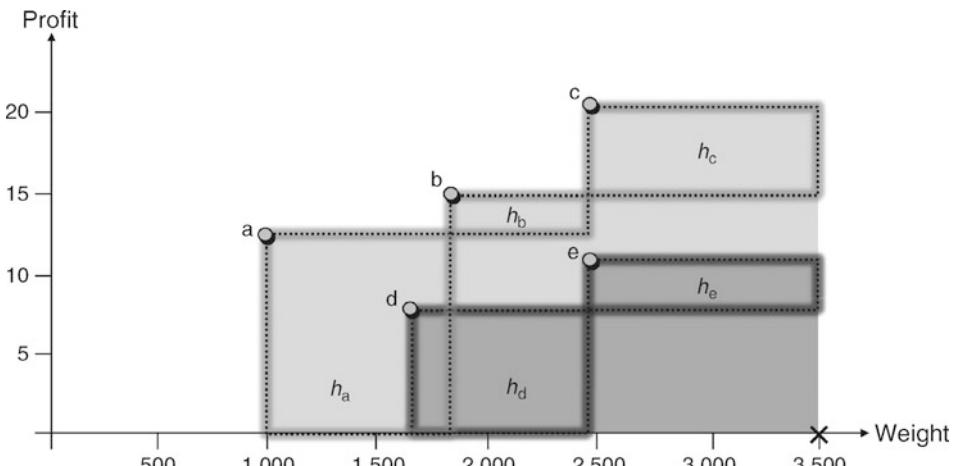

which equals the loss in hypervolume resulting from the removal of a .

Example 5 Consider the population in Fig. 9 consisting of five individuals. When using the hypervolume-based fitness assignment described above, the ranking of the individuals is a, c, b, d, e . The individuals a, b, c fall in the first dominance class A_1 and it holds $h_a > h_c > h_b$. The second dominance class A_2 contains the remaining population members where d contributes more to the overall hypervolume of A_2 than e , that is, $h_d > h_e$.

Unfortunately, the exact computation of the hypervolume values is computationally expensive (Bringmann and Friedrich 2008) and the available algorithms have a worst-case runtime complexity that is exponential in the number of objectives (Fonseca et al. 2006; Beume and Rudolph 2006). Therefore, different methods to speed up this computation have

Fig. 9

Hypervolume-based fitness assignment for a hypothetical population for the biobjective knapsack problem. The boxed areas represent the hypervolume contributions attributed to the specific individuals.

been proposed (Bradstreet et al. 2008; Bader et al. 2010) that enable hypervolume-based search also in high-dimensional objective spaces.

The majority of the proposed fitness assignment methods follows the principle sketched above, a combination of dominance-based partitioning and a quality indicator. It is interesting to note in this context that this scheme can be expressed in terms of a sequence of indicators as outlined in [Sect. 3.2](#). Regarding the example with the hypervolume indicator, let $I_H^{(i)}$ denote the indicator value of the i th dominance class A_i of a population P , that is, $I_H^{(i)}(P) := I_H(A_i)$. Then the fitness assignment procedure corresponds to a set preference relation induced by the sequence $(I_H^{(1)}, I_H^{(2)}, \dots, I_H^{(N)})$ of quality indicators where N is the population size. This idea can be extended to arbitrary set preference relations as proposed in Zitzler et al. (2008b).

Finally, also other fitness assignment variants exist that do not rely on a dominance-based partitioning (Schaffer 1985; Horn et al. 1994; Czyzak and Jaskiewicz 1998; Zitzler and Künzli 2004; Zitzler et al. 2008b). When, for instance, the quality indicator used is composed of scalarizing functions, the fitness values may be directly inferred from the scalarizing functions without further dominance checks.

4.2.2 Selection

The fitness values and the ranking of the individuals, respectively, provide the basis for mating selection and environmental selection.

Mating selection is often implemented in the same way as in single-objective evolutionary algorithms, although some concepts have been proposed that are different. For instance, Schaffer's vector evaluated genetic algorithm (Schaffer 1985) switches between the objectives during the mating selection phase, the niched pareto genetic algorithm by Horn et al. (1994) carries out dominance-based tournaments, and other approaches based on the weighted-sum method randomly choose weight combinations to determine the members of the mating pool (Ishibuchi and Murata 1996). These techniques can be regarded as randomized fitness assignment schemes; however, they are rather seldom used.

Environmental selection plays a much more important role in multiobjective search than mating selection. The first evolutionary methods for multiobjective optimization (Schaffer 1985; Fonseca and Fleming 1993; Srinivas and Deb 1994; Horn et al. 1994) used the standard genetic algorithm scheme where the offspring population entirely replaces the parent population (a comma strategy). However, when empirical studies demonstrated that elitism is of high importance when approximating the Pareto-optimal set (Zitzler and Thiele 1999; Knowles and Corne 2000b), the picture changed. Nowadays, most multiobjective search algorithms implement a plus strategy, that is, the best solutions from the union P^+ of parent population and offspring population are chosen for survival. This leads to a subset selection problem: from the N parents and M children a subset of N solutions needs to be determined that constitutes the next population. In the case of the hypervolume indicator for instance, one searches for a subset A with $|A| = N$ that has the largest hypervolume value among all subsets of size N , that is,

$$\forall B \subseteq P^+ : |B| = N \Rightarrow I_H(B) \leq I_H(A) \quad (23)$$

Determining the best subset can be computationally expensive, and often heuristic procedures are used instead. One strategy iteratively removes the worst solution from P^+ and updates the fitness values until the desired population size is reached (see Zitzler et al. 2002). Alternatively, one may remove the M worst solutions in a single step without intermediate fitness updates as,

for example, in Deb et al. (2002a); this strategy is faster, but also less accurate than the iterative approach.

The choice of the environmental selection scheme is also important for the convergence properties of a multiobjective optimizer as has been shown in Rudolph (1998, 2001), Rudolph and Agapie (2000), Laumanns et al. (2002), and Zitzler et al. (2008b). Therefore, sometimes a separate archive is maintained that stores the nondominated solutions (Knowles and Corne 2003a; Fieldsend et al. 2003). The archive may use a different selection scheme than the population; for instance, one can employ a strategy that ensures certain quality bounds (Laumanns et al. 2002).

4.3 Advanced Algorithmic Concepts

In the following, advanced concepts to integrate constraints, user preferences, and other types of optimizers are dealt with. The presentation is not exhaustive; for instance, other topics like uncertainty and robustness, which are of high practical relevance are not treated here. On the one hand, these issues can be addressed in the same manner as in single-objective optimization where various techniques have been developed (Jin and Branke 2005). On the other hand, the methodologies that have been specifically proposed in a multiobjective context (Hughes 2001; Teich 2001; Deb and Gupta 2006; Basseur and Zitzler 2006; Gaspar-Cunha and Covas 2008) form a relatively new area of research that is still maturing and does not provide a clear picture yet of potential standard concepts. Furthermore, specialized data structures and algorithms as well as parallelization schemes to speed up fitness assignment and selection are important when implementing a multiobjective optimizer (see Habenicht 1983; Mostaghim et al. 2002; Jensen 2003; Talbi et al. 2008). Such implementation issues are not covered in the following.

4.3.1 Constraint Handling

In principle, constraints can be handled in the same manner as in single-objective optimization, for example, by using repair methods, by not accepting infeasible solutions, or by employing penalty functions. However, multiobjective optimization offers new opportunities where the constraint functions are treated as objective functions. The idea is to modify the underlying preference relation such that the constraints are included and

1. Among feasible solutions, the original dominance relation holds,
2. Feasible solutions dominate infeasible solutions, and
3. Among infeasible solutions, the one with the lower constraint violation is preferred.

There are different ways how this principle can be implemented in practice, see Coello et al. (2007) for an extensive list of references. The following scheme reflects the notion proposed in Fonseca and Fleming (1998):

- ▶ Let $(X, Z, \mathbf{f}, \mathbf{g}, \leq)$ be a multiobjective optimization problem. The *constraint-integrating preference relation* \preceq_{con} is defined as

$$\begin{aligned} \mathbf{a} \preceq_{con} \mathbf{b} : \Leftrightarrow & (\mathbf{g}(\mathbf{a}) \leq \mathbf{0} \wedge \mathbf{g}(\mathbf{b}) \leq \mathbf{0} \wedge \mathbf{f}(\mathbf{a}) \leq \mathbf{f}(\mathbf{b})) \vee \\ & (\mathbf{g}(\mathbf{a}) \leq \mathbf{0} \wedge \mathbf{g}(\mathbf{b}) \not\leq \mathbf{0}) \vee \\ & (\mathbf{g}(\mathbf{a}) \not\leq \mathbf{0} \wedge \mathbf{g}(\mathbf{b}) \not\leq \mathbf{0} \wedge \mathbf{g}(\mathbf{a}) \leq_{par} \mathbf{g}(\mathbf{b})) \end{aligned} \quad (24)$$

for all $\mathbf{a}, \mathbf{b} \in X$.

This scheme compares infeasible solutions using weak Pareto dominance; alternatively, one may consider the overall constraint violation, for example, the sum of the individual violations, and only compare this scalar value.

The constraint-integrating preference relation can be used in the same way as described in [Sect. 4.2.1](#) to partition the population in dominance classes. The construction ensures that (1) a class contains either only feasible or only infeasible solutions, and (2) infeasible classes follow the feasible classes in the hierarchy of dominance classes.

Example 6 Consider the single-objective variant of the knapsack problem defined in [Eq. 3](#). To handle the weight constraint, a preference relation \preccurlyeq_{con} can be formulated as follows:

$$S \preccurlyeq_{con} T : \Leftrightarrow (f_p(S) \leq f_p(T) \wedge f_w(S) \leq w_{\max}) \vee f_w(S) \leq f_w(T) \quad (25)$$

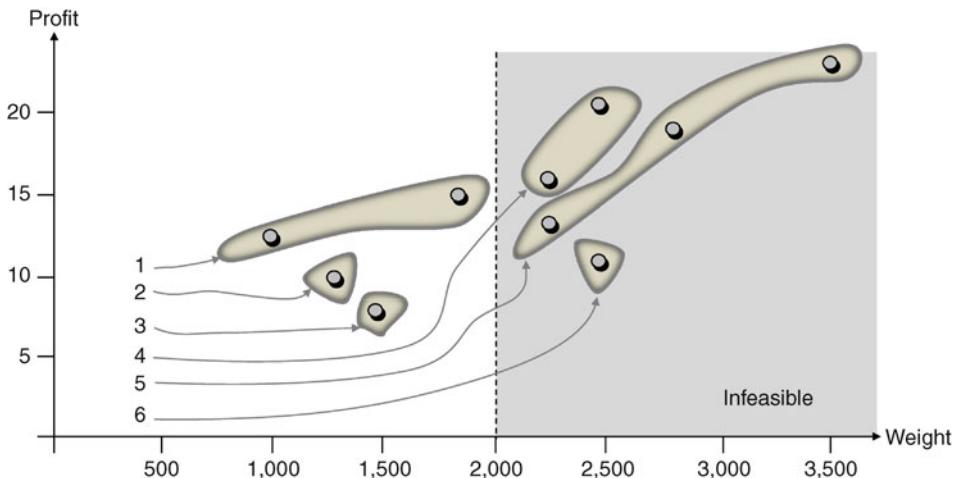

where S, T are arbitrary set of items. To illustrate how this preference relation can be used for partitioning the population, recall the knapsack problem instance from [Fig. 1](#). For a hypothetical population of ten individuals, the resulting dominance classes are depicted in [Fig. 10](#) assuming that dominance depth is used for partitioning.

4.3.2 Preference Articulation

Often, the decision maker is not interested in approximating the entire Pareto-optimal set, but has further preferences that specify certain regions of interest. Such preferences can be in the form of constraints, priorities, reference points, etc. To integrate such information in the search process is especially helpful when using the evolutionary algorithm in an interactive fashion (Jaskiewicz and Branke 2008): the optimizer first presents a general approximation set, for example, according to the hypervolume indicator, and afterward, the decision maker

Fig. 10

Partitioning of a population into dominance classes using dominance depth and a constraint-integrating preference relation. The problem is taken from [Fig. 1](#) with a weight threshold of $w_{\max} = 2,000$.

restricts respectively refines the search goal by adding further preferences; these two steps are iterated until the decision maker arrives at a final solution.

There basically exist two methodologies to guide the search on the basis of additional preference information: one can modify either the preference relation on solutions or the set preference relation. The first possibility corresponds to the aforementioned strategy to include constraints. For instance, the approach proposed in Fonseca and Fleming (1998) allows us to combine goals, which correspond to desired objective functions values, and priorities, which allow us to define a hierarchy of objectives and constraints. A further option is to change the dominance relation (Branke et al. 2001; Molina et al. 2009), for example, to reflect trade-off information or to incorporate reference points. Several other solution-oriented preference handling techniques exist (Cvetković and Parmee 2002; Rachmawati and Srinivasan 2006).

The second possibility consists in adapting the set preference relation resp. the underlying quality indicator according to the user preferences. Often, a reference point is used that specifies a region in the objective space that is of particular interest. In density-based fitness assignment procedures, this information can be incorporated by introducing a bias in the distance metric that is directly affected by the reference point (Branke and Deb 2004; Deb and Sundar 2006). Alternatively, one may consider an extension of the hypervolume indicator where a weight function puts emphasis on certain regions of the objective space (Zitzler et al. 2007); thereby, it is possible to concentrate the Pareto set approximation around one or several reference points. A similar approach can be implemented based on the epsilon indicator or the I_{RT} indicator (Zitzler et al. 2008b). Besides reference points, it is also possible to include directions: with the I_{RT} indicator, for instance, the chosen weight combinations determine which parts of the front are most important.

4.3.3 Hybridization

A promising approach to exploit knowledge about the problem structure in single-objective optimization is to combine an evolutionary algorithm with other techniques such as local search strategies or exact optimization methods. The same principle can be highly beneficial in multiobjective optimization (Knowles and Corne 2000a; Jaszkiewicz 2002), but some difficulties arise here: when for instance using a local search algorithm, this strategy focuses on the improvement of a single solution, while all population members together constitute a Pareto set approximation. Therefore, a search direction needs to be specified that corresponds to the population as a whole. In Jaszkiewicz (2002), for instance, hybrid multiobjective evolutionary algorithms based on scalarizing functions with weights have been investigated. Each time the local search procedure is invoked, a weight combination is chosen at random and the corresponding scalarizing function is taken as objective function for the local search strategy. Another approach does not use scalarizing functions, but relies on dominance to decide whether a newly generated solution replaces the current solution of the local search algorithm (Knowles and Corne 2000a).

4.4 Performance Assessment

When designing a multiobjective evolutionary algorithm or specific algorithmic concepts, it is crucial to compare the effectiveness of the new method to existing methods. To this end, both benchmark problems and comparison methodologies are needed.

4.4.1 Test Problems

Various suites of test functions have been proposed in the literature and many of them are widely used in the community, for example, the ZDT test functions (Zitzler et al. 2000), the DTLZ test functions (Deb et al. 2002b, 2005), the framework presented in Okabe et al. (2004), and the WFG suite (Huband et al. 2006). To ensure a consistent nomenclature, the proposed functions are often named according to the authors of the corresponding papers: the first letters of the authors' last names form the acronym, which may be extended by a number distinguishing specific functions of the same suite.

Artificial test functions can be designed and used to evaluate algorithms with respect to selected problem characteristics such as the shape of the front or the neighborhood structure in the decision space. Combinatorial optimization problems, in particular multiobjective versions of well-known NP hard problems, usually do not offer this flexibility, but they are often closer to reality since they can be found in various application areas. Although the problem formulation may be simple, a combinatorial problem as such can be hard to solve. Prominent examples are the multiobjective knapsack problem (Zitzler and Thiele 1999) and the multiobjective quadratic assignment problem (Knowles and Corne 2003b), which have been widely used in the EMO community.

Nevertheless, the ultimate benchmarks are real-world applications themselves (Künzli et al. 2004; Hughes 2007; Siegfried et al. 2009). The difficulty with these is that implementations need to be available in order to make them accessible for the research community. For instance, the PISA framework offers a methodology to facilitate the exchange of program code for performance assessment (Bleuler et al. 2003; Bader et al. 2008). PISA stands for "A Platform and Programming Language Independent Interface for Search Algorithms" and basically defines a text-based interface to separate general optimization principles (fitness assignment and selection) from application-specific aspects (representation, variation, and objective function evaluation). The PISA Web site (Bader et al. 2008) contains implementations of various multiobjective optimizers and benchmark problems that can be arbitrarily combined, independently of the computing platform.

4.4.2 Comparison Methodologies

Comparing stochastic algorithms for approximating the Pareto-optimal set involves comparing samples of solution sets. One can distinguish between three possibilities, how this can be accomplished: on the basis of (1) quality indicators, (2) set preference relations, and (3) attainment functions, which will be introduced later.

If the optimization goal is given in terms of a quality indicator, then the outcomes that have been obtained by running the different optimizers multiple times can be converted into samples of indicator values. Afterward, standard statistical testing procedures such as the Mann–Whitney rank sum test or Fisher's permutation test can be applied to make statistical statements about whether some algorithms generate higher quality solution sets than others, see Conover (1999). Note that multiple testing issues need to be taken into account when comparing more than two search methods (Zitzler et al. 2008a).

In the case that not a single indicator, but a more complex set preference relation is considered – possibly composed of multiple indicators – the solution sets under consideration can be compared pairwisely using this relation. On the basis of these comparisons, a standard

Mann–Whitney rank sum test can be applied, provided that the set preference relation is a total preorder. If totality is not given, for example, when directly using the weak Pareto dominance set relation, then a slightly modified testing procedure is necessary as described in Knowles et al. (2006).

The use of quality indicators or set preference relations in general implies that the outcome of the comparison is always specific to the encoded preference information. This means that Algorithm 1 can be better than Algorithm 2 when quality indicator I_1 is used, while the opposite can hold when another indicator I_2 is considered. This preference dependency can be circumvented by performing a comparison based on the weak Pareto dominance relation only. One possibility is the aforementioned methodology for set preference relations. Another possibility is the attainment function approach, which allows a more detailed analysis, but at the same time is only applicable in scenarios with few objectives.

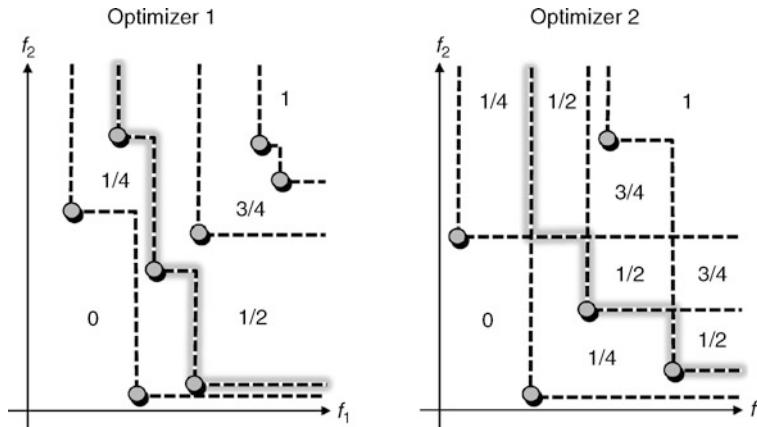

The *attainment function method* proposed in Fonseca and Fleming (1996) and Grunert da Fonseca et al. (2001) summarizes a sample of Pareto set approximations in terms of a so-called empirical attainment function. To explain the underlying idea, suppose that a certain stochastic multiobjective optimizer is run once on a specific problem. For each objective vector $\mathbf{u} \in Z$, there is a certain probability p that the resulting Pareto set approximation contains a solution \mathbf{a} such that $f(\mathbf{a})$ weakly dominates \mathbf{u} . We say p is the probability that \mathbf{u} is *attained* by the optimizer. The *attainment function* gives for each objective vector $\mathbf{u} \in Z$ the probability that \mathbf{u} is attained in one optimization run of the considered algorithm. The true attainment function is usually unknown, but it can be estimated on the basis of a sample of solution sets: one simply counts the number of Pareto set approximations by which each objective vector is attained and normalizes the resulting number with the overall sample size. The attainment function is a first-order moment measure, meaning that it estimates the probability that \mathbf{u} is attained in one optimization run of the considered algorithm *independently* of attaining any other \mathbf{u} ; however, also higher-order attainment functions may be considered (Grunert da Fonseca et al. 2001).

Example 7 Consider Fig. 11. For the scenario on the left, the four Pareto front approximations cut the objective space into five regions: the upper right region is attained in all of the runs and therefore is assigned a relative frequency of 1, the lower left region is attained in none of the runs, and the remaining three regions are assigned relative frequencies of $1/4$, $2/4$, and $3/4$ because they are attained, respectively, in one, two, and three of the four runs. In the scenario on the right, the objective space is partitioned into nine regions; the relative frequencies are determined analogously as shown in the figure.

The estimated attainment functions can be used to compare two optimizers by performing a corresponding statistical test as proposed in (Grunert da Fonseca et al. 2001). The test reveals in which regions in the objective space there are significant differences between the attainment functions. In addition, the estimated attainment functions can also be used for visualizing the outcomes of multiple runs of an optimizer. For instance, one may be interested in plotting all the goals that have been attained (independently) in 50% of the runs. The 50%-attainment surface represents the border of this subspace; roughly speaking, the 50%-attainment surface divides the objective space in two parts: the goals that have been attained and the goals that have not been attained with a frequency of at least 50%, see Fig. 11.

Fig. 11

Hypothetical outcomes of four runs for two different stochastic optimizers (left and right). The numbers in the figures give the relative frequencies according to which the distinct regions in the objective space are attained. The thick gray lines represent the 50%-attainment surfaces.

5 Applications

As outlined in the previous sections, the main use of evolutionary algorithms in multiobjective optimization scenarios lies in identifying a suitable set of compromise solutions, that is, in approximating the Pareto-optimal set. In the following, it will be briefly discussed why this type of optimization is beneficial.

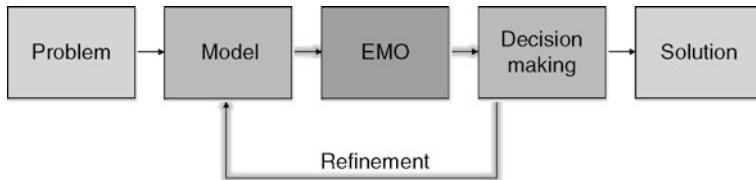

5.1 Learning and Decision Making

The main reason for formulating an optimization problem in terms of a multiple criteria model is the lack of knowledge: too little is known about the problem structure and the influence of the different optimization criteria; the same holds for user preferences, and it may even be that sufficient preferences are not available or cannot be quantified in a mathematical manner. Therefore, multiobjective optimization focuses on “modeling in progress” where the model is iteratively refined to best suit (the relevant aspects of) reality. Since evolutionary algorithms as black-box optimizers also provide high flexibility with regard to the model, evolutionary multiobjective optimization offers an excellent framework for successively learning about a problem. The workflow of this model-centered problem-solving strategy is depicted in **Fig. 12**.

Learning can have different meanings. First of all, an approximation of the Pareto-optimal set allows us to perform a trade-off analysis. Starting with a particular compromise solution, one may ask how much deterioration is necessary to obtain a certain improvement in another objective. Such information is basically given by the shape of the front. Non-convex regions of the front stand for large trade-offs, while convex parts represent low trade-offs.

Fig. 12

Model-centered problem solving using evolutionary multiobjective optimization.

Example 8 In Siegfried et al. (2009), a multiobjective groundwater management problem is tackled using an evolutionary algorithm. The task is to optimize the placement and the operation of pumping facilities over time, while considering multiple neighboring regions that are economically independent. For each region a separate cost objective function is considered, which reflects how much money needs to be spent for that region to ensure sufficient water supply for a prespecified time horizon.

⌚ [Figure 13](#) shows the approximated trade-off front for a three-region scenario. It is remarkable that there exists one solution which represents a so-called knee point (Branke et al. 2004a): it can be regarded as a decision vector that epsilon dominates the other decision vectors in the approximation set with a relatively small value for ε , cf. ⌚ [Eq. 7](#). Such information is highly useful for decision making, as it shows that – given the current estimate for the front – only small trade-offs need to be taken into account.

Another form of learning is to better understand the relationships between the considered objectives. Interesting questions in this context can be: how strongly are the objectives conflicting, can certain objectives be omitted without losing too much information, and which are the most important objectives? These are important aspects in particular from the perspective of decision making. It can become quickly infeasible to analyze a Pareto set approximation when the number of objectives increases. Therefore, an automatic dimensionality reduction of the objective space can be a valuable tool for a human user. Some studies addressed this problem and proposed methods based on (1) classical dimensionality reduction techniques such as principal component analysis (Deb and Saxena 2006; Saxena and Deb 2007), and (2) dedicated dominance-oriented reduction techniques (Brockhoff and Zitzler 2007, 2006). A remarkable result is that the notion of objective conflict always applies to groups of objectives and not to objective pairs only. Objective conflict can be defined in different ways (Deb 2001; Purshouse and Fleming 2003; Tan et al. 2005; Brockhoff and Zitzler 2007); the following notion is the most general (Brockhoff and Zitzler 2009):

- ▶ Let $(X, Z, \mathbf{f} = (f_1, \dots, f_n), \mathbf{g}, \leq_{par})$ be a multiobjective optimization problem. A set $\mathcal{F}_1 \subseteq \{f_1, \dots, f_n\}$ of objectives is denoted as *conflicting* with another set $\mathcal{F}_2 \subseteq \{f_1, \dots, f_n\}$ iff

$$\leq_{par}^{\mathcal{F}_1} \neq \leq_{par}^{\mathcal{F}_2} \quad (26)$$

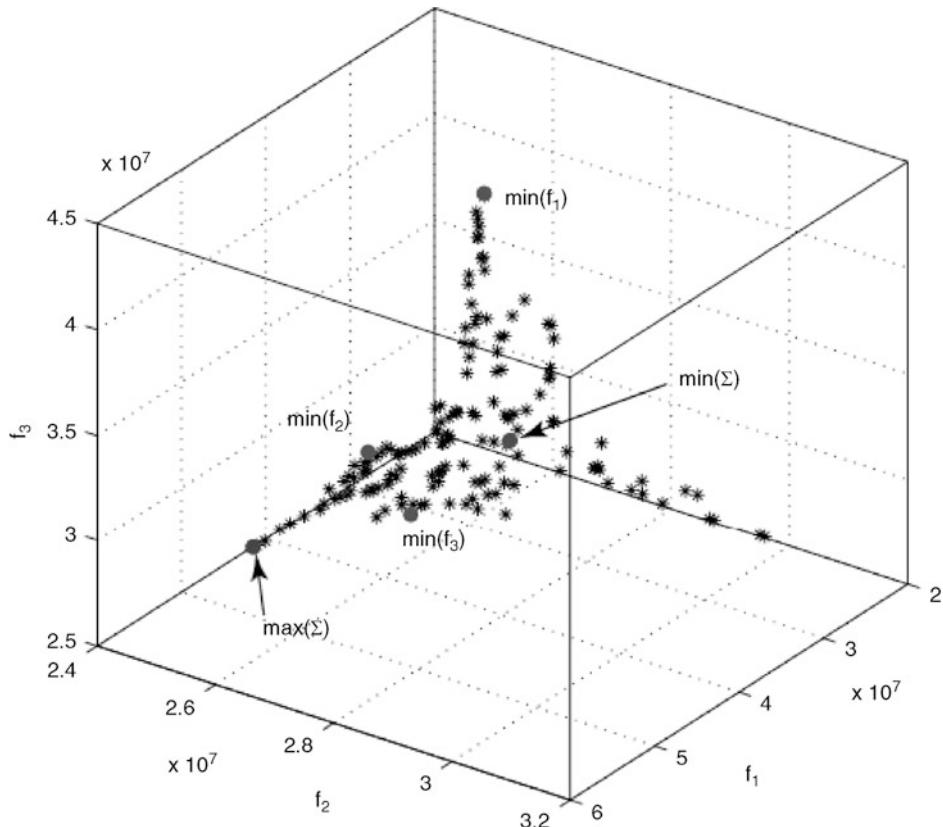

where the relation $\leq_{par}^{\mathcal{F}}$ restricts the weak Pareto dominance relation to the objectives in \mathcal{F} , that is,

$$\mathbf{u} \leq_{par}^{\mathcal{F}} \mathbf{v} : \Leftrightarrow \forall f \in \mathcal{F} : f(\mathbf{u}) \leq f(\mathbf{v}) \quad (27)$$

for all objective vectors $\mathbf{u}, \mathbf{v} \in Z$.

Fig. 13

Pareto set approximation obtained for the groundwater management application (Siegfried et al. 2009). Each axis corresponds to one cost function, all three are to be minimized. The annotated points represent the minima per objectives as well as the objective vectors providing the minimum resp. maximum unweighted sum over the objective components.

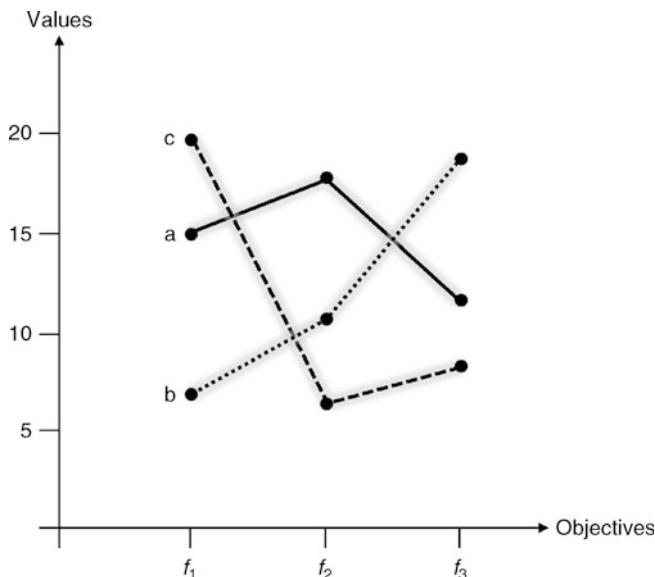

That means two groups of objectives are nonconflicting if they induce the same preference relation, which in turn implies that the Pareto-optimal sets are identical.

Example 9 [Figure 14](#) shows the parallel coordinates plot, cf. Purshouse and Fleming (2003), of three solutions **a** (solid line), **b** (dotted), and **c** (dashed) that are pairwisely incomparable. Assuming that X consists of only these three elements, the objective sets $\{f_1\}$, $\{f_2\}$, and $\{f_3\}$ are mutually conflicting, that is, all objectives are pairwisely conflicting, and also conflicting with the set $\{f_1, f_2, f_3\}$, that is, no objective alone can preserve the dominance relationships. However, the objective subset $\{f_1, f_3\}$ is not conflicting with $\{f_1, f_2, f_3\}$, which implies that the second objective could be omitted while preserving the dominance structure.

The above example shows that objectives may be removed without changing the dominance structure. Experimental results indicate that up to 50% of the objectives may be omitted

Fig. 14

Parallel coordinates plot for three solutions and three objectives. Each solution is represented by a line that connects the function values per objective.

when focusing on a subset $A \subseteq X$ of the decision space, for example, a Pareto set approximation (Brockhoff and Zitzler 2009). The same techniques can also be used to quantify the degree of conflict and to determine on this basis how strongly certain objectives are conflicting (Brockhoff and Zitzler 2006). Thereby, one can reveal which objectives are most influential and can explain the shape of the front best.

Thirdly, learning may include a combined decision space/objective space analysis of a Pareto set approximation in order to identify structural patterns. It is valuable information to reveal that certain regions of the Pareto-optimal front are correlated to and characterized by specific decision variable settings. However, to identify interesting structural patterns is itself a challenging optimization problem closely related to issues of data mining. Researchers have developed and applied dedicated clustering techniques for this purpose (Ulrich et al. 2008; Aittokoski et al. 2009). Such a clustering aims at finding groups of solutions (within a Pareto set approximation) that shows similarities in both decision space and objective space. The clustering results can later be used for a dimensionality reduction of the decision space, possibly in combination with the objective space.

5.2 Multiobjectivization

The term *multiobjectivization* has been coined by Knowles et al. (2001) and originally refers to reformulating a single-objective problem by means of a multiobjective model, which is then tackled using a set-based problem transformation. The idea is that the resulting problem is easier to solve or can be better handled than the original problem formulation – a principle that applies not only to single-objective problems, but also to multiobjective ones.

One can distinguish between three types of multiobjectivization, or more precisely ways to increase the number of objectives, to make a problem easier: (1) disaggregation, (2) decomposition, and (3) addition. The first type means that an originally multiobjective model, which was tackled using a solution-oriented problem transformation is now approached on the basis of a set-oriented problem transformation. The motivation for disaggregation is given by empirical and theoretical results. Different studies (Zitzler and Thiele 1999; Zitzler et al. 2000) have shown that a set-based multiobjective optimizer can be more effective than, for example, a weighted-sum single-objective optimizer for certain ranges of weight combinations. These empirical findings are supported by theoretical studies where a similar picture emerges (Laumanns et al. 2004a, b).

Decomposition, the second type of multiobjectivization, refers to reformulating an objective function in a different way in terms of several objectives. This reformulation can have the effect that the optimizer has more information available and therefore can search more efficiently. Scharnow et al. (2002) showed for the single-source shortest-paths problem and Neumann and Wegener (2006) demonstrated for the minimum spanning tree problem that a multiobjective approach is indeed faster in finding the (single-objective) optimum than a single-objective approach; these results are based on running time analyses. Practical evidence for these findings are provided in Knowles et al. (2001) and Handl et al. (2008).

As to the third type of multiobjectivization, adding objectives, there is a prominent application area, namely, the phenomenon of bloat in genetic programming, which was addressed first by different research groups simultaneously (Bleuler et al. 2001; Ekárt and Németh 2001; de Jong et al. 2001) and later further investigated in several follow-up studies (de Jong and Pollack 2003; Panait and Luke 2004; Bernstein et al. 2004; Kotanchek et al. 2006; Bleuler et al. 2007). The idea is to avoid useless growth of trees and the resulting decrease of search efficiency by considering the tree size as an additional objective. For different test problems, it was shown that a set-based multiobjective optimizer can find better and more compact solutions than a standard genetic programming approach and other solution-oriented approaches that combine quality and size in a single objective. In addition, there are theoretical results available that prove that a problem can become easier when adding an objective function (Brockhoff et al. 2007). Brockhoff et al. (2007) showed for a particular problem that optimizing each objective separately requires more steps in terms of running time complexity than treating the combined biobjective problem – although in the latter case a set of solutions has to be found. Clearly, the addition of objectives often makes a problem harder, as outlined in **• Sect. 2.3**, but if additional knowledge is integrated into the model using a further objective this can be beneficial for the search process.

Abstract

Memetic algorithms (MA) has become one of the key methodologies behind solvers that are capable of tackling very large, real-world, optimization problems. They are being actively investigated in research institutions as well as broadly applied in industry. This chapter provides a pragmatic guide on the key design issues underpinning memetic algorithms (MA) engineering. It begins with a brief contextual introduction to memetic algorithms and then moves on to define a pattern language for MAs. For each pattern, an associated design issue is tackled and illustrated with examples from the literature. The last section of this chapter “fast forwards” to the future and mentions what, in our mind, are the key challenges that scientists and practitioners will need to face if memetic algorithms are to remain a relevant technology in the next 20 years.

1 Introduction

Memetic algorithms (MAs) was the name given by Moscato (1989) to a class of stochastic global search techniques that, broadly speaking, combine within the framework of evolutionary algorithms (EAs) the benefits of problem-specific local search heuristics and multi-agent systems. MAs have been successfully applied to a wide range of domains that cover problems in combinatorial optimization (Reeves 1996; Burke et al. 1996; Fleurent and Ferland 1997; He and Mort 2000; Cheng and Gen 1997; Carr et al. 2002; Tang and Yao 2007; Gutin et al. 2007), continuous optimization (Hart 1994; Niesse and Mayne 1996; Morris et al. 1998), dynamic optimization (Vavak and Fogarty 1996; Caponio et al. 2007; Wang et al. 2008), multi-objective optimization (Liu et al. 2007; Ishibuchi and Kaige 2004; Jaskiewicz 2002), etc. It could be argued that, unlike other nature-inspired algorithms such as ant colony optimization (ACO) (Dorigo et al. 1997), simulated annealing (Kirkpatrick et al. 1983), neural networks (McCulloch and Pitts 1943), evolutionary algorithms (Holland 1976), etc., memetic algorithms lack, at their core, a clear natural metaphor. Whether this is a strength or weakness of the paradigm is a question for another time and this chapter focuses first on a pragmatic software engineering presentation of this remarkably malleable search technology and then, toward the end of the chapter, argues that there is indeed a potentially powerful nature-inspired metaphor that could lead to important new breakthroughs in the field.

Early in the history of the application of EAs to real-world problems, it became apparent that a *canonical GA*, namely, one using a simple binary representation, n-point crossover, bitwise mutation, and fitness proportionate selection, could not possibly compete with tailor-made algorithms. This empirical observation resonated well with theoretical (and experimental) studies on the so called “Baldwin effect” and on “Lamarckian evolution” (Hinton and Nowlan 1987; Bull et al. 2000; Houck et al. 1997; Mayley 1996; Turney 1996; Whitley et al. 1994; Whitley and Gruau 1993) that focused on how learning could affect the process of evolution. Thus, it became apparent that the global search dynamics of EAs ought to be complemented with local search refinement provided by a suitable hybridization using problem-specific solvers including heuristics, approximate, and exact algorithms. Moreover, further theoretical results (Wolpert and Macready 1997) (and similar subsequent work) debunked the idea that effective and efficient “black box” general problem solvers were attainable, and hence gave further impetus to the school of thought that supported, as an essential methodological component, the incorporation of problem (or domain)-specific information

in EAs. (Please note that everything said so far about evolutionary algorithms can also be applied to other search frameworks such as tabu search, simulated annealing or ant colony optimization, etc.) Domain-specific knowledge was thus added to the EA framework by means of specialized crossover and mutation operators, sophisticated problem-specific representations, smart population initialization, complex fitness functions (closer to the spirit of MAs), local search heuristics and, when available, approximate and exact methods. More recently, R. Dawkins' concept of "memes" (Dawkins 1976) has been gathering pace within the memetic algorithms literature as they can be thought of as representing "evolvable" strategies for problem solving, thus breaking the mould of a fixed and static domain knowledge captured once during the design of the MAs and left untouched afterward. Thus Dawkins' memes, and their extensions (Cavalli-Sforza and Feldman 1981; Durham 1991; Gabora 1993; Blackmore 1999) as evolvable search strategies (Krasnogor 1999, 2002, 2004b; Krasnogor and Gustafson 2004; Smith 2003; Burke et al. 2007a) provide a critical link to the possibility of open-ended combinatorial and/or continuous problem solving.

Software development is a process of knowledge acquisition (Armour 2007) and the development of successful memetic algorithms is no different. The popularity behind MAs is more closely related to the relative ease by which a reasonably good solver can be implemented than to any fundamental advantage over other optimization techniques such as tabu search or simulated annealing (to name but two). Indeed, any successful nature-inspired search method owes its popularity not to an intrinsic problem-solving feature, which might be absent from a competing method, but rather to the fact that, in spite of obvious design flaws (e.g., large number of parameters, lack of operational theory for their use, etc.), they help to structure around them a healthy research and practice milieu. That is, nature-inspired search methods are computational "research programs," or "research paradigms," in their own right (Kuhn 1962). Thus the question of what are the key components of the memetic algorithms research paradigm takes center stage. The literature has a large number of papers in which a variety of methods are classified as memetic algorithms. Thus, although the large majority of memetic algorithms are instances of evolutionary algorithms-local search hybrids, numerous MAs are derived from other metaheuristics, for example, ant colony optimization (ACO) (Lee and Lee 2005), particle swarm (Liu et al. 2005), artificial immune systems (AIS) (Yanga et al. 2008), etc. What all of these implementations have in common is a *carefully choreographed interplay between (stochastic) global search and local search strategies*. The remaining parts of this chapter consider some of the key implementation strategies that, over the course of the years, have (re)appeared in the form of tried and tested algorithmic design solutions to the ubiquitous problem of how to successfully orchestrate global and local search methods in complex search spaces.

2 A Pattern Language for Memetic Algorithms

Alexander et al. (1977) introduced, within the context of architecture and urban planning, the concept of "Patterns" and "Pattern Languages":

- ▶ In this book, we present one possible pattern language,... The elements of this language are entities called patterns. Each pattern describes a problem which occurs over and over again in our environment, and then describes the core of the solution to that problem, in such a way that you can use this solution a million times over, without ever doing it the same way twice.

A pattern language is then defined as a collection of interrelated patterns, with each and every one of them expressed in a concise, clear, and uniform format. The content of a pattern includes at least the following elements (Gamma et al. 1995):

- *The pattern name*, which is a concise handler to refer to both a specific problem and a tried and tested solution. By having a carefully selected set of pattern names (e.g., selection mechanism, crossover strategy, exploration strategy, diversification plan, etc.) the pattern language, that is, the vocabulary of, in our case, nature-inspired paradigms – for example, memetic algorithms – is enriched. Critically, a small increase in the size of a vocabulary creates a rich and expressive combinatorial explosion of patterns' compositions, thus opening the road for substantial research and practical experimentation. The importance of this observation will become apparent once we describe self-generating memetic algorithms.
- *The problem statement* depicting the situation in which the pattern is best applied, that is, the problem that the pattern attempts to provide a solution to, for example, maintaining pareto front diversity, etc. The problem statement might also contain a set of constraints describing situations where the pattern should not be applied or, symmetrically, conditions that must be fulfilled before the pattern can be used.
- *The solution*, in turn, provides a template on how to approach the solution of the problem to which the pattern is applied. The description in this section is not prescriptive but rather qualitative. As emphasized by Alexander et al. (1977), one might reuse a solution under myriads of different shapes, yet the essential core of all those implementations should be easily distinguishable and invariant.
- *The consequences* of applying the pattern. There are no free lunches, hence, even when a pattern might be the best (or perhaps only) solution to a given problem, its application might lead to a series of trade-offs. The more explicit and clearly stated these are, the more clear and precise the pattern language as a whole will be. For example, a pattern that calls for the reinitialization of a population due to a diversity crisis might carry with it, as obvious collateral damage, certain loss of information. Thus, by employing a reinitialization pattern, one might be forced to utilize a pattern that safeguards partial solutions.
- *Representative examples* briefly mentioning cases where the pattern has been used.

Thus, a collection of well-defined patterns, that is, a rich pattern language, substantially enhances one's ability to communicate solutions to recurring problems without the need to discuss specific implementation details. The pattern language thus serves the dual purpose of being both a taxonomy of problems and a catalog of solutions. This chapter provides a series of patterns that will be defined as per the tableaux that appears above. A reader interested in, for example, finding out about diversity handling strategies for MAs, irrespective of which underlying framework (e.g., evolutionary, ant colony, artificial immune system) the MA is

d

f

being implemented in, can quickly scan the various patterns in the pattern language catalog, identify the one related to diversity strategies and rapidly gain an idea of the tried and tested approaches, the pattern's motivation and consequences. Furthermore, the reader could then refer to the mentioned literature for concrete, detailed codes and methods.

It has been argued (Cooper 2000) that design patterns are seldom created but rather they are discovered through a process of datamining the source code base and literature base for reusable solutions to recurring problems. In this spirit, and before describing a specific pattern language for memetic algorithms, one sees the pseudocodes and flowcharts of some representative MA instances. These algorithms are reported in exactly the same form as found in the original publication so as to emphasize both the *invariants* in their architecture as well as the variety of “decorations” found in the many implementations of memetic algorithms. Other examples of “in the wild” MAs can be found in Krasnogor and Smith (2005).

Memetic improvements have been used in, for example, learning classifier systems (Bacardit and Krasnogor 2009) with the top level pseudocode shown in [Fig. 1a](#). An estimation of distribution (EDA) like MA, a compact memetic algorithm (Merz 2003) is shown in [Fig. 1b](#) (for a more recent EDA-MA see Duque et al. (2008)) while a memetic particle swarm optimization (PSO) (Petalas et al. 2007) pseudocode is depicted in [Fig. 1c](#). [Figure 1d](#) and [e](#) show a generic pseudocode of an ant colony optimization-based MA (Cordon et al. 2002) and its explicit use of solution-refining strategies (in the form of local search methods), respectively. An example of an immune system-inspired memetic algorithm's (Yanga et al. 2008) flowchart is shown in [Fig. 1f](#). The key invariant property that is present in the architecture of all these memetic algorithms is the combination of a search mechanism operating over (in principle) the entire search space with other search operators focusing on local regions of these search spaces. This key invariant holds true regardless of the nature-inspired paradigm the memetic algorithm is derived from or whether it is meant to solve an NP-hard combinatorial problem or a highly complex (e.g., multimodal, nonlinear, and multidimensional) continuous one.

We argue that the key problem that is addressed by memetic algorithms is the balance between global and local search, in other words, the strategy that different nature-inspired paradigms (e.g., ACO, AIS, etc.) might need to implement so as to benefit from a successful tradeoff between exploration and exploitation. Thus, the first top-level pattern can be defined.

Name: Memetic Algorithm Pattern (MAP) [1]

- *Problem statement:* A memetic algorithm provides solution patterns for the ubiquitous problem of how to successfully orchestrate a balanced tradeoff between exploring a search space and exploiting available (partial) solutions. It provides a suitable solution to complex problems where standard and efficient (i.e., approximation algorithms, exact algorithms, etc.) methods do not exist. The memetic algorithm is said to explore the search space through a “global” search technique, while exploitation is achieved through “local” search.
- *The solution:* This pattern relies on finding, for a given problem domain, an adequate instantiation of exploration and exploitation. Exploration is performed by “global search” methods usually implemented by means of a population-based nature-inspired method such as evolutionary algorithms, ant colony optimization, artificial immune systems, etc. Exploitation is commonly done through the use of local search methods and domain-specific heuristics. The global scale exploration is achieved by, for example, keeping track of multiple solutions or by virtue of specific “jump” operators that are able to connect

distant regions of the search space. The local scale exploitation focuses the search on the vicinity of a given candidate solution.

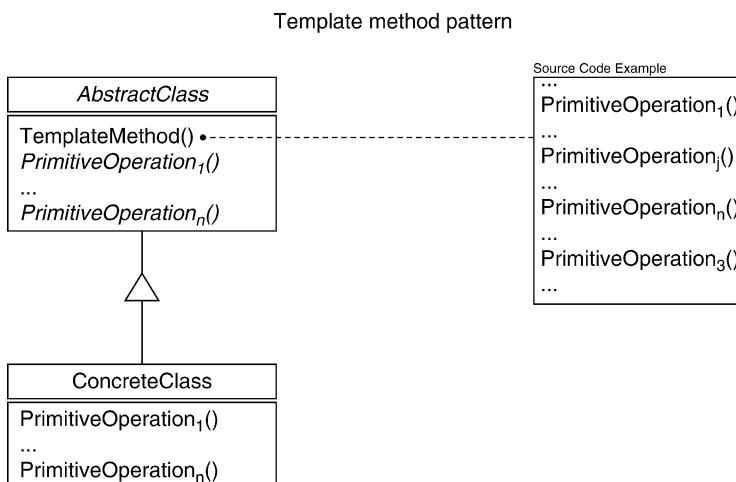

- *The consequences:* Hybridizing a global search method of any kind with local search and/or domain-specific heuristics usually results in better end-results, but this comes at the expense of increased computational time. The correct tradeoff between exploration and exploitation must be such that, were the global searcher given the same total CPU “budget” as the memetic algorithm, then, its solutions would still be worse than those derived from the MA. Needless to say, if the local searcher by itself, or through a naive multi-start shell could achieve the same quality of results as the memetic algorithm then the global searcher becomes irrelevant. Another likely consequence is that local search and domain-specific heuristics usually result in premature convergence (also called diversity crisis).
- *Examples:* Papers (Cordon et al. 2002; Yanga et al. 2008; Petalas et al. 2007; Duque et al. 2008; Bacardit and Krasnogor 2009) report on the use of memetic algorithms under a variety of nature-inspired incarnations.

The memetic algorithm patterns (MAP) can be refined through a variety of template patterns (TP) (Gamma et al. 1995), which allow for the definition of the *skeleton* of an algorithm, method, or protocol, through deferring problem-specific details to subclasses. In this way, through a judicious use of the template pattern, one can have a very generic and reusable recipe for implementing solutions to a range of, perhaps very different, problems.

⦿ *Figure 2* shows a class diagram capturing a template method pattern. The abstract class defines a template method that provides the algorithmic skeleton for a specific functionality. To achieve its functionality the template method calls one or more primitive operations (defined abstractly in the abstract class) that can be redefined in more specialized subclasses (concreteClass in the figure). ⦿ *Figures 1a-f* are examples of template method patterns for ACO, AIS, particle swarm optimization (PSO), EDA and LCS based memetic algorithms

■ Fig. 2

A UML class diagram sketching the structure for implementing Template Method patterns.
(Adapted from Gamma et al. (1995).)

respectively. Each TP captures the invariant properties of memetic algorithms when it is implemented from the perspective of a specific nature-inspired algorithm. It also captures the invariant features of MAs regardless of which nature-inspired route is used to implement it, for example, the entwining of global and local search procedures. The following sections will discuss other design patterns that are critical to the implementation of competent memetic algorithms thus extending the pattern language for MAs.

2.1 A Template Pattern for an Evolutionary Memetic Algorithm

As the design issues and critical considerations behind the implementation of MAs are almost identical across the various possible nature-inspired algorithms that could be used as templates, and as evolutionary memetic algorithms are the best known MAs, the focus of the following discussions will be on an evolutionary algorithm template pattern for MAs. The pattern language that will emerge, however, will be valid for other nature-inspired paradigms as well.

Name: Evolutionary Memetic Algorithm Template Pattern (EMATP) [2]

- *Problem statement:* the EMATP provides a viable route for solving the problem of how best to coordinate global and local search methods from within an evolutionary algorithms paradigm. Although in principle the simultaneous exploration of the search space by the evolutionary process and the exploitation (by refinement) of candidate solutions should result on an improved algorithm, this is not always the case. The expectation is that a hybridization of an EA would result in a synergistic net effect that would productively balance local and global search.
- *The solution:* the (almost) standard evolutionary cycle composed of *Initiate* → *Evaluate* → *Mate* → *Mutate* → *Select* → *RepeatUntilDone* is expanded with domain-specific operators that can refine this cycle. The refinement processes could vary for the different elements of the core EA's pipeline and could be implemented through exact, approximated or heuristic (e.g., local search) methods. Domain-specific operations are often implemented in the form of smart initializations, local search procedures, etc., that refine the input solutions to the mate and/or mutate processes as well as (more often) their outputs. Refinements could also be applied to the selection, initialization, and population management processes through, for example, fitness sharing, crowding, population structuring (e.g., cellular/lattice structures, demes, islands), and diversity management strategies.
- *The consequences:* paradoxically, although the key motivation for using memetic algorithms has been to refine solutions and converge toward good local optima (or ideally global optima) fast, sometimes the balance of local and global search is poorly implemented resulting in an untimely diversity crisis because the algorithm converges too fast. Another direct consequence of using memetic algorithms is that often, refining solutions by problem-specific strategies incurs in a substantial additional CPU commitment. Thus, it becomes essential to validate whether the exploration mechanisms of the core EA's pipeline when augmented with refining strategies do not end up producing worse solutions than having run the pure EAs with the same total CPU commitment (or the refinement strategies alone with an equivalent total CPU budget).

- Examples: Figure 3 shows a concrete example of an evolutionary memetic algorithm. A detailed description and analysis of several successful implementations of the EMATP pattern are described in Krasnogor and Smith (2005). The paper also provides a taxonomy for EMAs as well as a discussion of design issues.

Fig. 3

An evolutionary algorithm-based memetic algorithm template. The figure highlights the EA's core operators as well as the hotspots where the algorithm can be refined, that is, where "memetic" operators might come into play.

```
/* Variable and constants definitions:  
/* t is generation number  
/* IPi stands for intermediate population ith  
/* P(t) stands for the population at time t  
/* H stands for historical population archive  
*/  
Begin  
t ← 0;  
  
Initialize P(t);  
  
Evaluate P(t);  
Repeat Until (termination conditions = True) do  
  /* Mating FineGrainedScheduler, fSR, coordinates the application of */  
  /* Crossover and Refinement Operators to population P(t) */  
  
  IP1 ← fSR(Crossover, Refinement, P(t));  
  
  /* Mutation FineGrainedScheduler, fSM, coordinates the application of */  
  /* Mutation and Refinement Operators to population IP1 */  
  
  IP2 ← fSM(Mutation, Refinement, IP1);  
  
  /* Selection CoarseGrainedScheduler, cS, coordinates the application of */  
  /* Selection and Refinement Operators to population IP2 */  
  
  IP3 ← cS(Selection, Refinement, IP2);  
  
  t ← t+1;  
  P(t) ← IP3;  
  
  /* MetaScheduler, mS, coordinates the application of */  
  /* Refinement Operators to populations H ⊇ P(i) with i ∈ [0..t] */  
  
  H ← mS(Refinement, IP3);  
  
End;  
End;
```

Evolutionary algorithm backbone

Refinement hooks

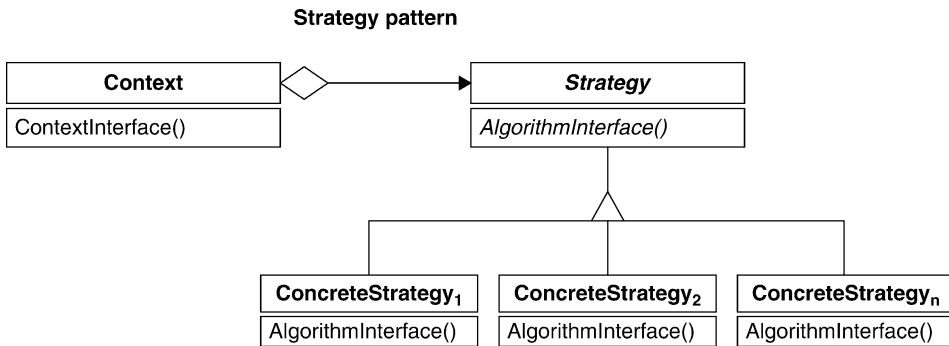

➊ *Figure 3* shows a concrete example of the EMATP. The figure identifies the key EA's components as the “backbone” and the potential places where refinement might take place as refinement hooks. Each hook is represented by a “scheduler” operator that manages the flow of information (e.g., partial/candidate solutions, time-dependent parameters, etc.) between each of the core EA's component and the refinement strategies associated with them. A formal notation for these schedulers can be found in Krasnogor and Smith (2005). A detailed study of the literature reveals that three types of schedulers can be abstracted from the various templates that are implemented. These schedulers are: a *fine-grain scheduler* for coordinating the operation of the genetic operators mutation and crossover with refinement methods, a *coarse-grain scheduler* for overseeing the interplay between population management strategies (e.g., selection) and refinement strategies and *meta scheduler* that orchestrate refinement procedures over longer timescales and larger spatial scales (e.g., islands, population structures, pareto archives). These schedulers receive their names because they operate at different level of granularities and timeframes. The fine-grain schedulers (represented by fS_R , fS_M in ➋ *Fig. 3*) have access to a very limited number of solutions and hence they have a very localized view of the current state of the search and thus the decision they can take in terms of parameter and operators adaptation is confined to small regions of the search space. The course-grain scheduler (represented by cS in ➋ *Fig. 3*), on the other hand, has access to a complete population and, perhaps, even to intermediate populations that could have been created in the main EA's pipeline. Thus it has a more global view of the search state that might be used to strategically guide the application of further refining methods to (parts of) the population it has access to. The meta scheduler (represented by mS in ➋ *Fig. 3*), on the other hand, has access to potentially the power set of all previously visited solutions and hence it has an even broader information base to decide the appropriate balance between exploration and exploitation. These schedulers also operate at different time-scales. Clearly, fS_* can operate very frequently indeed, potentially each time that a crossover or mutation event takes place. The coarse-grain scheduler operates once per generation and the mS , potentially, even less often. These differing spatial (i.e., access to solutions) and temporal (frequency of operation) features result in constraints on the complexity of the algorithmic strategies that these schedulers can implement and have a direct impact in several design issues such as whether or not a surrogate fitness function (Zhou 2004; Zhou et al. 2007) should be used, etc. Needless to say, EMATP can be implemented through a series of (object-oriented) class hierarchies. The EMATP pattern in ➋ *Fig. 3* can be encapsulated into an abstract class from which subclasses implement specific versions of the pattern. One could thus imagine a family of evolutionary memetic algorithms where one or more features are either removed from the pattern or added to it simply by overriding the behavior of the scheduler methods.

2.2 Strategy Patterns for Memetic Algorithms Design Issues

The memetic algorithms pattern language is extended by describing a series of strategy patterns associated with design issues arising from attempting to implement effective instances of the EMATP. The evolutionary algorithm's processes such as crossover and mutation, as well as the refinement strategies and the schedulers that coordinate their operations, are best thought of as strategy patterns (Gamma et al. 1995). These patterns are useful for defining a family of interchangeable algorithms.

Fig. 4

A UML class diagram sketching the structure for implementing strategy patterns. (Adapted from Gamma et al. (1995).)

The idea is that the client that employs a member of this family of algorithms, for example, the fine-grained scheduler coordinating a local search strategy with a crossover operator, should be able to use any of the available local search and/or crossover strategies without need for recoding. A most frequent example is provided when testing different, for example, crossover operators such as one-point crossover, two-point crossover and uniform crossover without the need to rewrite the EA's backbone. Similarly, one should be able to change the local search used without affecting the pattern in which it is used. That is, a strategy pattern should be used each time that a program, in this case a memetic algorithm, needs a specific service or function and when there are, in fact, several ways of executing these functions. To promote reusability, strategy patterns follow a scheme similar to the one depicted in **Fig. 4**. The choice of which strategy to implement as to perform the required function is problem- and instance-specific. Thus by using strategy patterns, one can change algorithms without causing a chain reaction of changes in the code that uses those algorithms. As argued below, there is a direct link between critical memetic algorithms design issues and strategy patterns.

2.2.1 Refinement Strategies

It has been argued that an EMATP provides conceptual solutions to the problem of balancing local and global search. The global search is performed through the implementation of some form of evolutionary algorithm while the local search is meant to be implemented by some form of refinement operator. The choice of operator refinement is a critical design decision in memetic algorithms engineering as it tremendously impacts the synergy between the EA's backbone and the refinement methods of choice.

Name: Refinement Strategy Pattern (RSP) [3]

- Problem statement:* this pattern attempts to address the following key questions: (1) what refinement operator should be used and, ultimately, (2) what fitness landscape will the MA be exploring? While the EMATP helps define the algorithmic skeleton of an

evolutionary-based memetic algorithm, it leaves to the strategy patterns the problem of how to decide what strategy would be implemented at the various refinement stages. Indeed, both theoretical and experimental work has analyzed the effectiveness of different local search strategies within memetic algorithms.

- *The solution:* the key design issue related to refinement strategies is how they prevent getting trapped in (poor) local optima, that is, search stagnation, while performing an efficient and fast local search. The answer to questions (1) and (2) above is problem, instance, and time dependent, hence a solution can only be provided at an abstract engineering level that allows for the seamless adaptation of the EMATP to different situations. More precisely, for a given set of low-level move operators, for example, n-exchange, n-swaps, bit-flip, etc., a variety of navigation rules have been implemented. Navigation rules specify how the search landscape induced by a given move operator is traversed. Some of the alternatives are breadth first search, depth first search, variable depth, etc. Besides the navigation method, the refinement strategy also needs to specify an acceptance criteria, for example, greedy, Monte Carlo, Great-Deluge (Dueck 1993; Burke et al. 2004), etc. Finally, the most sophisticated refinement strategies employ multiple move operators and acceptance criteria, for example, multimeme algorithms (Krasnogor 2004a; Krasnogor and Smith 2001), variable-neighborhood search (Hansen and Mladenovic 1998, 2001), etc. Indeed, a refinement strategy pattern might use at its core a full memetic algorithm pattern, see Romero-Campero et al. (2008) for an example. Thus, through the recursive nesting of MAP and RSP, it is possible to obtain extremely complex and versatile search methodologies.
- *The consequences:* the refinement strategy pattern comes with some “strings attached” to it. Its very flexibility means that a given memetic algorithm might be exploring not one but several search landscapes simultaneously. The precise nature of this combined search space should, ideally, be adequately analyzed either experimentally or theoretically (ideally in both ways). Fitness landscapes statistics were utilized in, for example, Kallel et al. (2001) and Merz and Freisleben (1999). Krasnogor and Smith (2008) resorted to polynomial local search theory to show the impact of various combinations of local search and genetic operators. The chapter provides a worst case analyzing for the complexity of heuristics applied to a well-known problem, the two-dimensional and Euclidean TSP. By way of simple arguments, the paper shows the PLS-completeness of a family of memetic algorithms for the TSP as well as graph partitioning and maximum network flow (both with important practical applications). It was shown that potentially very long paths to local optima exists even when the neighborhood used by some MAs are of polynomial size. Interestingly, the chapter’s arguments are also valid for a variable-neighborhood search, rather than evolutionary based, template pattern for global search. A similar result is also provided in Sudholt (2007) for MinCut, MaxSAT, and Knapsack problems.
- *Examples:* intelligent refinement strategy patterns can be seen in Jakob (2006) and Neri et al. (2007a).

2.2.2 Exact and Approximate Hybridization

The previous section presented a refinement strategy pattern that dealt with the general question of how to design a navigable fitness landscape for memetic algorithms through a

judicious selection of refinement strategies. One complementary and related design issue is that of the hybridization of evolutionary algorithms with exact and approximate methods for which a new strategy pattern is presented.

Name: Exact and Approximate Hybridization Strategy Pattern (EAHSP) [4]

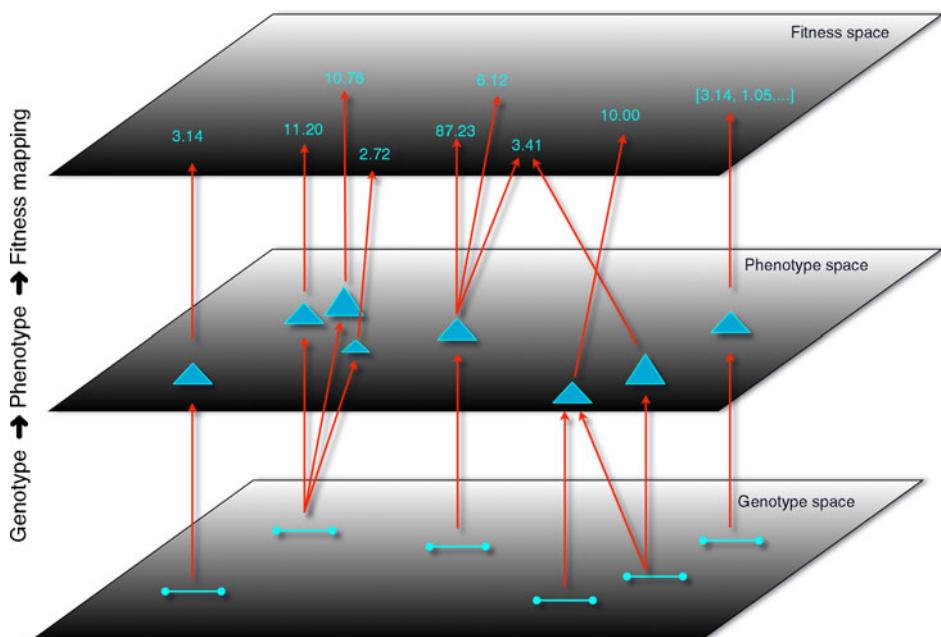

- *Problem statement:* The integration of exact and approximation method into an evolutionary memetic algorithm (EMA) pattern requires the consideration of specific design issues that are distinct than those of other (e.g., heuristic) refinement strategies. More specifically, the development of exact methods requires considerably more effort than that of a set of relatively simple local searchers. The majority of the effort goes into obtaining a tight formulation of the problem for the exact method or a suitable relaxation. Moreover, exact and approximation methods might take a substantial amount of CPU effort to run, sometimes dwarfing that is required by the EMA. Thus, how to synergistically exploit both approaches for obtaining a better solver remains a critical problem.
- *The solution:* It has been argued that there are essentially two main ways of integrating exact and EMA methods. The first approach is based on running the EMA and the exact method in tandem, that is, the EMA provides solutions to the exact method (for example, a branch and bound method) that could, in turn, use the evolved solutions as good bounds, thus helping reduce the branch and bound runtime. Symmetrically, the exact method might be used to seed EMA populations with good candidate solutions. In this loose integration, each algorithm runs essentially independent from each other but exchanging information from time to time. On the second implementation strategy the branch and bound calls the EMA from time to time and thus uses the EMA as a heuristic to produce bounds. It might call it only once as to provide initial solutions or many times over its execution, thus forming a more tightly coupled pipeline. Gallardo et al. (2007) calls these two strategies coercive and cooperative, respectively. Sometimes, when the problem is excessively large, for example, it does not fit in memory and there is no possibility of a distributed computation. Branch and bound is heuristically modified and converted into a beam search. Although this approximation loses performance, it does allow for much larger problems to be tackled (Gallardo et al. 2007). In Pirkwieser et al. (2008), the authors interleave the execution of an EMA with a Lagrangian relaxation method based on a loose coupling strategy.
- *The consequences:* the application of this strategy pattern requires a detailed modeling of the problem at hand and a realistic evaluation of the exact method and memetic algorithm relative runtimes. It should be clear that this strategy should be used if the added benefit of guaranteed results outweigh the additional efforts both in engineering the system and in running it.
- *Examples:* Mezmaz et al. (2007) explores the application of both tandem and pipeline strategies for the bi-objective flowshop scheduling problem. Raidl and Puchinger (2008) provide a detailed analysis of how to combine integer and linear programming methods with metaheuristics. Many of the strategies reported are directly applicable to EMAP.

2.2.3 Population Diversity Handling Strategies

A key characteristic of memetic algorithms is that, they combine search through a population of solutions with search focused around specific promising ones. The introduction of

Fig. 5

The mapping from genotype (i.e., solution encoding) to phenotype (i.e., encoding interpretation) to fitness (i.e., a concrete measure of a solution's worth) can be very complex.

refinement strategies to improve over a subset of solutions often produces additional selection that, in turn, brings a premature population diversity crisis. A population's lack of diversity causes the MA to allocate repeated reproductive, mutation, and refinement trials to the same individuals, thus wasting precious CPU resources. Balancing population diversity is a critical issue, that in itself necessitates a detailed analysis of what is meant by "diversity." The complexity of this task is represented in [Fig. 5](#). Only in the most idealized problem, the mapping from genotypes to phenotypes and then to fitness values is a one-to-one direct mapping. In real-world applications these mappings are highly complex. In some cases, the interpretation of a given solution representation (i.e., genotype) into a phenotype (i.e., actual solution) is nonlinear and/or stochastic and results in potentially different phenotypes for the same genotype. Similarly, fitness assignment to phenotypes might also be nonlinear and/or stochastic thus producing, for a given phenotype, potentially different fitness values. The existence of nonlinearities and stochasticity in the genotype → phenotype → fitness mappings gets compounded when multi-objective problems are tackled. Hence, the definition of population diversity used by diversity strategies must take these complex mappings into account.

Name: Population Diversity Handling Strategy Pattern (PDHSP) [5]

- Problem statement:* the goal of this pattern is to provide interchangeable strategies for the robust management of population diversity within memetic algorithms.
- The solution:* sustaining population diversity in memetic algorithms is a difficult task. It is usually tackled by a combination of strategies operating at various levels. First,

the population is usually initialized in an intelligent manner as to avoid resampling and nonrepresentative coverage of the search space at the beginning of the search. Examples of initialization mechanisms can be found in Burke et al. (1998) and Kretwski (2008). Later, during the search, population diversity maintenance can be implemented at various levels. For example Krasnogor et al. (2002) uses a memory of solution features during the mating process as to avoid generating phenotypes with over-represented features. In this work population diversity is controlled at the phenotype level. An example of a diversity preservation strategy at the fitness level is adopted by Kononova et al. (2007), where the selection of which local search to use is guided by the range of fitness in the population. Similarly, Krasnogor and Smith (2000) uses an adaptation in the local searcher to monitor and affect fitness distributions. In the context of AIS-based templates for memetic algorithms, the aging operator eliminates the oldest candidate solutions from a population so as to contribute to maintaining diversity and thus avoiding (poor) local optima. AIS and differential evolution (DE)-based solvers for multidimensional problems, where diversity handling and refinement strategies are compared, are reported in Cutello et al. (2007). Keeping track of the “age” of the solutions is quite an ubiquitous strategy used on several multi-solution templates. Sorensen and Sevaux (2006) propose several population management strategies based on measuring diversity in the solution space for multidimensional knapsack problem and weighted tardiness single-machine scheduling problems. For continuous problems, diversity is sometimes preserved through structuring the population using a cellular memetic algorithm (Nguyen et al. 2007).

- *The consequences:* Care should be taken in designing the diversity measure to use. In Burke et al. (2002, 2003) a variety of diversity measures for problems have been analyzed where mappings such as those depicted in Fig. 5 take place. Although the examples used in this chapter are based on genetic programming, the lessons learnt are universal for memetic algorithms, namely, (1) increased diversity does not always positively correlate with improved performance and (2) whether it leads to improved performance depends on the complex mapping between genotypes, phenotypes, and fitness. Thus population diversity handling strategies must be implemented in such a way that they should be easy to change and benchmark as to continuously assess their performance in specific problems.
- *Examples:* Neri et al. present a comparative study of several fitness diversity-based adaptation schemes for multimeme algorithms in Neri et al. (2007b). Landa Silva and Burke (2004) address the issue of the interplay between diversity and multi-objective optimization.

2.2.4 Surrogate Strategies

Evolutionary memetic algorithms are usually used to solve very complex and hard problems. Oftentimes, these problems also give rise to uncertainties in the assignment of the fitness values of individuals upon which selection can be applied. On the other hand, refinement strategies used within memetic algorithms are usually computationally expensive, there is no explicit knowledge of a fitness function (e.g., in interactive evolutionary design problems) and hence fitness must be “reverse-engineered.” Moreover, in some cases the objective function is extremely multi-modal and a smoothing criteria is required. The above considerations lead directly to an important design issue in memetic algorithms engineering, namely, the use of surrogate objective functions.

Name: Surrogate Objective Function Strategy Pattern (SOFSP) [6]

- *Problem statement:* Memetic algorithms are computationally intensive methods and one of the most important computational bottlenecks that must be considered when engineering an MA in the calculation of the objective (i.e., fitness) function. As shown in [Fig. 5](#), many problems are inherently noisy, that is, the same candidate solution might be assigned a different fitness value due to stochasticity or nonlinearities in their evaluation. In other cases, several promising solutions might be repeatedly improved by a refinement strategy pattern and this refinement, almost invariably, leads to a large number of additional objective function's evaluations. In optimal design problems, one often finds that no explicit knowledge of fitness is available and the quality of a solution must be inferred from samples given by experts. The aim of the surrogate objective function strategy pattern is to provide effective ways of replacing an expensive, noisy, or unknown fitness function with a suitably defined approximation. The goal is to ameliorate the cost of highly expensive fitness function evaluations while preserving fitness assignment quality by providing a “proxy” to the original objective function that is faster than the former, but of sufficient quality so that it can provide good quality estimations of the true fitness value of a candidate solution.
- *The solution:* Surrogate fitness functions have also been called metamodels, local models, and partial objective functions in the literature. Although the use of effective strategies for solving the surrogacy problem are also important to other branches of natural computation, it is particularly poignant in memetic algorithm's design. This is so because MAs should be able to cope with uncertainty in the genotype → phenotype → fitness mappings, which could lead to a noisy fitness assignment and ambiguity in the very definition of fitness but also MAs must contend with and balance the additional computational effort introduced by the refinement strategies. Explicit averaging has been used to ascertain the fitness of candidate solutions under uncertainty. This is exemplified by the reduction of variance techniques (e.g., latin hypercube sampling), reevaluation of distinct individuals (e.g., those with high fitness or variance), weighted histories (Branke [1998, 2001, 2002](#)), etc. Fitness inheritance (Llora et al. [2007](#)), artificial neural networks and related approaches (Ong et al. [2008](#)), models (Bull [1999](#)), and metamodels (Bhattacharya [2007](#)) as well as design of experiments (Sacks et al. [1989](#)) have also been used for surrogate fitness implementation. In Jin ([2005](#)) and Paenke and Jin ([2006](#)) the authors present a detailed analysis of surrogate methods for evolutionary computation.
- *The consequences:* The use of a surrogate objective function strategy is, in many real-world scenarios, unavoidable. However, its use brings forth a series of other design decisions the memetic algorithms engineer will need to take into account, for example, at what level will the approximation be more productive? the fitness level or the problem itself? Is it possible to use global models or should a collection of local approximations be preferred, etc.
- *Examples:* Zhou et al. ([2007](#)) provide specific recommendations for integrating approximate fitness models within memetic algorithms.

2.2.5 Continuous Problems

The utilization of EMATP for continuous problems presents, in addition to the previous design considerations, new opportunities and challenges. This section only focuses on the issue of integrating refinement strategies for continuous optimization within a memetic algorithm

framework. The reader must note that there is a large body of literature on the use of evolutionary computation for continuous domains, which is not dealt with here. Unlike combinatorial optimization, where it is always possible to detect when a given point is a local optimum, in the continuous case it is, in general, not possible and hence one must settle for an a priori decision on what solution precisions are acceptable, or provide a decision-making mechanism to the MA itself. This becomes even more critical when facing continuous design optimization problems with multiple optimality criteria (e.g., Siepmann et al. 2007). The following section describes a refinement strategy pattern for continuous problems that addresses some of the design issues reported in Hart et al. (2004).

Name: Continuous Problems Refinement Strategy Pattern (CPRSP) [7]

- *Problem statement:* Effective search requires an appropriate determination of search scales, which in continuous optimization is not always possible, for example, it is often impossible to determine, given a candidate solution, whether it represents a local optimum or not. The lack of explicit local scale might also result on very long searches, that when combined with lack of gradient information pose a very difficult problem for optimization techniques. Thus, whether one uses as a refinement strategy, a derivative-free method such as, for example, Nelder–Mead simplex (Nelder and Mead 1965) or Lagrangian interpolation (Berrut and Trefethen 2004), or methods that use first or second order information, for example, Gram–Schmidt orthogonalization or Broyden–Fletcher–Goldfarb–Shanno (Jongen et al. 2004; Hoshino 1971); in general, it is not advisable to rely on detecting a local optimum to stop a local search within a continuous problem.
- *The solution:* Schwefel (1993) surveys several continuous optimization methods, some of which use derivatives information and some which do not. Any of these methods can be integrated within an EMATP through a judicious balance of the amount of effort allocated to the local searchers. As in general it is not possible to run these standard methods all the way to stationary points or local optima, one relies on either truncated searches or a selective application of the local continuous optimization technique to some of the potential solutions in the population. Local search frequency and intensity parameters defining the proportion of individuals in the population that will undergo refinement and how much effort each one will be allocated are introduced. As mentioned in Nguyen et al. (2007), the values for these parameters and the decision on which of the above-mentioned refinement methods are to be used are very much problem dependent. As it is the case for discrete optimization problems, MAs applied to continuous domains also, if improperly engineered, might suffer from premature convergence through a rapid loss of diversity in the population. The use of infrequent or incomplete searches contributes to maintaining diversity but it has been shown, for example, Quang et al. (2009), that a lattice-type population structure promotes a more diverse search.
- *The consequences:* The difficulty of a priori deciding step sizes, local search probability, refinement strategy, etc., for each new problem suggests that, unless one knows beforehand the problem's characteristic features, an adaptive mechanism must be used to decide on the fly on the various choices available. Similarly to the combinatorial case (Krasnogor et al. 2002), Ong and Keane propose to use multimeme algorithms for continuous optimization problems (Ong and Keane 2004).
- *Examples:* Other examples on intelligent hybridization strategies for continuous problems could be seen in Lozano et al. (2004) and Molina et al. (2008). In Hart (2003, 2005) it is argued that many of the difficulties in guaranteeing an efficient combination of

local-global search resulting in adequate convergence properties might be tackled by discretizing the decision space. These papers provide both theoretical as well as practical guidance on how to achieve this.

2.2.6 Multimeme Strategy Pattern

In previous sections, it was argued that, for the evolutionary memetic algorithm Template Pattern to be of practical use, it should be further decorated with a series of strategy patterns. Most of these strategy patterns are conceptually linked to considerations about MA's design issues. Chief among these issues is the selection for a given problem instance, at a given point in time during the search process and for a given potential solution (out of a potentially large population), which refinement strategy to use. Deciding which refinement strategy to use can be further extended to decide not only among heuristic methods but also among approximate and exact methods in both the discrete and continuous case. The following strategy pattern addresses this design issue.

Name: Multimeme Strategy Pattern (MSP) [8]

- *Problem statement:* Deciding which type of refinement or complementary search strategy to use at any given time for a given problem instance and a set of candidate solutions is a far from trivial matter. This is particularly difficult in the absence of abundant statistical information on an algorithm's behavior in relation to problem instances' features.
- *The solution:* Rather than deciding *a priori* on a particular search strategy (meme) by which to complement an EMATP, one can incorporate adaptive or self-adaptive techniques that would allow the MA to dynamically change the refinement strategy accordingly to how search is progressing. These methods have been called multimeme algorithms. Several relatively simple schemes have been shown to be extremely successful both for discrete and continuous optimization. For example, Krasnogor and Smith (2001) Krasnogor et al. (2002), Krasnogor and Pelta (2002), Carr et al. (2002), and Krasnogor (2004a) assign to each available local search method-meme a label which, during crossover, is inherited by an offspring from the fittest parent. Thus, the most effective local search methods are adaptively used during the search process and the fittest problem-solving memes survive over generations. As to maintain local search diversity, the mutation operator can also override an inherited local search label and assign a new one, thus ensuring that search is also done in the heuristic (memetic) space. Similarly, for continuous optimization, Ong and Keane (2004) present multimeme algorithms that employ on-line reinforcement performance information to adaptively change the memes used. Also, a roulette wheel decision mechanism can be exploited for sampling memetic space, that is, stochastically selecting (with bias) from the set of available local searchers the one to use next. An extensive discussion on how to "schedule" various local searchers-memes within an EMATP, and the levels at which search performance information can be incorporated into the decision making process behind the selection of each refinement strategy, is available in Krasnogor and Smith (2005, 2008).
- *The consequences:* The on-line adaptation of the local search choice requires some kind of bookkeeping mechanism as to ascertain the usefulness of the various refinement memes during the search. Besides the simple mechanisms for scheduling multimeme algorithms

appearing in the references mentioned above, Smith (2007) discusses other ways of assigning credit to a potentially varying set of local searchers. In principle, any reinforcement-learning (Kaelbling et al. 1996) type of mechanism could be used. A related family of algorithms, called hyperheuristics (Burke et al. 2007c; Dowsland et al. 2007), has been proposed as an attempt to raise the level of generality in problem solving by intelligently managing the application of collections of “low level” heuristics. The learning mechanisms behind hyper-heuristics could also be used within multimeme algorithms (and viceversa).

- *Examples:* Other examples of multimeme strategies appear in Jakob (2006) and Neri et al. (2007a). Multimeme strategies are closely related to adaptive and self-adaptive methods, hence the reader should also refer to the vast literature on the subject. Some pointers are Smith and Smuda (1995), Smith (2001, 2007), and Landa-Silva and Le (2008).

2.2.7 Self-Generating Strategies

Before describing a strategy pattern for self-generating strategies, the etymology of “memetic” in memetic algorithms is revisited and it is argued that there indeed is a promising nature-inspired research direction that could lead to important new algorithmic variants. Memetic theory started as such with the introduction by R. Dawkins of the concept of a meme in Dawkins (1976) and later refined in Dawkins (1982):

- ▶ I think that a new kind of replicator has recently emerged on this very planet. It is staring us in the face. It is still in its infancy, still drifting clumsily about in its primeval soup, but already it is achieving evolutionary change at a rate that leaves the old gene panting far behind. The new soup is the soup of human culture. We need a name for the new replicator, a noun that conveys the idea of a unit of cultural transmission, or a unit of imitation. “Mimeme” comes from a suitable Greek root, but I want a monosyllable that sounds a bit like “gene”. I hope my classicist friends will forgive me if I abbreviate mimeme to meme. If it is any consolation, it could alternatively be thought of as being related to “memory”, or to the French word “même”. It should be pronounced to rhyme with “cream”. Examples of memes are tunes, ideas, catch-phrases, clothes fashions, ways of making pots or of building arches. Just as genes propagate themselves in the gene pool by leaping from body to body via sperms or eggs, so memes propagate themselves in the meme pool by leaping from brain to brain via a process which, in the broad sense, can be called imitation.

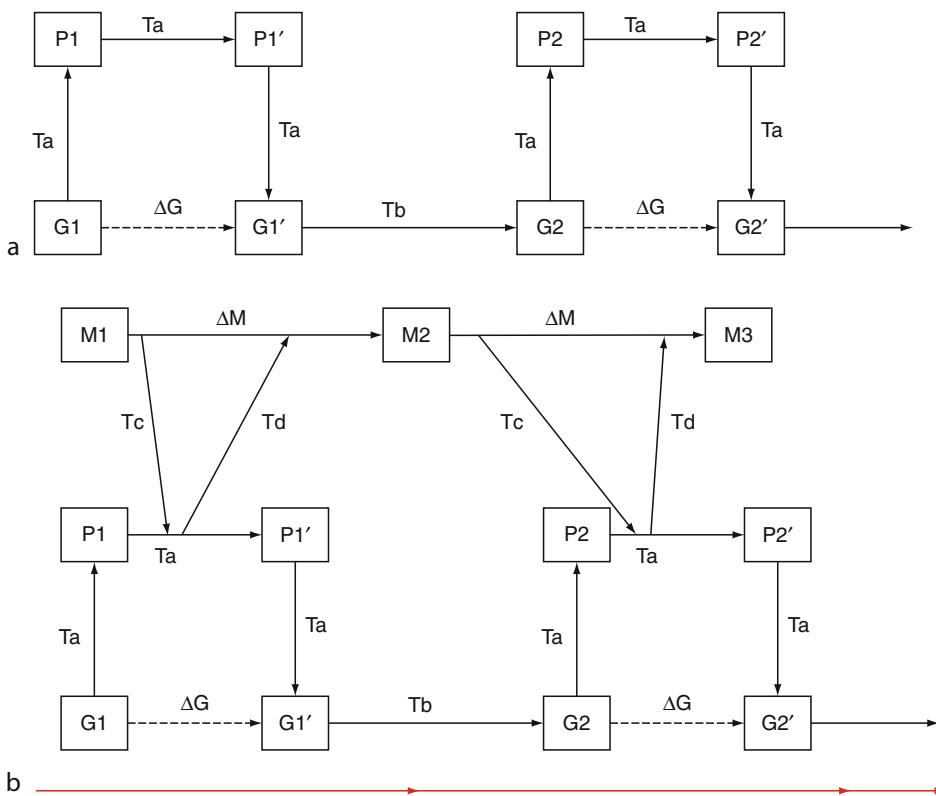

The fact that cultural phenomena could, in certain cases, be modeled or understood as some sort of evolutionary process was not a new idea, for example, the elementary unit of cultural change and/or transmission was sometimes called *m-culture* and *i-culture* (Cloak 1975), *culture-type* (Richerson and Boyd 1978), etc. Durham (1991) provides quite a compelling case for the coevolution of genes and culture in *H. Sapiens*. The fundamental innovation of memetic theory is the recognition that a dual system of inheritance, by means of the existence of two distinct replicators, moulds human culture. Moreover, these two replicators interact and co-evolve shaping each other’s environment. As a consequence, evolutionary changes at the gene level are expected to influence the second replicator, the memes. Symmetrically, evolutionary changes in the meme pool can have consequences for the genes. From a computer science perspective, this is a very appealing nature-inspired computation paradigm as it defines a possible two-scale learning and adaptation mechanism, one at the level of solutions to problems in exactly the same way in which EAs (or any other population-based

metaheuristic) attempts to solve problems and a second level in which the solving methods themselves evolve, or more generally, change. The distinction between standard EAs and a meme-gene evolutionary process can be seen in [Fig. 6a](#) and [Fig. 6b](#), respectively.

In [Fig. 6a](#) a hypothetical population of individuals is represented at two different points in time, generation 1 (G_1) and at a later generation (G_2). In the lower line, G_i for $i = 1, 2$ represents the distribution of genotypes in the population. In the upper line, P_i represents the distribution of phenotypes at the given time. Transformations, T_A , account for epigenetic phenomena, for example, interactions with the environment, in-migration and out-migrations, individual development, etc., all of them affecting the distribution of phenotypes and producing a change in the distribution of genotypes during this generation. On the other hand, transformations, T_B , account for the Mendelian principles that govern genetic inheritance and transform a distribution of genotypes G'_1 into another one G'_2 . Evolutionary computation endeavors to concentrate on the study and assessment of many different ways the cycle depicted in [Fig. 6a](#) can be implemented. This evolutionary cycle implicitly assumes the existence of only one replicator, namely genes, representing solutions to hard and complex problems. On the other hand, [Fig. 6b](#) reflects a coevolutionary system where two replicators

Fig. 6

In (a) evolutionary genetic cycle (adapted from Durham (1991) p 114), (b) Coevolutionary memetic-genetic cycle (adapted from Durham (1991) p 186).

of a different nature interact. In the context of memetic algorithms, memes represent instructions to self-improve. That is, memes specify sets of rules, programs, heuristics, strategies, behaviors, etc., defining the very essence of the underlying search algorithm. Cavalli-Sforza and Feldman (1981) suggest that memetic-genetic search processes might be driven by:

- ▶ the balance of several evolutionary forces: (1) *mutation*, which is both purposive (innovation) and random (copy error); (2) *transmission*, which is not as inert as in biology [i.e., conveyance may also be horizontal and oblique]; (3) *cultural drift* (sampling fluctuations); (4) *cultural selection* (decisions by individuals); and (5) *natural selection* (the consequences at the level of Darwinian fitness)

⦿ *Figure 6b* shows the type of transformations that are possible under a coevolutionary setting, namely, the usual transformations in terms of ‘genes’ and phenotypes distributions but also meme-phenotypes and memes-memes processes. There are mainly two transformations for memes that are depicted, T_C and T_D . Transformations T_C represents the various ways in which “cultural” instructions can reshape phenotypes distributions, for example, individuals learn, adopt, or imitate certain memes or modify other memes. T_D , on the other hand, reflects the changes in memetic distribution that can be expected from changes in phenotypic distributions, for example, those attributed to teaching, preaching, etc. Thus, Dawkin’s memes, and their extensions (Cavalli-Sforza and Feldman 1981; Durham 1991; Gabora 1993; Blackmore 1999) as evolvable search strategies (Krasnogor 1999, 2002, 2004b; Krasnogor and Gustafson 2004; Smith 2003; Burke et al. 2007a) provide a critical link to the possibility of open-ended combinatorial and/or continuous problem solving. Next, a self-generating strategy pattern is illustrated that captures some of the solutions for implementing the above concepts.

Name: Self-Generating Strategy Pattern (SGSP) [9]

- *Problem statement:* The essential problem these strategies tackle can be succinctly put as “how to implement a search mechanism that learns how to search?” or “how to optimize through learning in a reusable manner?” (Please note that this does not refer to the well-known fact that many learning processes can be recast as optimization ones.) This problem statement is not about adaptation or self-adaptation mechanisms that mainly deal with parameter learning within fixed algorithmic templates, but rather how to infer, on the fly, new algorithmic templates that could be useful at a later time.
- *The solution:* Needless to say, this is one of the more recent cutting-edge developments in MA and the proposed solutions are still in their infancy. Self-generating MAs (sometimes called coevolutionary MAs) were first proposed as coevolutionary MAs in Krasnogor (1999) and these first ideas were explained in some more detail in Krasnogor (2002). The first experimental confirmation of the potential behind these strategies came with Krasnogor and Gustafson (2002), Smith (2002a, b), Krasnogor and Gustafson (2003, 2004), and Krasnogor (2004b). The key concept behind these new algorithms was the capturing of algorithmic building blocks through a formal grammar. Through a process not unlike grammatical evolution (O’Neill and Ryan 2003), sentences in the language induced by the grammar were evolved. These evolved sentences represented entire search methods that were self-generated on the fly while attempting to solve a given problem. The above algorithms were used for a range of difficult problems such as polynomial time solvable with low epistasis NK landscapes, polynomial time solvable with high epistasis NK landscapes all the way up to NP hard NK landscapes with both low and high epistasis as well as in randomly generated benchmarks, simplified models of proteins structure prediction and on a real-world bioinformatics application, namely, protein structure comparison.

- *The consequences:* It is evident that a self-generating strategy can only be used in a setting where the problem is either sufficiently hard, that it is worth paying the additional cost of searching an algorithmic design space or for which no good heuristics are available and one is interested in evolving them. Interestingly, after one has evolved a set of refinement strategies, these can be readily used (without need to rediscover them) in new instances or problems, under a multimeme strategy setting. Thus, the self-generating mechanisms described in the papers mentioned above provide a concrete implementation for the nature-inspired gene-meme coevolutionary process depicted in [Fig. 6b](#).
- *Examples:* Recent papers exploiting GP-type learning processes for evolving problem solvers are Geiger et al. (2006), Burke et al. (2006, 2007a, b), Pappa and Freitas (2007), Bader-El-Din and Poli (2007, 2008), Fukunaga (2008), Tabacman et al. (2008), and Tay and Ho (2008). It is important to note that from this set of examples, only Fukunaga (2008) evolve algorithms, the others evolve rules or evaluation functions that guide other heuristics. Thus Krasnogor and Gustafson (2002, 2003, 2004), Smith (2002a, b), Krasnogor (2004b), and Fukunaga (2008) are the closest examples available of a coupled optimization-learning process such as the one depicted in [Fig. 6b](#).

3 A Pragmatic Guide to Fitting It All Together

In previous sections, the core nine terms defining a pattern language for memetic algorithms were described. From an analysis of the literature and software available, the following patterns define our language.

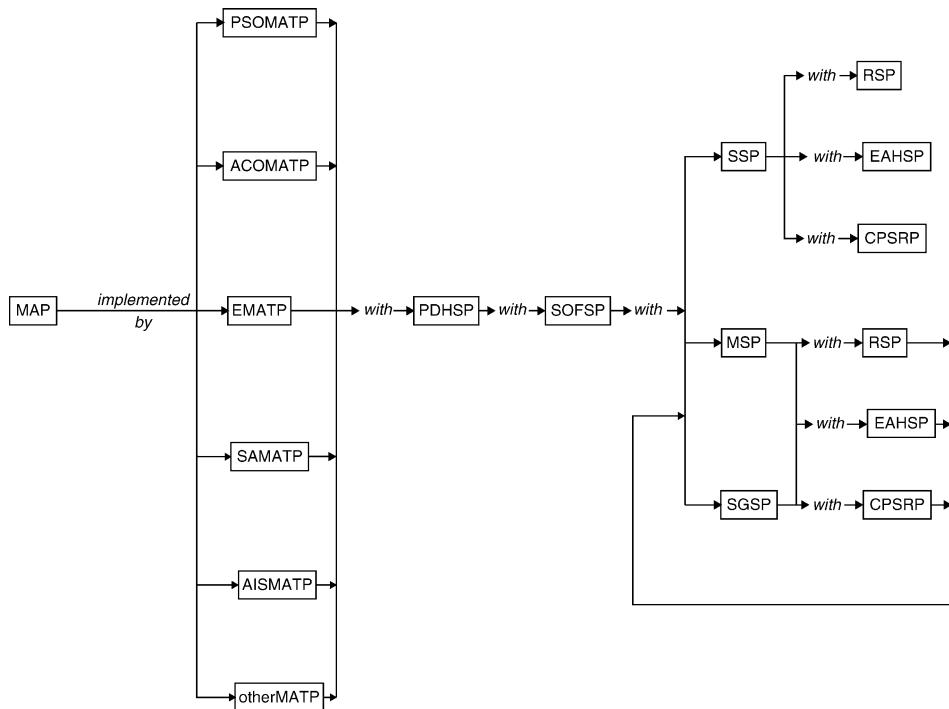

At the top of the conceptual hierarchy, the memetic algorithm pattern (MAP) appears. Its aim is to provide organizational principles for effective global-local search on hard problems. MAP can be implemented through a number of available (successful) templates some of which are based on particle swarm optimization, ant colony optimization, evolutionary algorithms, etc. Each of these gives rise to new terms in the language, namely, the EMATP (for the evolutionary memetic algorithm algorithmic template), the ACOMATP (for the ant colony memetic algorithm template), the SAMATP (for the simulated annealing memetic algorithm template), etc. Each of these nature-inspired paradigm templates have their own “idiosyncrasies.” However, at the time of implementing them as memetic algorithms, the following common features are captured in new design patterns, namely, the refinement strategy pattern (RSP), with focus on heuristic and local search methods, the exact and approximate hybridization strategy pattern (EAHSP) that defines ways in which expensive exact (or approximate) algorithms are integrated with a memetic algorithms template pattern under any nature-inspired realization. Two other terms in our pattern language are the population diversity handling strategy pattern (PDHSP), dealing with ways to preserve – in the face of aggressive refinement strategies – global diversity and the surrogate objective function strategy pattern (SOFSP) whose role is to define methods for dealing within a memetic algorithm with very expensive/noisy/undetermined objective functions. Finally, the pattern language presented also includes terms for defining the “generation” of memetic algorithm one is trying to implement. A memetic algorithm of the first generation in which only one refinement strategy is used, is called a simple strategy pattern (SSP) and that is the canonical MAs (e.g., see [Fig. 3](#)). The multimeme strategy pattern (MSP) and the self-generating strategy pattern (SGSP), which provide methods for utilizing several refinement strategies simultaneously and

for synthesizing new refinement strategies on the fly respectively, are second and third generation MAs. Thus the resulting pattern language has at least the following terms: {MAP, EMATP, PSOMATP, ACOMATP, SAMATP, . . . , AISMATP, RSP, EASHP, CPRSP, PDHSP, SOFSP, SSP, MSP, SGSP}.

These patterns are functionally related as depicted in [Fig. 7](#) that represents the series of design decisions involved in the implementation of memetic algorithms. One could choose to implement an MA by following, for example, an ant colony optimization template or – more often – an evolutionary algorithm template or any of the other template patterns. Each one of these nature-inspired template patterns will have their own algorithmic peculiarities, for example, crossovers and mutations for EAs, pheromones updating rules for ACOs, etc., but all of them when taken as a memetic algorithm will need to address the issues of population diversity, refinement strategies, exact algorithms, surrogate objective functions, single meme versus multimeme versus self-generation, etc. In order to instantiate code for any of these design patterns, one can simply look at the description of the design pattern provided in this chapter and refer to any of the literature references given within the pattern description. Thus, [Fig. 7](#) provides a reference handbook for MAs engineering.

Fig. 7

Integrative view of the design patterns for the memetic algorithms patterns language. A path through the graph represents a series of design decision that an algorithms engineer would need to take while implementing an MA. Each design pattern provides solutions to specific problems the pattern addresses. By indexing through the patterns' acronyms into the main text in this chapter, the reader can have access to examples from the literature where the issues have been solved to satisfaction.

4 Brief Notes on Theoretical Aspects

Memetic algorithms' notorious successes in practical applications notwithstanding, no systematic effort has been made to try to understand them from a theoretical viewpoint. Memetic algorithms do not adhere to pure EA theory, not even those applied to continuous problems for which convergence analysis are somewhat easier. Moreover, MAs are also much more complex than other heuristic methods such as greedy-like algorithms for which precise theoretical knowledge is possible. Thus, while the body of empirical knowledge is steadily growing, their theoretical underpinnings remain poorly understood. A collection of disjoint, but only partial, analyses were published in, e.g., Krasnogor and Smith (2005), Sudholt (2007) for MAs applied to combinatorial optimization and Hart (2003, 2005) for continuous optimization. Two emerging methodologies to assess heuristic performance that might in the future lead to important insights for MAs are PLS-theory (Johnson et al. 1988; Yannakakis 1997) and Domination analysis (Glover and Punnen 1997; Gutin and Yeo 2006). Recent results based on both of these theoretical approaches to heuristic analysis are compiled in Michiels et al. (2007). For an organizational perspective of the field, the reader is also referred to the papers by Krasnogor and Smith (2005) and Ong et al. (2006) in which several best practices are described and research lines proposed.

5 The Future: Toward Nature-Inspired Living Software Systems

Memetic algorithms have gone through three major transitions in their evolution. The first transition was coincidental with their introduction and the bulk of the research and applications produced was based on the use of, mainly, an evolutionary algorithm with one specialized local searcher. The second transition brought the concept of multimeme algorithms that expanded the repertoire of both the key skeleton, that is, EAs were no longer the only global search template used but rather any global-(population) based search could be employed, and gave way to the constraint on having a single local searcher. The third major transition is taking place right now and involves the incorporation of explicit learning mechanisms that can, while optimizing, "distill" new refinement operators. These new operators, in turn, can be reused in a later application of the MA, thus amortizing the cost invested in discovering them. This third transition is also producing more frequent and more confident use of exact methods in tandem or hybridized with MAs. This third major transition is likely to produce very exciting results over the next few years and indeed much research remains to be done in the theory and practice of memetic algorithms.

The question that needs to be briefly addressed is "what's next?" "where do memetic algorithms go from here?"

Memetic algorithms in particular and optimization algorithms in general are but one class of the millions of different software systems humans create to solve problems. The vast majority – if not all – of software systems development follows, to various degrees of formalism and details, a process of requirement collection, specification, design, implementation, testing, deployment, and long term maintenance. There are, indeed, a variety of software engineering techniques that advocate the concurrent realization or elimination altogether of (some of) these steps as a way to achieve a more agile software development. The unrelenting scaling up of available computational, storage, and communication power is

bringing closer the day when software will cease to be created following such a process and will, instead, be “planted/seeded” within a production environment (e.g., a factory, university, bank, etc.) and then “grown” from the bottom-up into a fully developed functional software system. Although within the remit of optimization problems, self-generating techniques such as Krasnogor and Gustafson (2002), Smith (2002a, b), Krasnogor and Gustafson (2003, 2004), Krasnogor (2004b), Burke et al. (2006, 2007a, b), Pappa and Freitas (2007), Bader-El-Den and Poli (2008), Fukunaga (2008), and Tabacman et al. (2008) are moving incrementally in this direction, perhaps an even more radical scenario can be imagined. Consider, for example, a given production environment, a factory, where a series of optimization problems must be solved routinely, such as personnel rostering (Π_{pr}), job-shop schedules (Π_{jss}), path planning (Π_{pp}), inventory management (Π_{in}), etc. Each of these problems, during long periods of time (weeks, months, years, and even decades) give rise to large collections of problem instances (I_{Π_j} with $j \in \{\Pi_{pr}, \Pi_{jss}, \Pi_{pp}, \Pi_{in}\}$). Current practice dictates that for each Π , a tailor-made solver is used that in practice works well for the associated $I(\Pi)$. A key observation worth making is that the distribution of instances for each of the problems arising from a given factory (or bank, university, supermarket, airport, etc.) is not random but rather strongly dependent on physical, legal, commercial, and societal constraints operating over the factory. That is, the instances derived from each one of these problems, for a given factory, will have strong common features and similarities. This, in turn, provides a tremendous opportunity for a more organic and autonomic problem solving. What we have in mind can best be described as a new discipline of “pluripotential problem solvers (PPS).” The idea behind pluripotential problem solvers is that a minimum set of self-generating features would be hardcoded into a given pluripotential solver cell (PSC), then this software cell would be immersed (in multiple copies) into the factory environment and bombarded with problem instances over a period of time. After a while, some of the PSC would differentiate along problem instance lines (very much as a stem cell differentiates along cell type lines). Once differentiated, a mature PSC (or solver cell for simplicity) would only be sensitive to new instances of the same problem. Furthermore, as time progresses, the solver cell would be able to incorporate new problem-specific and instance-distribution-specific problem solving capabilities (e.g., perhaps using some refinement of the technologies described in the self-generating strategy pattern) thus further specializing. In the end, the set of initially planted PSC would have been developing along very specialized lines within a specific production environment. Needless to say, if one were to transplant a specialized solver cell operating on, let’s say, Π_{jss} in factory 1 as a solver for Π_{jss} in factory 2, the performance of the solver will be limited because, unless the distributions of instances generated in both factories are very similar, the specialized solver cell would not be able to cope with the new ones as it would have lost its capacity to specialize. What one would rather do is seed again in factory 2 a new set of PSC and let them mature within their production environment. The scenario described above is predicated under two key assumptions. The first one is that one does not expect to have a cutting-edge solver “out of the tin” (for which arguably one would be willing to pay considerable amounts of money) but rather than one would pay less (or nothing) for a PSC and be willing to wait until the software grows into a very specialized, niche-specific, cutting-edge solver. The second assumption is that computational power, communication bandwidth, and storage capacity will keep increasing while the price per floating point operation and gigabytes transmitted/stored will go on decreasing. The advent of pluripotential problem solvers will require a concerted, creative, and unorthodox research on the amalgamation of optimization algorithms, data mining, and machine learning as well as more in-depth studies of nature-inspired

principles that – complementing evolutionary approaches – so far have not been tapped for optimization, namely, the creative power of self-assembly and self-organization (Krasnogor et al. 2008).

6 Conclusions

This chapter provided an unorthodox introduction to memetic algorithms. It analyzed memetic algorithms as they appear in the literature and are used in practice, rather than conforming to a top down definition of what a memetic algorithm is and then, based on a definition, prescribe how to implement them. The approach taken here allows for a pragmatic view of the field and provides a recipe for creating memetic algorithms by resorting to a shared pattern language. This emerging pattern language for memetic algorithms serves as a catalog of parts (or concerns) that an algorithms engineer might want to resort to for solving specific design issues arising from the need to interlink global search and local search for hard complex problems. Due to space and time constraints, design patterns for multiobjective (Burke and Landa-Silva 2004; Li and Landa-Silva 2008) problems, parallelization strategies (Alba and Tomassini 2002; Nebro et al. 2007), etc., have not been considered, and how these important new components of the pattern language would interact with the patterns described here is also not discussed. It is hoped that the pattern language for MAs presented in this chapter will, in the future, be expanded and refined by researchers and practitioners alike.

Acknowledgments

The author would like to acknowledge the many friends and colleagues with whom he has collaborated over the years. Their ideas, scientific rigor and enthusiasm for memetic algorithms has been a continuous source of inspiration and challenges. The author would also like to thank Jonathan Blakes and James Smaldon for their valuable comments during the preparation of this paper. The author wishes to acknowledge funding from the EPSRC for projects EP/D061571/1 and EP/C523385/1. Finally, the editors of this book are thanked for giving the author an opportunity to contribute.

Abstract

This is a survey of the field of genetics-based machine learning (GBML): the application of evolutionary algorithms (ES) to machine learning. We assume readers are familiar with evolutionary algorithms and their application to optimization problems, but not necessarily with machine learning. We briefly outline the scope of machine learning, introduce the more specific area of supervised learning, contrast it with optimization and present arguments for and against GBML. Next we introduce a framework for GBML, which includes ways of classifying GBML algorithms and a discussion of the interaction between learning and evolution. We then review the following areas with emphasis on their evolutionary aspects: GBML for subproblems of learning, genetic programming, evolving ensembles, evolving neural networks, learning classifier systems, and genetic fuzzy systems.

1 Introduction

Genetics-based machine learning (GBML) is the application of evolutionary algorithms (EAs) to machine learning. We assume readers are familiar with EAs, which are well documented elsewhere, and their application to optimization problems. In this introductory section we outline the scope of machine learning, introduce the more specific area of supervised learning, and contrast it with optimization. However, the treatment is necessarily brief and readers who desire to work in GBML are strongly advised to first gain a solid foundation in non-evolutionary approaches to machine learning. ➤ Sect. 2 describes a framework for GBML, which includes ways of classifying GBML algorithms and a discussion of the interaction between learning and evolution. ➤ Sect. 3 reviews the work of a number of GBML communities with emphasis on their evolutionary aspects. Finally, ➤ Sect. 4 concludes the chapter.

What is Missing

Given the breadth of the field and the volume of the literature, the coverage herein is necessarily somewhat arbitrary and misses a number of significant subjects. These include a general introduction to machine learning including the structure of learning problems and their fitness landscapes (which we must exploit in order to learn efficiently), non-evolutionary algorithms (which constitute the majority of machine learning methods, and include both simple and effective methods), and theoretical limitations of learning (such as the *no free lunch* theorem for supervised learning (Wolpert 1996) and the *conservation law of generalization* (Schaffer 1994)). Also missing is coverage of GBML for clustering, reinforcement learning, Bayesian networks, artificial immune systems, artificial life, and application areas. Finally, some areas which have been touched on have been given an undeservedly cursory treatment, including EAs for data preparation (e.g., feature selection), coevolution, and comparisons between GBML and non-evolutionary alternatives. However, Freitas (2002a) contains good treatments of GBML for, among others, clustering and data preparation.

1.1 Machine Learning

Machine learning is concerned with machines that improve with experience and reason inductively or abductively in order to optimize, approximate, summarize, generalize from specific examples to general rules, classify, make predictions, find associations, propose

explanations, and propose ways of grouping things. For simplicity, we will restrict ourselves to classification and optimization problems.

Inductive Generalization

Inductive generalization refers to the inference of unknown values from known values. Induction differs from deduction in that the unknown values are in fact *unknowable*, which gives rise to fundamental limitations in what can be learned. (If at a later time new data makes all such values known the problem ceases to be inductive.) Given that the unknown values are unknowable, we *assume* they are correlated with the known values and we seek to learn the correlations. We formulate our objective as maximizing a function of the unknown values. In evolutionary computation this objective is called the fitness function, whereas in other areas the analogous feedback signal may be known as the error function, or by other names. There is *no need for induction* if: (i) all values are known and (ii) there is enough time to process them. We consider two inductive problems: function optimization and learning. We will not deal with abduction.

1-Max: A Typical Optimization Problem

The 1-max problem is to maximize the number of 1s in a binary string of length n . The optimal solution is trivial for humans although it is less so for EAs. The *representation* of this problem follows. Input: none. Output: bit strings of length n . *Data generation*: we can generate as many output strings as time allows, up to the point where we have enumerated the search space (in which case the problem ceases to be inductive). *Training*: the fitness of a string is the number of 1s it contains. We can evaluate a learning method on this task by determining how close it gets to the known optimal solution. In more realistic problems, the optimum is not known and we may not even know the maximum possible fitness. Nonetheless, for both toy and realistic problems, we can evaluate how much training was needed to reach a certain fitness and how a learning method compares to others.

Classification of Mushrooms: A Typical Learning Problem

Suppose we want to classify mushroom species as poisonous or edible given some training data consisting of features of each species (color, size and so on) including edibility. Our task is to learn a hypothesis, which will classify new species whose edibility is unknown. *Representation*: the input is a set of nominal attributes and the output is a binary label indicating edibility. *Data generation*: a fixed dataset of input/output examples derived from a book. Typically the dataset is far, far smaller than the set of possible inputs, and we partition it into train and test sets. *Training*: induce a hypothesis which maximizes classification accuracy on the train set. *Evaluation*: evaluate the accuracy of the induced hypothesis on the test set, which we take as an indication of how well a newly encountered species might be classified.

Terminology in Supervised Learning

Although many others exist, we focus on the primary machine learning paradigm: standard supervised learning (SL), of which the preceding mushroom classification task is a good example. In SL we have a dataset of labeled input/output pairs. Inputs are typically called instances or exemplars and are factored into attributes (also called features), while outputs are called classes (for classification tasks) or the output is called the dependent variable (for regression tasks).

Comparison of Supervised Learning and Optimization

In SL we typically have limited training data and it is crucial to find a good inductive bias for later use on new data. Consequently, we *must* evaluate the generalization of the induced hypothesis from the train set to the previously unused test set. In contrast, in optimization we can typically generate as much data as time allows and we can typically evaluate any output. We are concerned with finding the optimum output in minimum time, and, specifically, inducing which output to evaluate next. As a result no test set is needed.

Issues in Supervised Learning

A great many issues arise in SL including overfitting, underfitting, producing human readable results, dealing with class imbalances in the training data, asymmetric cost functions, noisy and nonstationary data, online learning, stream mining, learning from particularly small datasets, learning when there are very many attributes, learning from positive instances only, incorporating bias and prior knowledge, handling structured data, and using additional unlabeled data for training. None of these will be dealt with here.

1.2 Arguments For and Against GBML

GBML methods are a niche approach to machine learning and much less well-known than the main non-evolutionary methods, but there are many good reasons to consider them.

Accuracy

Importantly, the classification accuracy of the best evolutionary and non-evolutionary methods are comparable (Freitas 2002a, Sect. 12.1.1).

Synergy of Learning and Evolution

GBML methods exploit the synergy of learning and evolution, combining global and local search and benefitting from the Baldwin effect's smoothing of the fitness landscape (Sect. 2.3).

Epistasis

There is some evidence that the accuracy of GBML methods may not suffer from epistasis as much as typical non-evolutionary greedy search (Freitas 2002a, Sect. 12.1.1).

Integrated Feature Selection and Learning

GBML methods can combine feature selection and learning in one process. For instance, feature selection is intrinsic in LCS methods (Sect. 3.5).

Adapting Bias

GBML methods are well-suited to adapting inductive bias. We can adapt representational bias by, for example, selecting rule condition shapes (Sect. 3.5.3), and algorithmic bias by, for example, evolving learning rules (Sect. 3.4).

Exploiting Diversity

We can exploit the diversity of a population of solutions to combine and improve predictions (the ensemble approach, (Sect. 3.3) and to generate Pareto sets for multi-objective problems.

Dynamic Adaptation

All the above can be done dynamically to improve accuracy, to deal with nonstationarity, and to minimize population size. This last is of interest in order to reduce overfitting, improve run-time, and improve readability.

Universality

Evolution can be used as a wrapper for *any* learner.

Parallelization

Population-based search is easily parallelized.

Suitable Problem Characteristics

From an optimization perspective, learning problems are typically large, non-differentiable, noisy, epistatic, deceptive, and multimodal (Miller et al. 1989). To this list we could add high-dimensional and highly constrained. EAs are a good choice for such problems. See Cantú-Paz and Kamath (2003) and [Sect. 3.4](#) for more arguments in favor of and against GBML.

Algorithmic Complexity

GBML algorithms are typically more complex than their non-evolutionary alternatives. This makes them harder to implement and harder to analyze, which means there is less theory to guide parameterization and development of new algorithms.

Increased Run-time

GBML methods are generally much slower than the non-evolutionary alternatives.

Suitability for a Given Problem

No single learning method is a good choice for all problems. For one thing the bias of a given GBML method may be inappropriate for a given problem. Problems to which GBML methods are particularly prone include prohibitive run-time (or set-up time) and that simpler and/or faster methods may suffice. Furthermore, even where GBML methods perform better, the improvements may be marginal. See the strengths, weaknesses, opportunities, threats (SWOT) analysis of GBML in Orriols-Puig et al. ([2008b](#)) for more.

2 A Framework for GBML

The aim of the framework presented in this section is to structure the range of GBML systems into more specific categories about which we can make more specific observations than we could about GBML systems as a whole. We present two categorizations. In the first ([Sect. 2.1](#)), GBML systems are classified by their role in learning; specifically their applications to i) subproblems of machine learning, ii) learning itself, or iii) meta-learning. In the second categorization ([Sect. 2.2](#)), GBML systems are classified by their high-level algorithmic approach as either Pittsburgh or Michigan systems. Following this, in [Sect. 2.3](#) we briefly review ways in which learning and evolution interact and in [Sect. 2.4](#) we consider various models of GBML not covered earlier.

Before proceeding, we note that evolution can output a huge range of phenotypes, from scalar values to complex learning agents, and that agents can be more or less plastic (independent of evolution). For example, if evolution outputs a fixed hypothesis, that hypothesis has no plasticity. In contrast, evolution can output a neural net which, when trained with backpropagation, can learn much. (In the latter approach, evolution may specify the network structure while backpropagation adapts the network weights.)

Structure of GBML Systems

We can divide any evolutionary (meta)-learning system into the following parts: (i) *Representation*, which consists of the genotype (the learner's genes) and phenotype (the learner itself, built according to its genes). In simple cases, the genotype and phenotype may be identical, for example with the simple ternary LCS rules of [Sect. 3.5.2](#). In other cases, the two are very different and the phenotype may be derived through a complex developmental process (as in nature); see [Sect. 3.4](#) on developmental encodings for neural networks. (ii) *Feedback*, which consists of the learner's objective function (e.g., the error function in supervised learning) and the fitness function which guides evolution. (iii) *The production system*, which applies the phenotypes to the learning problem. (iv) *The evolutionary system*, which adapts genes.

2.1 Classifying GBML Systems by Role

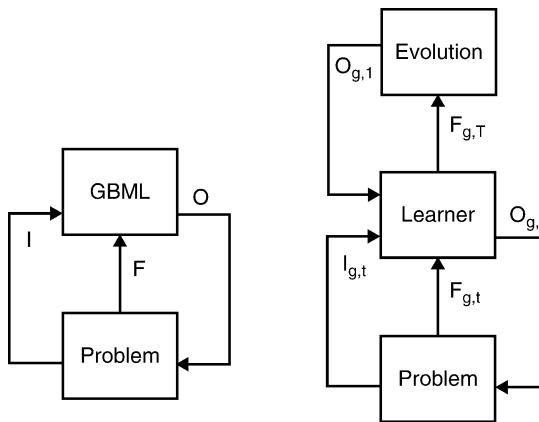

In order to contrast learning and meta-learning, we define learning as a process which outputs a fixed hypothesis. Accordingly, when evolution adapts hypotheses it is a learner and when it adapts learners it is a meta-learner. However, this distinction between learning and meta-learning should not be overemphasized; if evolution outputs a learner with little plasticity then evolution may be largely responsible for the final hypothesis, and in this case plays both a learning and a meta-learning role. Furthermore, both contribute to the ultimate goal of adaptation, and in [Sect. 2.3](#) we will see ways in which they interact.

Evolution as learning is illustrated in the left of [Fig. 1](#), which shows a GBML agent interacting directly with the learning problem. In contrast, the right of the figure shows GBML as meta-learning: the learner (or a set of learners) is the output of evolution, and the learner interacts directly with the learning problem while evolution interacts with it only through learners. At time step 1 of each generation, evolution outputs a learning agent and at the generation's final step, T, it receives an evaluation of the learner's fitness. During the intervening time steps the learner interacts with the problem. This approach to meta-learning is *universal* as any learner can be augmented by GBML, and is related to the wrapper approach to feature selection in [Sect. 3.1](#).

Meta-learning is a broad term with different interpretations but the essential idea is *learning about learning*. A meta-learner may optimize parameters of a learner, learn which learner to apply to a given input or a given problem, learn which representation(s) to use, optimize the update rules used to train learners, learn an algorithm which solves the problem, evolve an ecosystem of learners, and potentially be open ended. See Vilalta and Drissi ([2002](#)) and Giraud-Carrier and Keller ([2002](#)) on non-evolutionary meta-learning and Burke et al. ([2003](#)), Krasnogor ([2004](#)), Krasnogor and Gustafson ([2004](#)), and Burke and Kendall ([2005](#)) on the hyperheuristics (*heuristics to learn heuristics*) approach, of which a subset is evolutionary.

Fig. 1

(Left) GBML as learner. Input, Output, and Fitness shown. (Right) GBML as meta-learner. Subscripts denote generation and time step ($1 \dots T$).

A third role for evolution is application to various subproblems of learning including feature selection, feature construction, and other optimization roles within learning agents. In these cases evolution neither outputs the final hypothesis nor outputs a learning agent which does so. **Section 3.1** deals with such applications.

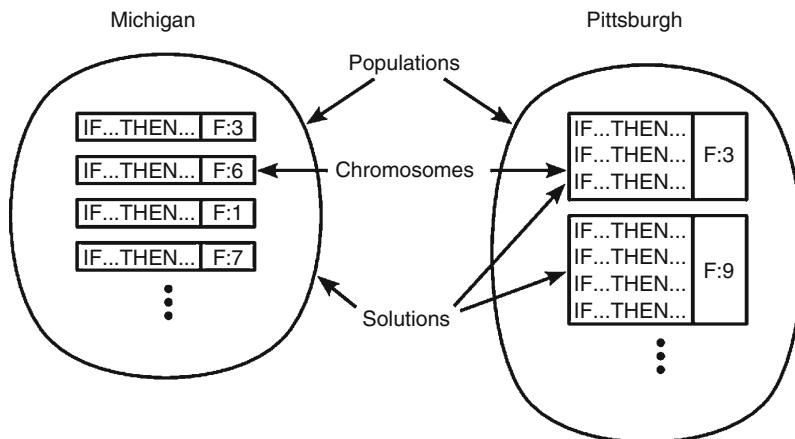

2.2 Classifying GBML Systems Algorithmically

In the Pittsburgh (Pitt) approach, one chromosome encodes one solution. We assume that fitness is assigned to chromosomes, so in Pitt systems it is assigned to solutions. This leaves a credit assignment problem: how did the chromosome's component genes contribute to the observed fitness of the chromosome? This is left to evolution as this is what EAs are designed to deal with. In the Michigan approach, one solution is (typically) represented by many chromosomes and so fitness is assigned to partial solutions. Credit assignment differs from the Pitt case as chromosomes not only compete for reproduction but may also complement and cooperate with each other. This gives rise to the issues of how to encourage cooperation, complementarity, and coverage of the inputs, all of which makes designing an effective fitness function more complex than in Pitt systems. In Michigan systems, the credit assignment problem is how to measure a chromosome's contributions to the overall solution, as reflected in the various aspects of fitness just mentioned. To sum up the difficulty in Michigan systems: the best set of chromosomes may not be the set of best (i.e., fittest) chromosomes (Freitas 2002a). To illustrate, **Fig. 2** depicts the representation used by Pitt and Michigan versions of the rule-based systems called learning classifier systems (LCS) (see **Sect. 3.5**). In a Pittsburgh LCS, a chromosome is a variable-length *set* of rules, while in a Michigan LCS, a chromosome is a single fixed-length rule.

Although the Pittsburgh and Michigan approaches are generally presented as two discrete cases, some hybrids exist (e.g., Wilcox (1995)).

Fig. 2

Michigan and Pittsburgh rule-based systems compared. The F:x associated with each chromosome indicates its fitness.

Pittsburgh and Michigan Compared

Pittsburgh systems (especially naive implementations) are slower, since they evolve more complex structures and they assign credit at a less specific (and hence less informative) level. (See, however, [Sect. 3.5.5](#) on the windowing approach to improving run-time and Bacardit et al. (2009a) for an approach which avoids performing matching operations between rule conditions and irrelevant features.) Additionally, their chromosomes and their genetic operators are more complex. On the other hand they face less complex credit assignment problems and hence are more robust, that is, more likely to adapt successfully. Michigan systems use a finer grain of credit assignment than the Pittsburgh approach, which means bad partial solutions can be deleted without restarting from scratch. This makes them more efficient and also more suitable for incremental learning. However, credit assignment is more complex in Michigan systems. Since the solution is a *set* of chromosomes: (i) the population must not converge fully, and (ii) as noted, the best set of chromosomes may not be the set of best chromosomes.

The two approaches also tend to be applied in different ways. Pitt systems are typically used offline and are algorithm-driven; the main loop processes each chromosome in turn and seeks out data to evaluate them (which is how a standard genetic algorithm (GA) works, although fitness evaluation is typically simpler in a GA). In contrast, Michigan systems are typically used online and are data-driven; the main loop processes each data input in turn and seeks out applicable chromosomes (see [Fig. 3](#)). As a result, Michigan systems are more often used as learners (though not necessarily more often as meta-learners) for reinforcement learning, which is almost always online. The Michigan approach has mainly been used with LCS. See Greene and Smith (1993), Janikow (1993), Wilcox (1995), Freitas (2002b) and Kovacs (2004) for comparison of the approaches.

Iterative Rule Learning

IRL is a variation on the Michigan approach in which, as usual, one solution is represented by many chromosomes, but only the single best chromosome is selected after each run, which

Fig. 3**A basic Michigan algorithm.**

On each time step:

1. Identify match set: subset of population which match current input
2. Compute support in match set for each class
3. Select class
4. Identify action set: subset of match set which advocate selected class
5. Update action set based on feedback
6. Optionally alter population

alters the coevolutionary dynamics of the system. The output of multiple runs is combined to produce the solution. The approach originated with SIA (Supervised Inductive Algorithm) (Venturini 1993; Juan Liu and Tin-Yau Kwok 2000), a supervised genetic rule learner.

Genetic Cooperative-Competitive Learning

GCCL is another Michigan approach in which each generation is ranked by fitness and a *coverage-based filter* then allocates inputs to the first rule which correctly covers them. Inputs are only allocated to one rule per generation and rules which have no inputs allocated die at the end of a generation. The collective accuracy of the remaining rules is compared to the previous best generation, which is stored offline. If the new generation is more accurate (or the same but has fewer rules) it replaces the previous best. Examples include COGIN (Greene and Smith 1993, 1994), REGAL (Giordana and Neri 1995), and LOGENPRO (Wong and Leung 2000).

2.3 The Interaction of Learning and Evolution

This section briefly touches on the rich interactions between evolution and learning.

Memetic Learning

We can characterize evolution as a form of global search, which is good at finding good basins of attraction, but poor at finding the optimum of those basins. In contrast, many learning methods are forms of local search and have the opposite characteristics. We can get the best of both by combining them, which generally outperforms either alone (Yao 1999). For example, evolving the initial weights of a neural network and then training them with gradient descent can be two orders of magnitude faster than using random initial weights (Floreano et al. 2008). Methods which combine global and local search are called *memetic* algorithms (Hart et al. 2004, 2005; Ong et al. 2006, 2007; Smith 2007; Ong et al. 2009; Rozenberg et al. 2012). See Krasnogor and Smith (2005) for a self-contained tutorial.

Darwinian and Lamarckian Evolution

In Lamarckian evolution/inheritance, learning during an individual's lifetime directly alters the genes passed to offspring, so offspring inherit the result of their parents' learning. This does not occur in nature but can in computers and has the potential to be more efficient than Darwinian evolution since the results of learning are not thrown away. Indeed, Ackley and

Littman (1992) showed Lamarckian evolution was much faster on stationary learning tasks but Sasaki and Tokoro (1997) showed Darwinian evolution was generally better on nonstationary tasks. See also Whitley et al. (1994), Yamasaki and Sekiguchi (2000), Pereira and Costa (2001), and Whiteson and Stone (2006).

The Baldwin Effect

The Baldwin effect is a two-part dynamic between learning and evolution which depends on *Phenotypic Plasticity* (PP): the ability to adapt (e.g., learn) during an individual's lifetime. The first aspect is this. Suppose a mutation would have no benefit except for PP. Without PP, the mutation does not increase fitness, but with PP it does. Thus PP helps evolution to adopt beneficial mutations; it effectively smooths the fitness landscape. A possible example from nature is lactose tolerance in human adults. At a recent point in human evolution a mutation occurred, which allowed adult humans to digest milk. Subsequently, humans learned to keep animals for milk, which in turn made the mutation more likely to spread. The smoothing effect on the fitness landscape depends on PP; the greater the PP the more potential there is for smoothing. All GBML methods exploit the Baldwin effect to the extent that they have PP. See Whiteson and Stone (2006, Sect. 7.2) for a short review of the Baldwin effect in reinforcement learning.

The second aspect of the Baldwin effect is genetic assimilation. Suppose PP has a cost (e.g., learning involves making mistakes). If PP can be replaced by new genes, it will be; for instance a learned behavior can become instinctive. This allows learned behaviors to become inherited without Lamarckian inheritance.

Turney (1996) has connected the Baldwin effect to inductive bias. All inductive algorithms have a bias and the Baldwin effect can be seen as a shift from weak to strong bias. When bias is weak, agents rely on learning; when bias is strong, agents rely on instinctive behavior.

Evaluating Evolutionary Search by Evaluating Accuracy

Kovacs and Kerber (2004) point out that high classification accuracy does not imply effective genetic search. To illustrate, they initialized XCS (Wilson 1995) with random condition/action rules and disabled evolutionary search. Updates to estimates of rule utility, however, were made as usual. They found the system was still able to achieve very high training set accuracy on the widely used 6 and 11 multiplexer tasks since ineffective rules were simply given low weight in decision making, though neither removed nor replaced. Care is therefore warranted when attributing good accuracy to genetic search. A limitation of this work is that test set accuracy was not evaluated.

2.4 Other GBML Models

This section covers some models which are orthogonal to those discussed earlier.

Online Evolutionary Computation

In many problems, especially sequential ones, feedback is very noisy and needs averaging. Whiteson and Stone (2006) allocated trials to chromosomes in proportion to their fitness with the following procedure. At each new generation, each chromosome is evaluated once only. Subsequent evaluations are allocated using a softmax distribution based on the initial fitnesses and the average fitness of a chromosome is recalculated after each evaluation. In nonstationary

problems a recency-weighted average of fitness samples is used. This approach is called *online evolutionary computation*. Its advantages are that less time is wasted evaluating weaker chromosomes, and in cases where mistakes matter, fewer mistakes are made by agents during fitness evaluations. However, the improvement is only on average; worst case performance is not improved. This is related to other work on optimizing noisy fitness functions (Stagge 1998; Beielstein and Markon 2002), except that they do not reduce online mistakes.

Steady-State EAs

Whereas standard generational EAs replace the entire population each generation, steady state EAs replace a subset (e.g., only two in XCS). This approach is standard in Michigan LCS because they minimize disruption to the population, which is useful for online learning. Steady state EAs introduce selection for deletion as well as reproduction and this is typically biased toward lower fitness chromosomes or to reduce crowding.

Co-evolving Learners and Problems

Another possibility not mentioned in our earlier classifications is to coevolve both learners and problems. When successful, this allows learners to gradually solve harder problems rather than tackling the most difficult problems from the start. It also allows us to search the space of problems to find those which are harder for a given learner, and to explore the dynamics between learners and problems.

3 GBML Areas

This section covers the main GBML research communities. These communities are more disjoint than the methods they use and the lines between them are increasingly blurring. For example, LCS often evolve neural networks and fuzzy rules, and some are powered by genetic programming. Nonetheless, the differences between the communities and their approaches is such that it seemed most useful to structure this section by community and not, for example, by phenotype or learning paradigm; such integrated surveys of GBML are left to the future. Many communities have reinvented the same ideas, yet each has its own focus and strengths and so each has much to learn from the others.

3.1 GBML for Subproblems of Learning

This section briefly reviews ways in which evolution has been used not for the primary task of learning – generating hypotheses – but for subproblems including data preparation and optimization within other learning methods.

Evolutionary Feature Selection

Some attributes (features) of the input are of little or no use in classification. We can simplify and speed learning by selecting only useful attributes to work with, especially when there are very many attributes and many contribute little. EAs are widely used in the wrapper approach to feature selection (John et al. 1994) in which the base learner (the one which generates hypotheses) is treated as a black box to be optimized by a search algorithm. In this, EAs usually give good results compared to non-evolutionary methods (Jain and Zongker 1997;

Sharpe and Glover (1999); Kudo and Skalansky (2000) but there are exceptions (Jain and Zongker 1997). In Cantú-Paz (2002) Estimation of Distribution Algorithms were found to give similar accuracy but run more slowly than a GA. More generally we can weight features (instead of making an all-or-nothing selection) and some learners can use weights directly, for example, weighted k-nearest neighbors (Raymer et al. 2000). The main drawback of EAs for feature selection is their slowness compared to non-evolutionary methods. See Martin-Bautista and Vila (1999) and Freitas (2002a, b) for overviews, and Stout et al. (2008), Bacardit et al. (2009b) for some recent real-world applications.

Evolutionary Feature Construction

Some features are not very useful by themselves but can be when combined with others. We can leave the base learner to discover this or we can preprocess data to construct informative new features by combining existing ones, for example new feature $f_{\text{new}} = f_1 \text{ AND } f_3 \text{ AND } f_8$. This is also called constructive induction and there are different approaches. GP has been used to construct features out of the original attributes, for example, Hu (1998), Krawiec (2002), and Smith and Bull (2005). The original features have also been linearly transformed by evolving a vector of coefficients (Kelly and Davis 1991; Punch et al. 1993). Simultaneous feature transformation and selection has had good results (Raymer et al. 2000).

Other Subproblems of Learning

EAs have been used in a variety of other ways. One is training set optimization in which we can partition the data into training sets (Romaniuk 1994), select the most useful training inputs (Ishibuchi and Nakashima 2000), and even generate synthetic inputs (Zhang and Veenker 1991; Cho and Cha 1996). EAs have also been used for optimization within a learner, for example, Kelly and Davis (1991) optimized weighted k-nearest neighbors with a GA, Cantú-Paz and Kamath (2003) optimized decision tree tests using a GA and an evolution strategy (ES) and Thompson (1998, 1999) optimized voting weights in an ensemble. Janikow (1993) replaced beam search in AQ with a genetic algorithm and similarly Tameddoni-Nezhad and Muggleton (2000, 2003), Divina and Marchiori (2002), and Divina et al. (2002, 2003) have investigated inductive logic programming driven by a GA.

3.2 Genetic Programming

Genetic Programming (GP) is a major evolutionary paradigm which evolves programs (Vanneschi and Poli 2012). The differences between GP and GAs are not precise but typically GP evolves variable-length structures, typically trees, in which genes can be functions. See Woodward (2003) for discussion. Freitas (2002a) discusses differences between GAs and GP which arise because GP representations are more complex. Among the pros of GP: (i) it is easier to represent complex languages, such as first-order logic in GP, (ii) it is easier to represent complex concepts compactly, and (iii) GP is good at finding novel and complex patterns overlooked by other methods. Among the cons of GP: (i) expressive representations have large search spaces, (ii) GP tends to overfit / does not generalize well, and (iii) variable-length representations suffer from bloat (see, e.g., Poli et al. 2008)).

While GAs are typically applied to function optimization, GP is widely applied to learning. To illustrate, there are many learning problems among the set of “typical GP problems” defined by Koza (1992), which have become more-or-less agreed benchmarks for the

GP community (Vanneschi and Poli 2012), there are many learning problems. These include the multiplexer and parity Boolean functions, symbolic regression of mathematical functions and the intertwined spirals problem, which involves the classification of two-dimensional points as belonging to one of the two spirals. GP usually follows the Pittsburgh approach. We cover the two representations most widely used for learning with GP: GP trees and decision trees.

3.2.1 GP Trees

GP Trees for Classification

Figure 4 shows the 3 multiplexer Boolean function as a truth table on the left and as a GP tree on the right. To classify an input with the GP tree: (i) instantiate the leaf variables with the input values, (ii) propagate values upward from leaves through the functions in the non-leaf nodes and (iii) output the value of the root (top) node as the classification.

GP Trees for Regression

In regression problems leaves may be constants or variables and non-leaves are mathematical functions. Figure 5 shows a real-valued function as an algebraic expression on the left and as

Fig. 4

a GP tree on the right. (Note that $x^2 + 2y^2 - 13 = ((x*x) + (2*(y*y))) - 13$.) The output of the tree is computed in the same way as in the preceding classification example.

3.2.2 Decision Trees

► *Figure 6* shows the 3 multiplexer as a truth table and as a decision tree. To classify an input in such a tree: (i) start at the root (top) of tree, (ii) follow the branch corresponding to the value of the attribute in the input, (iii) repeat until a leaf is reached, and (iv) output the value of the leaf as the classification of the input.

Evolving First-Order Trees

First-order trees use both propositional and first-order internal nodes. Rouwhorst and Engelbrecht (2000) found first-order logic made trees more expressive and allowed much smaller solutions than found by the rule learner CN2 or the tree learner C4.5, with similar accuracy.

Oblique (Linear) Trees

Whereas conventional tree algorithms learn axis-parallel decision boundaries, oblique trees make tests on a linear combination of attributes. The resulting trees are more expressive but have a larger search space. See Bot and Langdon (2000).

Evolving Individual Nodes in Decision Trees

In most GP-based tree evolvers, an individual is a complete tree but in Marmelstein and Lamont (1998) each individual is a tree node. The tree is built incrementally: one GP run is made for each node. This is similar to IRL in ► Sect. 2.2 but results are added to a tree structure rather than a list.

3.2.3 Extensions to GP

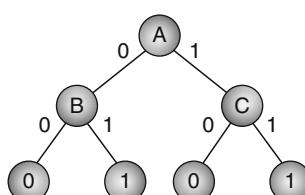

Ensemble Methods and GP

Ensemble ideas have been used in two ways. First, to reduce fitness computation time and memory requirements by training on subsamples of the data. The bagging approach has been used in Folino et al. (2003) and Iba (1999) and the boosting approach in Song et al. (2005).

1	1	1	1

Although not an ensemble technique, the limited error fitness (LEF) method introduced in Gathercole and Ross (1997) as a way of reducing GP run-time works in a similar manner: in LEF, the proportion of the training set used to evaluate fitness depends on the individual's performance. The second ensemble approach improves accuracy by building an ensemble of GP trees. In Keijzer and Babovic (2000) and Paris et al. (2001) each run adds one tree to the ensemble and weights are computed with standard boosting.

GP Hyperheuristics

Schmidhuber (1987) proposed a meta-GP system evolving evolutionary operators as a way of expanding the power of GP's evolutionary search. Instead of evolving decision rules Krasnogor proposes applying GP to the much harder task of evolving classification algorithms, represented using grammars (Krasnogor 2002, 2004; Krasnogor and Gustafson 2004). Freitas (2002a, Sect. 12.2.3) sketches a similar approach, which he calls *algorithm induction*, while (Pappa and Freitas 2010) goes into the subject in much more detail. Burke et al. (2009) also deal with GP hyperheuristics.

3.2.4 Conclusions

Lack of Test Sets in GP

GP terminology follows a convention in the GA field since at least (Holland 1986) in which *brittleness* refers to overfitting or poor generalization to unseen cases, and *robustness* refers to good generalization. A feature of the GP literature is that GP is usually evaluated only on the training set (Kushchu 2002; Vanneschi and Poli 2012). Kushchu has also criticized the way in which test sets have been used (Kushchu 2002). Nonetheless GP has the same need for test sets to evaluate generalization as other methods (Kuschu 2002) and as a result, the ability of GP to perform inductive generalization is one of the open issues for GP identified in Vanneschi and Poli (2012). See Kushchu (2002) and Vanneschi and Poli (2012) for methods which have been used to encourage generalization in GP, many of which can be applied to other methods.

Reading

See Koza's 1994 book (Koza 1994) for the basics of evolving decision trees with GP, Wong and Leung's 2000 book on data mining with grammar-based GP (Wong and Leung 2000), Freitas' 2002 book (Freitas 2002a) for a good introduction to GP, decision trees and both evolutionary and non-evolutionary learning, Poli, Langdon, and McPhee's free 2008 GP book (Poli et al. 2008), and Vanneschi and Poli's chapter on GP in this volume (Vanneschi and Poli 2012). The GP bibliography has over 5,000 entries (Langdon et al. 2009).

3.3 Evolving Ensembles

Ensembles, also called *multiple classifier systems* and *committee machines*, is the field which studies how to combine predictions from multiple sources. Ensemble methods are widely applicable to evolutionary systems where a population intrinsically provides multiple predictors. Ensemble techniques can be used with any learning method, although they are most useful for unstable learners, whose hypotheses are sensitive to small changes in their training. Ensembles can be heterogeneous (composed of different types of predictors) in which case they are called *hybrid* ensembles. Relatively few studies of hybrid systems exist (Brown et al. 2005)

but see for example Woods et al. (1997), Cho and Park (2001), and Chandra and Yao (2006). Ensembles enjoy good theoretical foundations (Brown et al. 1996; Tumer and Ghosh 1996), perform very well in practice (Caruana and Niculescu-Mizil 2006) and were identified by Dietterich as one of the four current directions for machine learning in 1998 (Dietterich 1998). While the key advantage of using ensembles is better test-set generalization, there are others: ensembles can perform more complex tasks than individual members, the overall system can be easier to understand and modify and ensembles are more robust/degrade more gracefully than individual predictors (Sharkey 1996).

Working with an ensemble raises a number of issues. How to create or select ensemble members? How many members are needed? When to remove ensemble members? How to combine their predictions? How to encourage diversity in members? There are many approaches to these issues, among the best known of which are bagging (Breiman 1996, 1998) and boosting (Chandra and Yao 2006a; Meir and Rätsch 2003).

Creating a good ensemble is an inherently multi-objective problem (Valentini and Masulli 2002). In addition to maximizing accuracy we also want to maximize diversity in errors; after all, having multiple identical predictors provides no advantage. On the other hand, an ensemble of predictors which make different errors is very useful since we can combine their predictions so that the ensemble output is at least as good on the training set as the average predictor (Krogh and Vedelsby 1995). Hence we want to create accurate predictors with diverse errors (Dietterich 1998; Hansen and Salamon 1990; Krogh and Vedelsby 1995; Opitz and Maclin 1999; Opitz and Slavlik 1996). In addition we may want to minimize ensemble size in order to reduce run-time and to make the ensemble easier to understand. Finally, evolving variable-length chromosomes without pressure toward parsimony results in bloat (Poli et al. 2008), in which case we have a reason to minimize the size of individual members.

3.3.1 Evolutionary Ensembles

Although most ensembles are non-evolutionary, evolution has many applications within ensembles. (i) *Classifier creation and adaptation*: providing the ensemble with a set of candidate members. (ii) *Voting*: Lam and Suen (1995), Thompson (1998, 1999), and Cho (1999) evolve weights for the votes of ensemble members. (iii) *Classifier selection*: the winners of evolutionary competition are added to the ensemble. (iv) *Feature selection*: generating diverse classifiers by training them on different features (see [Sect. 3.1](#) and Kuncheva (2004, Sect. 8.1.4)). (v) *Data selection*: generating diverse classifiers by training on different data (see [Sect. 3.1](#)). All these approaches have non-evolutionary alternatives. We now go into more detail on two of the above applications.

Classifier Creation and Adaptation

Single-objective evolution is common in evolving ensembles. For example, Liu and Yao (1999) combines accuracy and diversity into a single objective. In comparison, multiobjective evolutionary ensembles are rare (Chandra and Yao 2006) but they are starting to appear for example Abbass (2003) and Chandra and Yao (2006a, b). In addition to upgrading GBML to multi-objective GBML, other measures can be taken to evolve diversity, for example, fitness sharing (Liu et al. 2000) and the coevolutionary fitness method we describe next. Gagné et al. (2007) compare boosting and coevolution of learners and problems – both gradually focus on

cases which are harder to learn – and argue that coevolution is less likely to overfit noise. Their coevolution-inspired fitness works as follows: Let Q be a set of reference classifiers. The hardness of a training input, x_i , is based on how many members of Q misclassify it. The fitness of a classifier is the sum of hardnesses of the inputs, x_i , it classifies correctly. This method results in accurate, yet error-diverse classifiers, since both are required to obtain high fitness. Gagné et al. exploit the population of classifiers to provide Q . They also introduce a greedy margin-based scheme for selection of ensemble members. They find that a simpler off-line version of their evolving ensemble learning (EEL) approach dominates their online version as the latter lacks a way to remove bad classifiers. Good results were obtained compared to Adaboost on six UCI (Asuncion and Newman 2009) datasets.

Evolutionary Selection of Members

There are two extremes. Usually each run produces one member of the ensemble and many runs are needed. Sometimes, however, the entire population is eligible to join the ensemble, in which case only one run is needed. The latter does not resolve the *ensemble selection problem*: which candidates to use? There are many combinations possible from just a small pool of candidates, and, as with selecting a solution set from a Michigan population, the set of best individuals may not be the best set of individuals (that is, the best ensemble). The selection problem is formally equivalent to the feature selection problem (Gagné et al. 2007) (☞ Sect. 3.2). See, for example, Sirlantzis et al. (2001) and Ruta and Gabrys (2001) for evolutionary approaches.

3.3.2 Conclusions

Research directions for evolutionary ensembles include multiobjective evolution (Chandra and Yao 2006a), hybrid ensembles (Chandra and Yao 2006b), and minimizing ensemble complexity (Liu et al. 2000).

Reading

Key works include Opitz and Shavlik's classic 1996 paper on evolving NN ensembles (Opitz and Shavlik 1996), Kuncheva's 2004 book on ensembles (Kuncheva 2004), Chandra and Yao's 2006 discussion of multiobjective evolution of ensembles (Chandra and Yao 2006a), Yao and Islam's 2008 review of evolving NN ensembles (Yao and Islam 2008) and Brown's 2005 and 2010 surveys of ensembles (Brown et al. 2005; Brown 2010). We cover evolving NN ensembles in ☞ Sect. 3.4.

3.4 Evolving Neural Networks

The study of neural networks (NNs) is a large and interdisciplinary area. The term artificial neural network (ANN) is often used to distinguish simulations from biological NNs, but having noted this we shall refer simply to NNs. When evolution is involved such systems may be called evolving artificial neural networks (EANNs) Yao (1999) or evolving connectionist systems (ECosSs) (Kasabov 2007).

A neural network consists of a set of nodes, a set of directed connections between a subset of nodes, and a set of weights on the connections. The connections specify inputs and outputs to and from nodes and there are three forms of nodes: input nodes (for input to the network from the outside world), output nodes, and hidden nodes, which only connect to other nodes.

Nodes are typically arranged in layers: the input layer, hidden layer(s), and output layer. Nodes compute by integrating their inputs using an activation function and passing on their activation as output. Connection weights modulate the activation they pass on and in the simplest form of learning weights are modified while all else remains fixed. The most common approach to learning weights is to use a gradient descent-based learning rule such as back-propagation. The *architecture* of a NN refers to the set of nodes, connections, activation functions, and the plasticity of nodes (that is, whether they can be updated or not). Most often all nodes use the same activation function and in virtually all cases all nodes can be updated. Evolution has been applied at three levels: weights, architecture, and learning rules. In terms of architecture, evolution has been used to determine connectivity, select activation functions, and determine plasticity.

Representations

Three forms of representations have been used: (i) direct encoding (Yao 1999; Floreano et al. 2008) in which all details (connections and nodes) are specified, (ii) indirect encoding (Yao 1999; Floreano et al. 2008) in which general features are specified (e.g., number of hidden layers and nodes) and a learning process determines the details, and (iii) developmental encoding (Floreano et al. 2008) in which a developmental process is genetically encoded (Kitano 1990; Gruau 1995; Nolfi et al. 1994; Husbands et al. 1994; Pal and Bhandari 1994; Sziranyi 1996). Implicit and developmental representations are more flexible and tend to be used for evolving architectures, while direct representations tend to be used for evolving weights alone.

Credit Assignment

Evolving NNs virtually always use the Pittsburgh approach although there are a few Michigan systems (Andersen and Tsoi 1993; Smith and Cribbs 1994; Smith and Cribbs 1997). In Michigan systems, each chromosome specifies only one hidden node, which raises issues. How should the architecture be defined? A simple method is to fix it in advance. How can we make nodes specialize? Two options are to encourage diversity during evolution, for example with fitness sharing, or, after evolution, by pruning redundant nodes (Andersen and Tsoi 1993).

Adapting Weights

Most NN learning rules are based on gradient descent, including the best known: back-propagation (BP). BP has many successful applications, but gradient descent-based methods require a continuous and differentiable error function and often get trapped in local minima (Sutton 1986; Whitley et al. 1990).

An alternative is to evolve the weights which has the advantages that EAs do not rely on gradients and can work on discrete fitness functions. Another advantage of evolving weights is that the same evolutionary method can be used for different types of network (feedforward, recurrent, and higher order), which is a great convenience for the engineer (Yao 1999). Consequently, much research has been done on evolution of weights. Unsurprisingly fitness functions penalize NN error but they also typically penalize network complexity (number of hidden nodes) in order to control overfitting. The expressive power of a NN depends on the number of hidden nodes: fewer nodes = less expressive = fits training data less, while more nodes = more expressive = fits data better. As a result, if a NN has too few nodes it underfits, while with too many nodes it overfits. In terms of training rate, there is no clear winner between evolution and gradient descent; which is better depending on the problem

(Yao 1999). However, Yao (1999) states that evolving weights and architecture is better than evolving weights alone and that evolution seems better for reinforcement learning and recurrent networks. Floreano (2008) suggests evolution is better for dynamic networks. Happily we do not have to choose between the two approaches.

Evolving and Learning Weights

Evolution is good at finding a good basin of attraction but poor at finding the optimum of the basin. In contrast, gradient descent has the opposite characteristics. To get the best of both (Yao 1999) we should evolve initial weights and then train them with gradient descent. Floreano (2008) claims that this can be two orders of magnitude faster than beginning with random initial weights.

Evolving Architectures

Architecture has an important impact on performance and can determine whether a NN under- or over-fits. Designing architectures by hand is a tedious, expert, trial-and-error process. Alternatives include constructive NNs, which grow from a minimal network and destructive NNs, which shrink from a maximal network. Unfortunately, both can become stuck in local optima and can only generate certain architectures (Angeline et al. 1994). Another alternative is to evolve architectures. Miller et al. (1989) make the following suggestions (quoted from Yao (1999)) as to why EAs should be suitable for searching the space of architectures.

- ▶ The surface is infinitely large since the number of possible nodes and connections is unbounded.
- ▶ The surface is nondifferentiable since changes in the number of nodes or connections are discrete and can have a discontinuous effect on EANN's performance.
- ▶ The surface is complex and noisy, since the mapping from an architecture to its performance is indirect, strongly epistatic, and dependent on the evaluation method used.
- ▶ The surface is deceptive since similar architectures may have quite different performance.
- ▶ The surface is multimodal since different architectures may have similar performance.

There are good reasons to evolve architectures and weights simultaneously. If we learn with gradient descent there is a many-to-one mapping from NN genotypes to phenotypes (Yao and Liu 1997). Random initial weights and stochastic learning lead to different outcomes, which makes fitness evaluation noisy, and necessitates averaging over multiple runs, which means the process is slow. On the other hand, if we evolve architectures and weights simultaneously we have a one-to-one genotype to phenotype mapping, which avoids the problem above and results in faster learning. Furthermore, we can co-optimize other parameters of the network (Floreano 2008) at the same time. For example, Belew et al. (1992) found the best networks had a very high learning rate which may have been optimal due to many factors such as initial weights, training order, and amount of training. Without co-optimizing, architecture and weights evolution would not have been able to take all factors into account at the same time.

Evolving Learning Rules (Yao 1999)

There is no one best learning rule for all architectures or problems. Selecting rules by hand is difficult and if we evolve the architecture then we do not know *a priori* what it will be.

A way to deal with this is to evolve the learning rule, but we must be careful: the architectures and problems used in learning the rules must be representative of those to which it will eventually be applied. To get general rules, we should train on general problems and architectures, not just one kind. On the other hand, to obtain a training rule specialized for a specific architecture or problem type, we should train just on that architecture or problem.

One approach is to evolve only learning rule parameters (Yao 1999) such as the learning rate and momentum in backpropagation. This has the effect of adapting a standard learning rule to the architecture or problem at hand. Non-evolutionary methods of adapting training rules also exist. Castillo et al. (2007), working with multi-layer perceptrons, found evolving the architecture, initial weights, and rule parameters together as good or better than evolving only the first two or the third.

We can also evolve new learning rules (Yao 1999; Radi and Poli 2003). Open-ended evolution of rules was initially considered impractical and instead Chalmers (1990) specified a generic, abstract form of update and evolved its parameters to produce different concrete rules. The generic update was a linear function of ten terms, each of which had an associated evolved real-valued weight. Four of the terms represented local information for the node being updated while the other six terms were the pairwise products of the first four. Using this method Chalmers was able to rediscover the delta rule and some of its variants. This approach has been used by a number of others and has been reported to outperform human-designed rules (Dasdan and Oflazer 1993). More recently, GP was used to evolve novel types of rules from a set of mathematical functions and the best new rules consistently outperformed standard backpropagation (Radi and Poli 2003). Whereas architectures are fixed, rules could potentially change over their lifetime (e.g., their learning rate could change) but evolving dynamic rules would naturally be much more complex than evolving static ones.

3.4.1 Ensembles of NNs

Most methods output a single NN (Yao and Islam 2008) but a population of evolving NNs is naturally treated as an ensemble and recent work has begun to do so. Evolving NNs is inherently multiobjective: we want accurate yet simple and diverse networks. Some works combine these objectives into one fitness function while others are explicitly multiobjective.

Single-Objective Ensembles

Yao and Liu (1998) used EPNet's (Yao and Liu 1997) population as an ensemble without modifying the evolutionary process. By treating the population as an ensemble, the result outperformed the population's best individual. Liu and Yao (1990) pursued accuracy and diversity in two ways. The first was to modify backpropagation to minimize error and maximize diversity using an approach they call negative correlation learning (NCL) in which the errors of members become negatively correlated and hence diverse. The second method was to combine accuracy and diversity in a single objective. Evolutionary ensembles for NCL (EENCL) (Liu et al. 2000) automatically determines the size of an ensemble. It encourages diversity with fitness sharing and NCL, and it deals with the ensemble member selection problem (● Sect. 3.3.1) with a cluster-and-select method (see Jin and Sendhoff (2004)). First we cluster candidates, based on their errors, on the training set so that clusters of

candidates make similar errors. Then we select the most accurate in each cluster to join the ensemble; the result is the ensemble can be much smaller than the population. Cooperative neural net ensembles (CNNE) (Islam et al. 2003) used a constructive approach to determine the number of individuals and how many hidden nodes each has. Both contribute to the expressive power of the ensemble and CNNE was able to balance the two to obtain suitable ensembles. Unsurprisingly, it was found that more complex problems needed larger ensembles.

Multiobjective Ensembles

Memetic pareto artificial NN (MPANN) (Abbass 2003) was the first ensemble of NNs to use multiobjective evolution. It also uses gradient-based local search to optimize network complexity and error. Diverse and accurate ensembles (DIVACE) (Chandra and Yao 2006a) uses multi-objective evolution to maximize accuracy and diversity. Evolutionary selection is based on non-dominated sorting (Srinivas and Deb 1994), a cluster-and-select approach is used to form the ensemble, and search is provided by simulated annealing and a variant of differential evolution (Storn and Price 1996). DIVACE-II (Chandra and Yao 2006) is a heterogeneous multi-objective Michigan approach using NNs, support vector machines, and radial basis function nets. The role of crossover and mutation is played by bagging (Breiman 1996) and boosting (Freund and Schapire 1996), which produce accurate and diverse candidates. Each generation bagging and boosting make candidate ensemble members and only dominated members are replaced. The accuracy of DIVACE-II was very good compared to 25 other learners on the Australian credit card and diabetes datasets and it outperformed the original DIVACE.

3.4.2 Yao's Framework for Evolving NNs

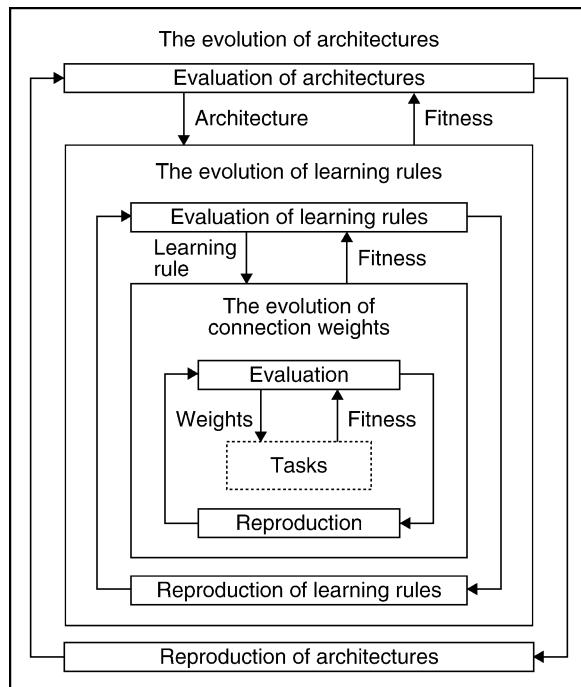

❶ *Figure 7* shows Yao's framework for evolving architectures, training rules, and weights as nested processes (Yao 1999). Weight evolution is the innermost as it occurs at the fastest time scale, while either rule or architecture evolution is outermost. If we have prior knowledge, or are interested in a specific class of either rule or architecture, this constrains the search space and Yao suggests the outermost should be the one which constrains it most. The framework can be thought of as a three-dimensional space of evolutionary NNs where 0 on each axis represents one-shot search and infinity represents exhaustive search. If we remove references to EAs and NNs, it becomes a general framework for adaptive systems.

3.4.3 Conclusions

Evolution is widely used with NNs, indeed according to Floreano et al. (2008) most studies of neural robots in real environments use some form of evolution. Floreano et al. go on to claim that evolving NNs can be used to study “brain development and dynamics because it can encompass multiple temporal and spatial scales along which an organism evolves, such as genetic, developmental, learning, and behavioral phenomena. The possibility to coevolve both the neural system and the morphological properties of agents . . . adds an additional valuable perspective to the evolutionary approach that cannot be matched by any other approach.” (Floreano et al. 2008, p. 59).

Fig. 7

Yao's framework for evolving architectures, training rules, and weights.

Reading

Key reading on evolving NNs includes Yao's classic 1999 survey (Yao 1999), Kasabov 2007 book (Kasabov 2007), Floreano, Dürr, and Mattiussi's 2008 survey (Floreano et al. 2008), which includes reviews of evolving dynamic and neuromodulatory NNs, and Yao and Islam's 2008 survey of evolving NN ensembles (Yao and Islam 2008).

3.5 Learning Classifier Systems (LCS)

Learning classifier systems (LCS) originated in the GA community as a way of applying GAs to learning problems. The LCS field is one of the oldest, largest, and most active areas of GBML. The majority of LCS research is currently carried out on XCS (Wilson 1995; Butz and Wilson 2001) and its derivatives XCSF (Wilson 2001b, 2002a) for regression/function approximation, and UCS (Bernadó-Mansilla and Garrell-Guiu 2003; Orriols-Puig and Bernadó-Mansilla 2008) for supervised learning.

The Game of the Name

Terminology has been contentious in this area (Heitkötter and Beasley 2001). LCS are also widely simply called classifier systems (abbreviated CS or CFS) and sometimes evolutionary (learning) classifier systems. At one time GBML referred exclusively to LCS. None of these names is very satisfactory but the field appears to have settled on LCS.

The difficulty in naming the field relates in part to the difficulty in defining what an LCS is (Smith 1992; Holland et al. 2000). In practice, what is accepted as an LCS has become more inclusive over the years. A reasonable definition of an LCS would be an evolutionary rule-based system – except that a significant minority of LCS are not evolutionary! On the other hand, most non-evolutionary rule-based systems are not considered LCS, so the boundaries of the field are defined more by convention than principle. Even EA practitioners are far from unanimous; work continues to be published which some would definitely consider forms of LCS, but which make no reference to the term and which contain few or no LCS references.

(L)CS has at times been taken to refer to Michigan systems only (see, e.g., Greene and Smith (1993)) but it now generally includes Pitt systems as well, as implied by the name and content of the international workshop on learning classifier systems (IWLCS) which includes both Pitt and Michigan, evolutionary and non-evolutionary systems. As a final terminological note, rules in LCS are often referred to as “classifiers”.

3.5.1 Production Systems and Rule(Set) Parameters

LCS evolve condition-action (IF–THEN) rules. Recall from [Sect. 2.2](#) and [Fig. 2](#) that in Michigan rule-based systems a chromosome is a single rule, while in Pittsburgh systems a chromosome is a variable-length *set* of rules. Pittsburgh, Michigan, IRL, and GCCL are all used. Michigan systems are rare elsewhere but are the most common form of LCS. Within LCS, IRL is most common with fuzzy systems, but see Aguilar-Ruiz et al. (2003) for a non-fuzzy version. In LCS, we typically evolve rule conditions and actions although non-evolutionary operators may act upon them. In addition, each phenotype has parameters associated with it and these parameters are typically learned rather than evolved using the Widrow–Hoff update or similar (see Lanzi et al. (2006b) for examples). In Michigan LCS parameters are associated with each rule but in Pittsburgh systems they are associated with each ruleset. For example, in UCS the parameters are: fitness, mean action set size (to bias a deletion process, which seeks to balance action set sizes), and experience (a count of the number of times a rule has been applied, in order to estimate confidence in its fitness). In GAssist (a supervised Pittsburgh system) the only parameter is fitness. Variations of the above exist; in some cases, rules predict the next input or read and write to memory.

3.5.2 Representing Conditions and Actions

The most common representation in LCS uses fixed-length strings with binary inputs and outputs and ternary conditions. In a simple Michigan version (see, e.g., Wilson (1995)), each rule has one action and one condition from $\{0, 1, \#\}$ where # is a wildcard, matching both 0 and 1 in inputs. For example, the condition 01# matches two inputs: 010 and 011. Similar representations were used almost exclusively prior to approximately 2000 and are inherited from GAs and their preference for minimal alphabets. (Indeed, ternary conditions have an interesting parallel with ternary schemata (Reeves and Rowe 2002) for binary GAs.) Such rules individually have limited expressive power (Schuurmans and Schaeffer 1989) (but see also Booker (1991)), which necessitates that solutions are sets of rules. More insidiously, the lack of individual expressiveness can be a factor in pathological credit assignment (strong/fit overgeneralis

(Kovacs 2004)). Various extensions to the simple scheme described above have been studied (see (Kovacs 2004, Sect. 2.2.2)).

Real-Valued Intervals

Following Bacardit (2004, p. 84) we distinguish two approaches to real-valued interval representation in conditions. The first is representations based on discretization: HIDER* uses *natural coding* (Giraldez et al. 2003), ECL clusters attribute values and evolves constraints on them (Divina et al. 2003) while GAssist uses *adaptive discretization intervals* (Bacardit 2004). The second approach is to handle real values directly. In HIDER genes specify a lower and upper bound (where lower is always less than upper) (Aguilar-Ruiz et al. 2003). In Corcoran and Sen (1994) a variation of HIDER's scheme is used where the attribute is ignored when the upper bound is less than the lower. Interval representations are also used in Wilson (2001a) and Stone and Bull (2003). Finally, Wilson (2000) specifies bounds using centre and spread genes.

Default/Exception Structures

Various forms of default/exception rule structures have been used with LCS. It has been argued that they should increase the number of solutions possible without increasing the search space and should allow gradual refinement of knowledge by adding exceptions (Holland 1986). However, the space of *combinations* of rules is much larger than the set of rules and the evolutionary dynamics of default/exception rule combinations have proved difficult to manage in Michigan systems. Nonetheless, default rules can significantly reduce the number of rules needed for a solution (Valenzuela-Rendón 1989) and there have been some successes.

➤ *Figure 8* illustrates three representations for a Boolean function. The leftmost is a truth table, which lists all possible inputs and their outputs. The middle representation is the ternary language commonly used by LCS, which requires only four rules to represent the eight input/output pairs, thanks to the generalization provided by the # symbol. Finally, on the right, a default rule ($\#\# \rightarrow 1$) has been added to the ternary representation. This rule matches all inputs and states that the output is always 1. This rule is incorrect by itself, but the two rules above it provide exceptions and, taken together, the three accurately represent the function using one less rule than the middle representation. One difficulty in evolving such

■ Fig. 8

Three representations for the 3 multiplexer function.

Truth table			
A	B	C	Output
0	0	0	0

Ternary rules
0 0 # → 0
0 1 # → 1
1 # 0 → 0
1 # 1 → 1

Default rule
0 0 # → 0
1 # 0 → 0
→ 1

default/exception structures lies in identifying which rules are the defaults and which the exceptions; a simple solution is to maintain the population in some order and make earlier rules exceptions to later ones (as in a decision list (Rivest 1987)). This is straightforward in Pitt systems in which individual rulesets are static but is more complex in Michigan populations in which individual rules are created and deleted dynamically. The other issue is how to assign credit to the overall multi-rule structure. In Pittsburgh systems this is again straightforward since fitness is assigned only at the level of rulesets, but in Michigan systems each rule has a fitness, and it is not obvious how to credit the three rules in the default/exception structure in a way which recognizes their cooperation.

The Pittsburgh GABIL (De Jong and Spears 1991) and GAssist (Bacardit 2004) use decision lists and often evolve default rules spontaneously (e.g., a fully general last rule). Bacardit found that enforcing a fully general last rule in each ruleset in GAssist (and allowing evolution to select the most useful class for such rules) was effective (Bacardit 2004).

In Michigan systems, default/exception structures are called default hierarchies. Rule specificity has been used as the criterion for determining which rules are exceptions and accordingly conflict resolution methods have been biased according to specificity. There are, however, many problems with this approach (Smith and Goldberg 1991). It is difficult for evolution to produce these structures since they depend on cooperation between otherwise competing rules. The structures are unstable since they are interdependent; unfortunate deletion of one member alters the utility of the entire structure. As noted, they complicate credit assignment and conflict resolution since exception rules must override defaults (Wilson 1989; Smith and Goldberg 1991). There are also problems with the use of specificity to prioritize rules. For one, having fewer #s does not mean a rule actually matches fewer inputs; counting #s is a purely syntactic measure of generality. For another, there is no reason why exception rules should be more specific. The consequence of these difficulties is that there has not been much interest in Michigan default hierarchies since the early 1990s (but see Vallim et al. (2003)) and indeed not all Michigan LCS support them (e.g., ZCS (Wilson 1995), XCS/XCSF and UCS do not). Nonetheless, the idea should perhaps be revisited and an ensembles perspective might prove useful.

Other Representations for Conditions and Actions

A great range of other representations has been used, particularly in recent years. These include VL₁ logic (Michalski et al. 1986) as used in GIL (Janikow 1993), first-order logic (Mellor 2005a, b, 2008), decision lists as used in GABIL (De Jong and Spears 1991) and GAssist (Bacardit 2004), messy encoding (Lanzi 1999a), ellipses (Butz 2005) and hyperellipses (Butz et al. 2006), hyperspheres (Marshall and Kovacs 2006), convex hulls (Lanzi and Wilson 2006a), tile coding (Lanzi et al. 2006) and a closely related hyperplane coding (Booker 2005a, b), GP trees (Ahluwalia and Bull 1999; Lanzi 1999b, 2001), Boolean networks defined by GP (Bull 2009), support vectors (Loiacono et al. 2007), edges of an augmented transition network (Landau et al. 2005), gene expression programming (Wilson 2008), fuzzy rules (see **• Sect. 3.6**), and neural networks (Smith and Cribbs 1994; Cribbs and Smith 1996; Smith and Cribbs 1997; Bull and O’Hara 2002; O’Hara and Bull 2005; Dam et al. 2008; Howard et al. 2008; Howard and Bull 2008). GALE (Llorá and Garrell 2001; Llorá 2002; Llorá and Wilson 2004) has used particularly complex representations, including the use of GP to evolve trees defining axis-parallel and oblique hyper-rectangles (Llorá and Wilson 2004), and evolved prototypes, which are used with a k-nearest-neighbor classifier. The prototypes need not be fully specified; some attributes can be left undefined. This representation has also been used in

GAssist (Bacardit 2004). There has been limited work with alternative action representations including computed actions (Tran et al. 2007; Lanzi and Loiacono 2007) and continuous actions (Wilson 2007).

3.5.3 Evolutionary Selection of Representations

As we have seen, there are many representations to choose from. Unfortunately, it is generally not clear which might be best for a given problem or part of a problem. One approach is to let evolution make these choices. This can be seen as a form of meta-learning in which evolution adapts the inductive bias of the learner. In Bacardit (2004) and Bacardit et al. (2007), evolution was used to select default actions in decision lists in GAssist. GAssist's initial population was seeded with last rules, which together advocated all possible classes and over time evolution selected the most suitable of these rules. To obtain good results, it was necessary to encourage diversity in default actions. In GALE (Llorá 2002), evolution selects both classification algorithms and representations. GALE has elements of cellular automata and artificial life: individuals are distributed on a two-dimensional grid. Only neighbors within r cells interact: two neighbors may perform crossover, an individual may be cloned and copied to a neighboring cell, and an individual may die if its neighbors are fitter. A number of representations have been used: rule sets, prototypes, and decision trees (orthogonal, oblique, and multivariate based on nearest neighbor). Decision trees are evolved using GP while prototypes are used by a k-nearest-neighbor algorithm to select outputs. An individual uses a particular representation and classification algorithm and hence evolutionary selection operates on both. Populations may be homogeneous or heterogeneous and in Llorá and Wilson (2004) GALE was modified to interbreed orthogonal and oblique trees.

In the representational ecology approach (Marshall and Kovacs 2006) condition shapes were selected by evolution. Two Boolean classification tasks were used: a plane function, which is easy to describe with hyperplanes, but hard with hyperspheres, and a sphere function, which has the opposite characteristics. Three versions of XCS were used: with hyperplane conditions (XCS-planes), with hyperspheres (XCS-spheres), and both (XCS-both). XCS was otherwise unchanged, but in XCS-both the representations compete due to XCS's pressure against overlapping rules (Kovacs 2004). In XCS-both planes and spheres do not interbreed; they constitute genetically independent populations, that is, species. In terms of classification accuracy XCS-planes did well on the plane function and poorly on the sphere function while XCS-sphere showed the opposite results. XCS-both performed well on both; there was no significant difference in accuracy compared to the better single-representation version on each problem. Furthermore, XCS-both selected the more appropriate representation for each function. In terms of the amount of training needed, XCS-both was similar to XCS-sphere on the sphere function but was significantly slower than XCS-plane on the plane function.

Selecting Discretization Methods and Cut Points

GAssist's Adaptive Discretization Intervals (ADI) approach has two parts (Bacardit 2004). The first consists of adapting interval sizes. To begin, a discretization algorithm proposes cut points for each attribute and this defines the finest discretization possible, said to be composed of micro-intervals. Evolution can merge and split macro-intervals, which are composed of micro-intervals, and each individual can have different macro-intervals. The second part consists of selecting discretization algorithms. Evolution is allowed to select discretization

algorithms for each attribute or rule from a pool including uniform width, uniform frequency, ID3, Fayyad and Irani, M  ntaras, USD, ChiMerge, and random. Unfortunately, evolving the best discretizers was found to be difficult and the use of ADI resulted in only small improvements in accuracy. However, further work was suggested.

3.5.4 Optimization of Population Representation: Macroclassifiers

Wilson (1995) introduced an optimization for Michigan populations called macroclassifiers. He noted that as an XCS population converges on the solution set, many identical copies of this set accumulate. A macroclassifier is simply a rule with an additional *numerosity* parameter, which indicates how many identical virtual rules it represents. Using macroclassifiers saves a great deal of run-time compared to processing a large number of identical rules. Furthermore, macroclassifiers provide interesting statistics on evolutionary dynamics. Empirically, macroclassifiers perform essentially as the equivalent “micro” classifiers (Kovacs 1996).  Figure 9 illustrates how the rules m and m' in the top can be represented by m alone in the bottom by adding a numerosity parameter.

3.5.5 Rule Discovery

LCS are interesting from an evolutionary perspective, particularly Michigan systems in which evolutionary dynamics are more complex than in Pittsburgh systems. Where Pittsburgh systems face two objectives (evolving accurate and parsimonious rulesets) Michigan systems face a third: coverage of the input (or input/output) space. Furthermore, Michigan systems have coevolutionary dynamics as rules both cooperate and compete. Since the level of selection (rules) is lower than the level of solutions (rulesets) researchers have attempted to coax better results by modifying rule fitness calculations with various methods. Fitness sharing and crowding have been used to encourage diversity and, hence, coverage. Fitness sharing is naturally based on inputs (see ZCS) while crowding has been implemented by making deletion probability proportional to the degree of overlap with other rules (as in XCS). Finally, restricted mating as implemented by a niche GA plays an important role in XCS and UCS (see  Sect. 3.5.5).

 Fig. 9

A population of microclassifiers (top) and the equivalent macroclassifiers (bottom).

Rule	Cond.	Action	Strength
m	# # 0 0 1 1	1	200.0
m'	# # 0 0 1 1	1	220.0
n	# # 0 0 1 1	0	100.0
o	0 0 1 1 1 0	1	100.0

Rule	Cond.	Action	Strength	Numerosity
m	# # 0 0 1 1	1	200.0	2
n	# # 0 0 1 1	0	100.0	1
o	0 0 1 1 1 0	1	100.0	1

Windowing in Pittsburgh LSS

As noted in [Sect. 2.2](#) naive implementations of the Pittsburgh approach are slower than Michigan systems, which are themselves slow compared to non-evolutionary methods. The naive Pitt approach is to evaluate each individual on the entire data set, but much can be done to improve this. Instead, windowing methods (Fürnkranz 1998) learn on subsets of the data to improve runtime. Windowing has been used in Pitt LCS since, at least, ADAM (Greene and Smith 1987). More recently GAssist used incremental learning by alternating strata (ILAS) (Bacardit 2004) which partitions the data into n strata, each with the same class distribution as the entire set. A different stratum is used for fitness evaluation each generation. On larger data sets speed-up can be an order of magnitude. Windowing has become a standard part of recent Pittsburgh systems applied to real-world problems (e.g., Bacardit and Krasnogor (2008) and Bacardit et al. (2008, 2009)).

Many ensemble methods improve classification accuracy by sampling data in similar ways to windowing techniques, which suggests the potential for both improved accuracy and runtime, but this has not been investigated in LCS.

Michigan Rule Discovery

Most rule discovery work focuses on Michigan LCS as they are more common and their evolutionary dynamics are more complex. The rest of this section deals with Michigan systems although many ideas, such as self-adaptive mutation, could be applied to Pitt systems. Michigan LCS use the steady state GAs introduced in [Sect. 2.4](#) as they minimize disruption to the rule population during on-line learning. An unusual feature of Michigan LCS is the emphasis placed on minimizing population size, for which various techniques are used: niche GAs, the addition of a generalization term in fitness, subsumption deletion, condensation and various compaction methods.

Niche GAs

Whereas in a standard panmictic GA all rules are eligible for reproduction, in a niche GA mating is restricted to rules in the same action set (which is considered a niche). (See [Fig. 3](#) on action sets.) The input spaces of rules in an action set overlap and their actions agree, which suggests their predictions will tend to be related. Consequently, mating these related rules is more effective, on average, than mating rules drawn from the entire population. This is a form of speciation since it creates non-interbreeding sub-populations. However, the niche GA has many other effects (Wilson 2001). First, a strong bias toward general rules, since they match more inputs and hence appear in more action sets. Second, pressure against overlapping rules, since they compete for reproduction (Kovacs 2004). Third, complete coverage of the input space, since competition occurs for each input. The niche GA was introduced in Booker (1989) and originally operated in the match set but was later further restricted to the action set (Wilson 1998). It is used in XCS and UCS and is related to *universal suffrage* (Giordana and Saitta 1994).

EDAs Instead of GAs

Recently Butz et al. (2005, 2006) and Butz and Pelikan (2006) replaced XCS's usual crossover with an estimation of distribution algorithm (EDA)-based method to improve solving of difficult hierarchical problems, while (Llorà et al. 2005a, b) introduced CCS: a Pitt LCS based on compact GAs (a simple form of EDA).

Subsumption Deletion

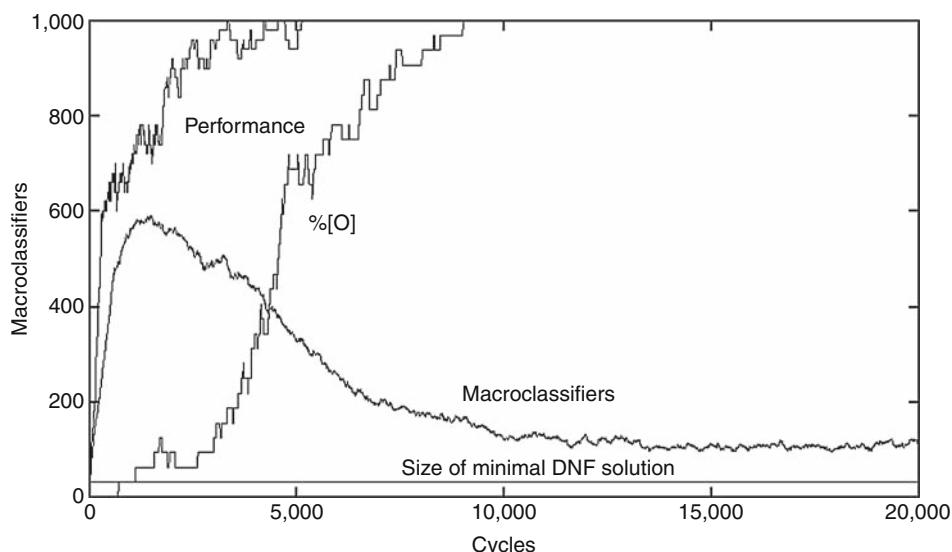

A rule x logically subsumes a rule y when x matches a superset of the inputs y matches and they have the same action. For example, $00\# \rightarrow 0$ subsumes $000 \rightarrow 0$ and $001 \rightarrow 0$. In XCS x is allowed to subsume y if: (i) x logically subsumes y , (ii) x is sufficiently accurate and (iii) x is sufficiently experienced (has been evaluated sufficiently) so we can have confidence in its accuracy. Subsumption deletion was introduced in XCS (see Butz and Wilson (2001)) and takes two forms. In *GA subsumption*, when a child is created, we check to see if its parents subsume it, which constrains accurate parents to only produce more general children. In *action set subsumption*, the most general of the sufficiently accurate and experienced rules in the action set is given the opportunity to subsume the others. This removes redundant, specific rules from the population but is too aggressive for some problems.

Michigan Evolutionary Dynamics

Michigan LCS have interesting evolutionary dynamics and plotting macroclassifiers is a useful way to monitor population convergence and parsimony. [Figure 10](#) illustrates by showing XCS learning the 11 multiplexer function. The performance curve is a moving average of the proportion of the last 50 inputs which were classified correctly, $\%[O]$ shows the proportion of the minimal set of 16 ternary rules XCS needs to represent this function (indicated by the straight line labeled “Size of minimal DNF solution” in the figure) and macroclassifiers were explained in [Sect. 3.5.4](#). In this experiment, the population was initially empty and was seeded by covering [Sect. 3.5.5](#). “Cycles” refers to the number of inputs presented, inputs were drawn uniform randomly from the input space, the population size limit was 800, all input/output pairs were in both the train and test sets, GA subsumption was used but action set subsumption was not and curves are the average of 10 runs. Other settings are as in Wilson (1995).

Fig. 10

Evolutionary dynamics of XCS on the 11 multiplexer.

Note that XCS continues to refine its solution (population) after 100% performance is reached and that it finds the minimal representation (at the point where $\%[O]$ reaches the top of the figure) but that continued crossover and mutation generate extra transient rules, which make the population much larger.

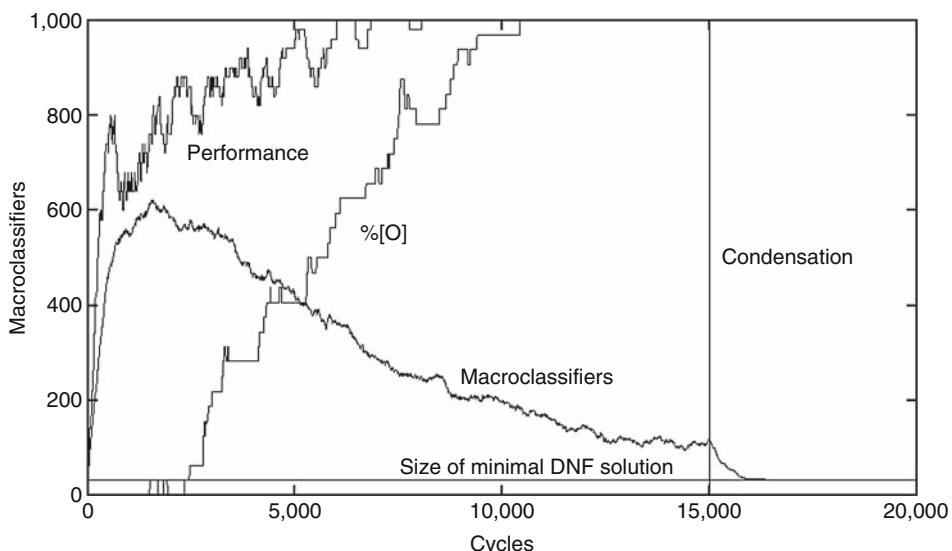

Condensation

As illustrated by [Fig. 10](#), an evolved population normally contains many redundant and low-fitness rules. These rules are typically transient, but more are generated while the GA continues to run. Condensation (Wilson 1998; Kovacs 1996) is a very simple technique to remove such rules, which consists of running the system with crossover and mutation turned off; we only clone and delete existing rules. [Figure 11](#) repeats the experiment from [Fig. 10](#) but switches after 15,000 cycles to condensation after which the population quickly converges to the minimal solution. Other methods of compacting the population have been investigated (Kovacs 1997; Wilson 2002b; Dixon et al. 2002).

Tuning Evolutionary Search

XCS is robust to class imbalances (Orriols-Puig and Bernadó-Mansilla 2006) but for very high imbalances tuning the GA based on a facetwise model improved performance (Orriols-Puig and Bernadó-Mansilla 2006; Orriols-Puig et al. 2007b). Self-tuning evolutionary search has also been studied. The mutation rate can be adapted during evolution for example Hurst and Bull (2003, 2004), Howard et al. (2008), and Butz et al. (2008), while De Jong et al. (1993) dynamically controls use of two generalization operators: each has a control bit specifying whether it can be used and control bits evolve with the rest of the genotypes.

Fig. 11
XCS with condensation on the 11 multiplexer.

Non-evolutionary Rule Discovery

Evolution has been supplemented by heuristics in various ways. Covering, first suggested in Holland (1976), creates a rule to match an unmatched input. It can be used to create (“seed”) the initial population (Venturini 1993; Wilson 1995; Hekanaho 1995) or to supplement the GA throughout evolution (Wilson 1995). Kovacs (2004, p. 42) found covering each action set was preferable to covering the match set when applying XCS to sequential tasks. Most covering/seeding is done as needed but instead (Juan Liu and Tin-Yau Kwok 2000) selects inputs at the center of same-class clusters. For other non-evolutionary operators see (Booker 1989; Riolo 1987), the work on corporations of rules (Wilson and Goldberg 1989; Smith 1994; Tomlinson and Bull 1998, 2002; Tomlinson 1999) and the work on non-evolutionary LCS.

Non-evolutionary LCS

Although LCS were originally conceived as a way of applying GAs to learning problems (Holland and Reitman 1978), not all LCS include a GA. Various heuristics have been used to create and refine rules in for example YACS (Gerard et al. 2002) and MACS (Gérard and Sigaud 2003). A number of systems have been inspired by psychological models of learning. ACS (Stolzmann 1996; Butz 2002) and ACS2 (Butz 2002a) are examples, although ACS was also later supplemented by a GA (Butz et al. 2000a, b). Another is AgentP, a specialized LCS for maze tasks (Zatuchna 2004, 2005).

3.5.6 LCS Credit Assignment

While credit assignment in Pittsburgh LCS is a straightforward matter of multiobjective fitness evaluation, as noted in [Sect. 3.5.5](#) it is far more complex in Michigan systems with their more complex evolutionary dynamics. Credit assignment is also more complex in some learning paradigms, particularly reinforcement learning, which we will not cover here. Within supervised learning, credit assignment is more complex in regression tasks than in classification. These difficulties have been the major issue for Michigan LCS and have occupied a considerable part of the literature, particularly prior to the development of XCS, which provided a reasonable solution for both supervised and reinforcement learning.

Strength and Accuracy in Michigan LCS

Although we are not covering reinforcement learning, Michigan LCS have traditionally been designed for such problems. XCS/XCSF are reinforcement learning systems, but since supervised learning can be formulated as simplified reinforcement learning, they have been applied to SL tasks. Consequently, we now very briefly outline the difference between the two major forms of Michigan reinforcement learning LCS.

In older (pre-1995) reinforcement learning, LCS fitness is proportional to the magnitude of reward and is called *strength*. Strength is used both for conflict resolution and as fitness in the GA (see e.g., ZCS (Wilson 1994)). Such LCS are referred to as strength-based and they suffer from many difficulties with credit assignment (Kovacs 2004), the analysis of which is quite complex. Although some strength-based systems incorporate accuracy as a component of fitness, their fitness is still proportional to reward. In contrast, the main feature of XCS is that it adds a prediction parameter, which estimates the reward to be obtained if the action advocated by a rule is taken. Rule fitness is proportional to the accuracy of reward prediction and not to its magnitude, which avoids many problems strength-based systems have with

credit assignment. In XCS, accuracy is estimated from the variance in reward and since overgeneral rules have high variance they have low fitness. Although XCS has proved robust in a range of applications, a major limitation is that the accuracy estimate conflates several things: (i) overgenerality in rules, (ii) noise in the training data, and (iii) stochasticity in the transition function in sequential problems. In contrast, strength-based systems may be less affected by noise and stochasticity since they are little affected by reward variance. See Kovacs (2004) for analysis of the two approaches.

Prediction Updates

To update rule predictions while training, the basic XCS system (Wilson 1995; Butz and Wilson 2001) uses the Widrow–Hoff update for nonsequential problems and the Q-learning update for sequential ones. Various alternatives have been used: average rewards (Tharakunnel and Goldberg 2002; Lanzi and Loiacono 2006), gradient descent (Butz et al. 2005b; Lanzi et al. 2007), and eligibility traces (Drugowitsch and Barry 2005). The basic XCSF uses NLMS (linear piecewise) prediction (Wilson 2000b, 2002a) but Lanzi et al. (2006b) has compared various alternative classical parameter estimation (RLS and Kalman filter) and gain adaptation algorithms (K1, K2, IDBD, and IDD). He found that Kalman filter and RLS have significantly better accuracy than the others and that Kalman filter produces more compact solutions than RLS. There has also been recent work on other systems; UCS is essentially a supervised version of XCS and the main difference is its prediction update. Bull has also studied simplified LCS (Bull 2005).

Evolutionary Selection of Prediction Functions

In Lanzi et al. (2008), Lanzi selects prediction functions in XCSFHP (XCSF with Heterogeneous Predictors) in a way similar to the selection of condition types in the representational ecology approach in [Sect. 3.5.3](#). Polynomial functions (linear, quadratic, and cubic) and constant, linear and NN predictors were available. XCSFHP selected the most suitable predictor for regression and sequential tasks and performed almost as well as XCSF using the best single predictor.

Theoretical Results

Among the notable theoretical works on LCS, Lanzi (2002a) demonstrates that XCS without generalization implements tabular Q-learning, Butz et al. (2005a) investigate the computational complexity of XCS in a probably approximately correct (PAC) setting, and Wada et al. (2005a, b, c, 2007) analyze credit assignment and relate LCS to mainstream reinforcement learning methods. Kovacs (2004) identifies pathological rule types: strong overgeneral and fit overgeneral rules, which are overgeneral yet stronger/fitter than not-overgeneral competitors. Fortunately, such rules are only possible under specific circumstances. A number of papers seek to characterize problems which are hard for LCS (Goldberg et al. 1992; Kovacs 2000, 2001, 2004; Bernadó-Mansilla and Ho 2005; Bagnall and Zatuchna 2005) while others model evolutionary dynamics (Butz et al. 2004a, b, 2007; Butz 2006; Orriols-Puig 2007c, d) and yet others attempt to reconstruct LCS from first principles using probabilistic models (Drugowitsch 2007, 2008; Edakunni et al. 2009).

Hierarchies and Ensembles of LCS

Hierarchical LCS have been studied for some time and Barry (1996) reviews early work. Dorigo and Colombetti (1998), Donnart and Meyer (1996a, b), and Donnart (1998) apply hierarchical LCS to robot control while Barry (2000) uses hierarchical XCSs to learn long

sequences of actions. The ensembles field (● Sect. 3.3) studies how to combine predictions (Kuncheva 2004) and all the above could be reformulated as ensembles of LCS. Some recent work has taken this approach (Dam et al. 2005; Bull et al. 2007).

3.5.7 Conclusions

LCS face certain inherent difficulties; Michigan systems face complex credit assignment problems while in Pittsburgh systems, run-time can be a major issue. The same is true for all GBML systems, but the Michigan approach has been explored far more extensively within LCS than elsewhere. Recently, there has been much integration with mainstream machine learning and much research on representations and credit assignment algorithms. Most recent applications have been to data mining and function approximation, although some work continues on reinforcement learning. Future directions are likely to include exposing more of the LCS to evolution and further integration with machine learning, ensembles, memetic algorithms, and multiobjective optimization.

Reading

No general up-to-date introduction to LCS exists. For the basics see Goldberg (1989) and the introductory parts of Kovacs (2004) or Butz (2006). For a good introduction to representations and operators see chapter 6 of Freitas (2002a). For a review of early LCS see Barry (2000). For reviews of LCS research see Wilson and Goldberg (1989), Lanzi and Riolo (2000), and Lanzi (2008). For a review of state-of-the-art GBML and empirical comparison to non-evolutionary pattern recognition methods see Orriols-Puig et al. (2008b). For other comparisons with non-evolutionary methods see Bonelli and Alexandre (1991), Greenyer (2000), Saxon and Barry (2000), Wilson (2000), Bernadó et al. (2002), and Bernadó-Mansilla and Garrell-Guiu (2003). Finally, the LCS bibliography (Kovacs 2009) has over 900 references.

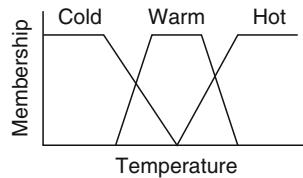

3.6 Genetic Fuzzy Systems

Following the section on LCS, this section covers a second actively developing approach to evolving rule-based systems. We will see that the two areas overlap considerably and that the distinction between them is somewhat arbitrary. Nonetheless, the two communities and their literatures are somewhat disjoint.

Fuzzy logic is a major paradigm in soft computing which provides a means of approximate reasoning not found in traditional crisp logic. Genetic fuzzy systems (GFS) apply evolution to fuzzy learning systems in various ways: GAs, GP, and evolution strategies have all been used. We will cover a particular form of GFS called genetic fuzzy rule-based systems (FRBS), which are also known as learning fuzzy classifier systems (LFCS) (Bonarini 2000) or referred to as, for example, “genetic learning of fuzzy rules” and (for reinforcement learning tasks) “fuzzy Q-learning”. Like other LCS, FRBS evolve if-then rules but in FRBS the rules are fuzzy. Most systems are Pittsburgh, but there are many Michigan examples (Valenzuela-Rendón 1991, 1998; Geyer-Schulz 1997; Bonarini 2000; Orriols-Puig et al. 2007a, 2008a; Casillas et al. 2007). In addition to FRBS, we briefly cover genetic fuzzy NNs, but we do not cover genetic fuzzy clustering (see Oscar-Cordón et al. (2001)).

In the terminology of fuzzy logic, ordinary scalar values are called *crisp* values. A *membership function* defines the degree of match between crisp values and a set of fuzzy linguistic

terms. The set of terms is a *fuzzy set*. The following figure shows a membership function for the set {cold, warm, and hot}.

Each crisp value matches *each* term to some degree in the interval [0,1], so, for example, a membership function might define 5° as 0.8 cold, 0.3 warm and 0.0 hot. The process of computing the membership of each term is called fuzzification and can be considered a form of discretization. Conversely, defuzzification refers to computing a crisp value from fuzzy values.

Fuzzy rules are condition/action (IF–THEN) rules composed of a set of linguistic variables (e.g., temperature, humidity), which can each take on linguistic terms (e.g., cold, warm, and hot). For example:

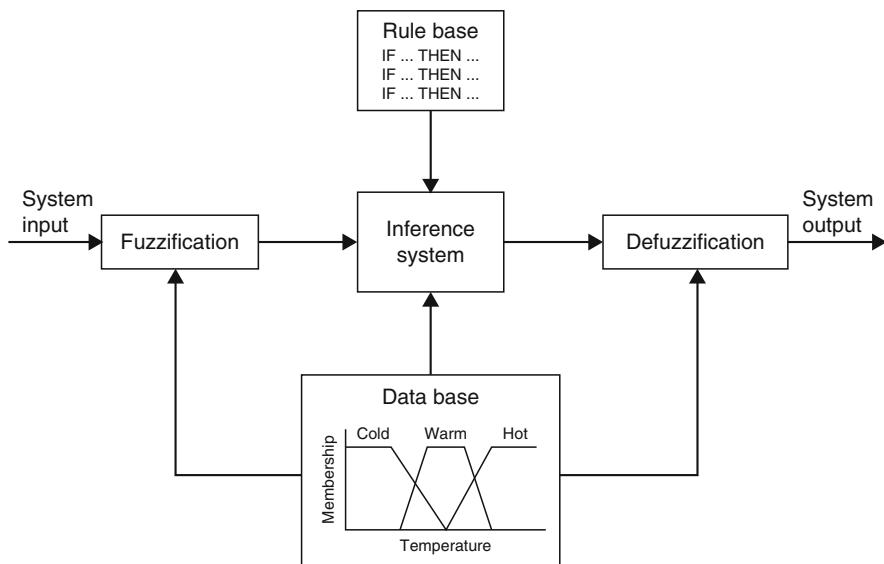

```
IF temperature IS cold AND humidity IS high THEN heater IS high
IF temperature IS warm AND humidity IS low THEN heater IS medium
```

As illustrated in Fig. 12, a fuzzy rule-based system consists of:

- A rule base (RB) of fuzzy rules
- A data base (DB) of linguistic terms and their membership functions
- Together the RB and DB are the *knowledge base* (KB)
- A fuzzy inference system which maps from fuzzy inputs to a fuzzy output
- Fuzzification and defuzzification processes

Fig. 12

Components and information flow in a fuzzy rule-based system. (Adapted from Hekanaho 1995.)

3.6.1 Evolution of FRBSs

We distinguish (i) genetic tuning and (ii) genetic learning of DB, RB, or inference engine parameters.

Genetic Tuning

The concept behind genetic tuning is to first train a hand-crafted FRBS and then to evolve the DB (linguistic terms and membership functions) to improve performance. In other words, we do not alter the hand-crafted rule base but only tune its parameters. Specifically, we can adjust the shape of the membership functions and the parameterized expressions in the (adaptive) inference system and adapt defuzzification methods.

Genetic Learning

The concept of genetic learning is to evolve the DB, RB, or inference engine parameters. There are a number of approaches. In *genetic rule learning*, we usually predefine the DB by hand and evolve the RB. In *genetic rule selection* we use the GA to remove irrelevant, redundant, incorrect, or conflicting rules. This is a similar role to condensation in LCS (see [Sect. 3.5.5](#)). In *genetic KB learning* we learn both the DB and RB. We either learn the DB first and then learn the RB or we iteratively learn a series of DBs and evaluate each one by learning an RB using it.

It is also possible to learn components simultaneously, which may produce better results though the larger search space makes it slower and more difficult than adapting components independently. As examples, Morimoto et al. (1997) learn the DB and RB simultaneously while Homaitar and McCormick (1995) learn KB components and inference engine parameters simultaneously.

Recently, Sánchez and Couso (2007) claimed that all existing GFS have been applied to crisp data and that with such data the benefits of GFS compared to other learning methods are limited to linguistic interpretability. However, GFS has the potential to outperform other methods on fuzzy data and they identify three cases (Sánchez and Couso 2007, p. 558):

1. Crisp data with hand-added fuzziness
2. Transformations of data based on semantic interpretations of fuzzy sets
3. Inherently fuzzy data

They argue that GFS should use fuzzy fitness functions in such cases to deal directly with the uncertainty in the data and propose such systems as a new class of GFS to add to the taxonomy of Herrera (2008).

3.6.2 Genetic Neuro-fuzzy Systems

A neuro-fuzzy system (NFS) or fuzzy neural network (FNN) is any combination of fuzzy logic and neural networks. Among the many examples of such systems, Liangjie and Yanda (1996) use a GA to minimize the error of the NN, Hanebeck and Schmidt (1996) use both a GA and backpropagation to minimize error, Perneel and Thelen (1995) optimize a fuzzy expert system using a GA and NN, and Morimoto et al. (1997) use a NN to approximate the fitness function for a GA, which adapts membership functions and controls rules. See Cordón et al.

(2001) for an introduction to NFS, Linkens and Nyongesa (1996) for a review of EAs, NNs, and fuzzy logic from the perspective of intelligent control, and He et al. (1999) for a discussion of combining the three. Kolman and Margaliot (2009) introduce fuzzy all-permutations rule-bases (FARBs), which are mathematically equivalent to NNs.

3.6.3 Conclusions

Herrera (2008, p. 38) lists the following active areas within GFS:

1. Multi-objective genetic learning of FRBSs: interpretability–precision trade-off
2. GA-based techniques for mining fuzzy association rules and novel data mining approaches
3. Learning genetic models based on low quality data (e.g., noisy data)
4. Genetic learning of fuzzy partitions and context adaptation
5. Genetic adaptation of inference engine components
6. Revisiting the Michigan-style GFSs

Herrera also lists (p. 42) current issues for GFS:

1. Human readability
2. New data mining tasks: frequent and interesting pattern mining, mining data streams
3. Dealing with high dimensional data

Reading

There is a substantial GFS literature. Notable works include the four seminal 1991 papers on genetic tuning of the DB (Karr 1991), the Michigan approach (Valenzuela-Rendón 1989), the Pittsburgh approach (Thrift 1991), and relational matrix-based FRBS (Pham and Karaboga 1991). Subsequent work includes Geyer-Schulz's 1997 book on Michigan fuzzy LCS learning RBs with GP (Geyer-Schulz 1997), Bonarini's 2000 introductory chapter from an LCS perspective (Bonarini 2000), Mitra and Hayashi's 2000 survey of neuro-fuzzy rule generation methods (Mitra and Hayashi 2000), Cordon et al.'s 2001 book on genetic fuzzy systems in general (Cordón et al. 2001), Angelov's 2002 book on evolving FRBS (Angelov 2002), chapter 10 of Freitas' 2002 book on evolutionary data mining (Freitas 2002a), Herrera's 2008 survey article on GFS (Herrera 2008) (which lists further key reading), and finally Kolman and Margaliot's 2009 book on the neuro-fuzzy FARB approach (Kolman and Margaliot 2009).

4 Conclusions

The reader should need no convincing that GBML is a very diverse and active area. Although much integration with mainstream machine learning has taken place in the last 10 years, more is needed. The use of multiobjective EAs in GBML is spreading. Integration with ensembles is natural given the population-based nature of EAs but it is only just beginning. Other areas which need attention are memetics, meta-learning, hyperheuristics, and estimation of distribution algorithms. In addition to further integration with other areas, the constituent areas of GBML need more interaction with each other.

Two persistent difficulties for GBML are worth highlighting. First, run-time speed remains an issue as EAs are much slower than most other methods. While this sometimes matters little

(e.g., in off-line learning with modest datasets), it is sometimes equally critical (e.g., in stream mining). Various methods to speed up GBML exist (see e.g., Freitas (2002a, Sect. 12.1.3) and more research is warranted, but this may simply remain a weakness. The second difficulty is theory. EA theory is notoriously difficult and when coupled with other processes becomes even less tractable. Nonetheless, substantial progress has been made in the past 10 years, most notably with LCS.

Other active research directions will no doubt include meta-learning such as the evolution of bias (e.g., selection of representation), evolving heuristics and learning rules for specific problem classes, and other forms of self-adaptation. In the area of data preparation, Freitas (2002a, Sect. 12.2.1) argues that attribute construction is a promising area for GBML and that filter methods for feature selection are faster than wrappers and deserve more GBML research. Finally, many specialized learning problems (not to mention specific applications) remain little or unexplored with GBML, including ranking, semi-supervised learning, transductive learning, inductive transfer, learning to learn, stream mining, and no doubt others that have not yet been formulated.

Acknowledgments

Thanks to my editor Thomas Bäck for his patience and encouragement, and to Larry Bull, John R. Woodward, Natalio Krasnogor, Gavin Brown and Arjun Chandra for comments.

Glossary

EA	Evolutionary Algorithm
FRBS	Fuzzy Rule-Based System
GA	Genetic Algorithm
GBML	Genetics-Based Machine Learning
GFS	Genetic Fuzzy System
GP	Genetic Programming
LCS	Learning Classifier System
NN	Neural Network
SL	Supervised Learning

Abstract

Coevolutionary algorithms approach problems for which no function for evaluating potential solutions is present or known. Instead, algorithms rely on the aggregation of outcomes from interactions among evolving entities in order to make selection decisions. Given the lack of an explicit yardstick, understanding the dynamics of coevolutionary algorithms, judging whether a given algorithm is progressing, and designing effective new algorithms present unique challenges unlike those faced by optimization or evolutionary algorithms. The purpose of this chapter is to provide a foundational understanding of coevolutionary algorithms and to highlight critical theoretical and empirical work done over the last two decades. This chapter outlines the ends and means of coevolutionary algorithms: what they are meant to find, and how they should find it.

1 Introduction

The inspiration for coevolutionary algorithms (CoEAs) is the same as for traditional evolutionary algorithms (EAs): attempt to harness the Darwinian notions of *heredity* and *survival of the fittest* for simulation or problem-solving purposes. To put it simply, a *representation* is chosen to encode some aspects of potential solutions to a problem into individuals, those individuals are altered during search using genetic-like *variation* operators such as mutation and crossover, and search is directed by selecting better individuals as determined by a fitness *evaluation*. With any luck, the iteration of these steps will eventually lead to high-quality solutions to a problem, if problem solving is the aim, or to interesting or realistic system behavior.

Usually, EAs begin with a *fitness function*, which for the purposes of this chapter is a function of the form $f : G \rightarrow \mathbb{R}$ that assigns a real value to each possible genotype in G . (Note that in certain branches of biology, fitness refers to the number of offspring an individual receives; thus, the use of the term fitness function in this way, while common in the evolutionary computation literature, breaks somewhat with biological tradition. However, seemingly less loaded alternative terms such as *objective function* evoke multi-objective optimization, a topic that will also be discussed briefly. In order to avoid confusion with other uses of the term *objective*, the term fitness function is used throughout the chapter.) Given such a function, the fitness relationship between any two genotypes $g_1, g_2 \in G$ is clear: $f(g_1)$ is compared with $f(g_2)$ to see which is more fit. By contrast, CoEAs do not use such a direct metric of the fitness of individuals. Instead, two individuals are compared on the basis of their outcomes from interactions with other individuals. (For this reason, the fitness in a CoEA has been called *subjective fitness*, subject as it is to the changing population(s). The objectively given and unchanging fitness function used in typical EA applications is *objective*.) As should become apparent as this chapter unfolds, this seemingly small change to how evaluation is done creates a variety of fundamental differences from traditional evolutionary computation. Most importantly, the fitness ranking of two individuals can change over time, a phenomenon that cannot happen in an ordinary EA. Indeed, virtually all of the techniques and ideas presented in this chapter are affected one way or another by this fundamental question: How could one possibly build an effective algorithm when any time one believes A is better than B it is possible that later one will believe B is better than A ?

This chapter is constructed to provide a foundational understanding of coevolutionary algorithms from a problem-solving point of view. Along the way, it will survey some of the many CoEAs that have been developed and the wide variety of domains to which they have been applied. Before going into detail, however, two coevolutionary algorithm schemes and problem classes are presented to give context for what follows.

1.1 Two Simple Coevolutionary Algorithms

In a *single population* CoEA (☞ [Algorithm 1](#)), individuals are evaluated by interacting with other individuals from that population. In a *multi-population* CoEA (☞ [Algorithm 2](#)), individuals in one population interact with individuals in one or several other populations.

Algorithm 1 SINGLE POPULATION CoEA

```
Initialize population
Select evaluators from population
Evaluate individuals from population by interacting with evaluators
while not done do
    Select parents from population
    Produce children from parents via variation
    Select evaluators from (children+, parents)
    Evaluate individuals from children by interacting with evaluators
    Select survivors for next generation
end while
return solution
```

Algorithm 2 MULTI POPULATION CoEA

```
for each pop ∈ populations do
    Initialize pop
    Select evaluators from (populations – pop)
    Evaluate individuals from pop by interacting with evaluators
end for
while not done do
    for each pop ∈ populations do
        Select parents from pop
        Produce children from parents via variation
        Select evaluators from (populations – pop)
        Evaluate individuals from children by interacting with evaluators
        Select survivors for next generation
    end for
end while
return solution
```

There has been some amount of controversy over whether a single-population algorithm could be fairly called coevolutionary. After all, biologists use the term coevolution to refer to genetic influence of two species over each other. Since a population refers to a collection of members of a species, it seems that one must have two populations to have coevolution. A pragmatic approach to the term is taken here. Problems in which the ranking of two entities can change depending on the presence or absence of other entities cause a certain set of issues for population-based problem-solving algorithms, issues that do not arise with ordinary optimization or multi-objective optimization problems. While these issues manifest differently in single- and multi-population algorithms, they are nevertheless present and must be taken into account if one hopes to design a successful problem-solving algorithm. Thus, at the risk of breaking with the biological terminology, both single- and multi-population algorithms are referred to as coevolutionary.

While many CoEAs are variations of these two main frameworks, several details have been omitted, some of which will be discussed later in this chapter. For example, a common mechanism not addressed by those frameworks is for a CoEA (either single- or multi-population) to have an *archive* that serves to evaluate individuals or to store potential solutions and is updated from the main population(s). Also, multi-population CoEAs can perform simultaneous or concurrent evolutionary steps, while the example algorithm is sequential. Finally, these two algorithmic schemes do not specify which interactions occur or how the results of interaction outcomes are aggregated into an evaluation that can be used by a selection method. These points will be addressed in [Sect. 2](#).

1.2 Problem Classes

As a consequence of subjective evaluation, the dynamics of coevolutionary algorithms can be frustratingly complex. One can view the interactions oneself as the basic unit of evaluation; in that view, the fitness landscape for an individual changes as a function of the content of the population(s). Intuitions about fitness landscapes from evolutionary computation do not easily map to this population-dependent, dynamic landscape situation. Nevertheless, coevolutionary algorithms ideally will leverage this mutability of the fitness landscape, adaptively focusing on relevant areas of a search space. This can be particularly helpful when problem spaces are very large or infinite. Additionally, some coevolutionary algorithms appear natural for domains that contain certain, known structure (Potter 1997; Stanley 2004) since search on smaller components in the larger structure can be emphasized. Most usefully, though, coevolution is appropriate for domains that have no intrinsic objective measure, which will be called *interactive domains*.

While the analogy with dynamic optimization (where the landscape also changes, but independently of the search process) may ground the reader, historically it has not generated insights into how to design successful coevolutionary algorithms. Instead, a fruitful approach has been to view interactive domains (and the problems that can be defined over them) as static, but structurally different and more complex than those of traditional optimization. This chapter is structured around this view.

Historically, the terms *cooperative* and *competitive* have been used to classify the domains to which coevolution is often applied. Indeed, game theory provides some guidance for making such distinctions. It can be argued that while such distinctions are relevant and at times useful for classifying the interactive domain over which an algorithm operates, they have

not been appropriate for classifying *problems* or algorithms. The interactive domain, like the fitness function, simply gives values to interactions. The problem specifies what to find and the algorithm finds it. Chess is an interactive domain, finding a chess-playing strategy capable of grand master rating is a problem. Experience shows that details of the problem definition and algorithm design have much more impact on the overall behavior of a CoEA than details of the interactive domain.

Thus, problems are primarily divided into classes based on what constitutes a solution. Two types of problems are highlighted: *test-based* problems and *compositional* problems. A test-based problem is one in which the quality of a potential solution is determined by its performance when interacting with some set of tests. By contrast, in compositional problems the quality of a solution to the problem involves an interaction among many components that together might be thought of as a team or assembly.

1.3 Successful Applications of Coevolutionary Algorithms

In the subsequent sections interactive domains and coevolutionary algorithms will be described in detail; however, it is useful to have some context with which to begin the discussion. Below are three simple successful applications of coevolution to three different problems. They will be presented as examples for the ideas discussed above, but they were also chosen for their historical impact.

1.3.1 Single Population CoEA Applied to a Test-Based Problem

In single population CoEAs applied to test-based problems, individuals serve two roles: at times they are used as (components of) potential solutions, while at other times they are used as tests to provide evaluation information about other individuals. The problem of finding good game-playing strategies can be viewed as a test-based problem since strategies are tested by playing against other strategies. Chellapilla and Fogel's AI checkers player *Blondie24* is a popular and successful application of a CoEA to such a problem (Chellapilla and Fogel 1999). A strategy in Blondie24 employs a traditional minimax algorithm, but uses a neural network for board evaluation. Individuals in the CoEA are vectors of weights for a fixed-structure neural network, and are evaluated by playing against other individuals. Points are awarded based on the win/loss/draw record, and fairly standard evolutionary programming methods are used to select players, hence weight vectors, with better records. The CoEA employed for this problem was able to produce a checkers player that is competitive with the best existing human and AI players.

- ▶ *Interactive Domain:* Game of checkers; *Test:* Opponent playing strategy; *Potential Solution:* Playing strategy; *Problem:* Find a strategy that beats the most opponents.

1.3.2 Two-Population CoEA Applied to a Test-Based Problem

Hillis' coevolution of sorting networks and challenging data sets uses two populations (Hillis 1990). One population represents sorting networks (that is, arrangements of

compare-and-swap circuits) while another represents unsorted data sets to test a network's sorting capability. The goal of the algorithm is to produce the smallest network possible that correctly sorts any given data set, but it does this while simultaneously honing ever more challenging and representative data sets. The technique produced a 61-comparator network, which is just one comparison larger than what was, at the time, the smallest-known network for a 16-input problem. A similar, non-coevolutionary technique described in that work was unable to produce networks smaller than 63 comparators.

- ▶ *Interactive Domain:* Running sorting network on data set; *Test:* Data set; *Potential Solution:* Sorting network; *Problem:* Find smallest, correct network.

1.3.3 Multi-population CoEA Applied to a Compositional Problem

There are a number of successful applications of CoEAs to compositional problems wherein problems are decomposed in some way and separate EAs are applied in parallel to the components, even though evaluation must involve some kind of aggregation or composition of components from the whole system. Perhaps the oldest, and still among the most successful, of these is Husbands and Mills' work on job-shop scheduling (Husbands and Mill 1991). In this work, individuals encode potential floor plans for managing jobs involving the processing of a particular widget constructed by the shop, and separate populations are used to optimize these process plans for each widget. Fitness, however, includes accounting for shared resources in the shop (time, space, etc.). There is also a population of arbitrators, agents that resolve conflicts between process plans for different widgets. Resulting schedulers can deal with a great deal of uncertainty on the job-shop floor.

While perhaps not as well known as the Blondie24 or sorting network examples, this work showcases the difference between a cooperative *domain* and compositional *problem*. In this case, the solution to the problem is a collection of floor plans (one for each component) and an arbitrator, which means the problem is compositional. However, the floor plans compete with one another in the evaluation function because they must share resources, so it is not strictly cooperative.

- ▶ *Interactive Domain:* Determination of complete job-shop schedule; *Components:* floor plans for different widgets, arbitrator for conflict resolution; *Potential Solution:* set of floor plans for each widget plus an arbitrator; *Problem:* Find an efficient and robust job-shop schedule.

1.4 Chapter Organization

History has shown that the naïve application of CoEAs to ill-understood domains is as likely to produce confusing and unsatisfactory results as to succeed. Therefore, at least from the perspective of problem solving, a careful algorithm design process is critical. This chapter is organized to emphasize this process: define the problem, define the relationship between the algorithm and the problem, implement the algorithm in a principled way, and analyze its behavior based on these principles.

The next section establishes clear definitions of domains, problems, and the types of solutions one expects to find. ◉ [Section 3](#) describes how problems relate to evaluation and

representation choices within a coevolutionary algorithm. This is followed by the presentation of analytical approaches currently available for understanding coevolutionary algorithm design, performance, and behavior. The concluding section provides some broader views of coevolutionary systems and outlines possible future directions of research and application.

2 Problems and Solutions

Coevolutionary algorithms are typically applied to interactive domains. Such domains generally lack an objective function giving a value to each potential solution. Rather, interactive domains encode the outcomes of interactions between two or more entities; depending on the domain, individual entities or the interaction itself may receive value as a result of an interaction. An algorithm must then decide how to use these outcomes to make decisions about which entities to promote in the next generation and which entities to demote or discard.

In a problem-solving context, an algorithm will need more than just an interactive domain. It will also require some way of deciding which entities in the domain are better than others. Coupled with information like that, an interactive domain becomes a co-search or co-optimization problem.

This section is concerned with detailing interactive domains, co-search, and co-optimization problems in the abstract, surveying some examples from both test-based and compositional problems, and beginning the discussion of what it means to extract a solution from such problems. Here, all dynamic or algorithmic considerations are left aside and instead the focus is on formalizing static definitions of problem classes to which CoEAs have been applied. Coevolutionary algorithms and their behavior on these problem classes are discussed in subsequent sections.

2.1 Interactive Domains

The formal notion of interactive domain can be defined as follows.

Definition 1 (Interactive Domain) An *interactive domain* consists of one or more functions, called *metrics*, of the form $p : X_1 \times X_2 \times \dots \times X_n \rightarrow R$, where

- Each i with $1 \leq i \leq n$ is a *domain role*
- An element $x \in X_i$ is an *entity* (playing the domain role i)
- Each X_i is an *entity set* (for the domain role i)
- A tuple $(x_1, x_2, \dots, x_n) \in X_1 \times \dots \times X_n$ is an *interaction*
- The value $p(x_1, x_2, \dots, x_n) \in R$ is an *outcome* (of the interaction)
- The ordered set R is the *outcome set*

□

Some remarks about this definition are in order.

Interactions may be relatively simple, such as applying a sorting network to an input sequence; or highly complex, such as simulating the job-shop scheduling activities given some arbitrator and several floor plans. Further, they may be direct, such as, again, applying a sorting network to an input sequence; or indirect, via an *environment*, such as the board

and dice in a checkers game or the shared resources in the scheduling example. We abstract away from such low level details and we are merely concerned with the outcome of the interaction.

The discussion of problem classes in [Sect. 1.2](#) touched on the distinction between cooperative and competitive domains. Here, those terms will be linked directly to the interactive domain. *Cooperative domains* have n metrics p_i , one for each domain role. The metric p_i is interpreted as giving an outcome to the entities playing role i . In many examples, $p_i = p_j$ for all roles i and j , so that the metrics only differ by which entity receives the outcome (but see [\(Popovici 2006\)](#) for a more nuanced discussion of cooperative domains). *Competitive domains*, by contrast, typically have only two roles. The two corresponding metrics often obey $p_2 = -p_1$, making the domain equivalent to a zero-sum game. Naturally, there is an enormous space of interactive domains that do not fall into either the cooperative or competitive categories. Note also that the terms “cooperative coevolution” and “competitive coevolution” refer to coevolutionary algorithms operating on such domains.

While an interactive domain has n entity sets, two or more of these sets may be the same. The word *type* will be used to refer to the sets from which entities are drawn, independently of what domain roles the entities are playing. There are special cases in which all domain roles are played by entities of the same set and, furthermore, the outcomes a particular entity receives do not depend on which role it plays. These will be referred to as *role-symmetric* domains.

Example 1 (Rock–paper–scissors) The game rock–paper–scissors furnishes a particularly simple example of an interactive domain. This game is generally expressed with a payoff matrix

	<i>Rock</i>	<i>Paper</i>	<i>Scissors</i>
<i>Rock</i>	0	-1	0
<i>Paper</i>	1	0	-1
<i>Scissors</i>	-1	1	0

To view rock–paper–scissors as an interactive domain, observe

- There are two roles
- $X_1 = X_2 = \{rock, paper, scissors\}$ are the entity sets, so there is one type
- The matrix encodes a single metric p , whose value is given to the entity on the line. This domain is role symmetric; for instance, *rock* receives the same payoff versus *paper* regardless of whether it is playing the first role or the second.

Example 2 Here is another example coming from an abstract game

	t_1	t_2	t_3
s_1	1	1	0
s_2	0	1	2
s_3	2	1	1

As an interactive domain, note

- There are two roles
- $X_1 = \{s_1, s_2, s_3\}; X_2 = \{t_1, t_2, t_3\}$ are the entity sets (there are two types)
- The matrix encodes a single metric p . This domain is not role symmetric

For a large majority of interactive domains that have been studied in practice, the outcome set R is a subset of \mathbb{R} ; however, that requirement is not strictly necessary (see (Bucci and Pollack 2002) for a discussion of ordered outcome sets that are not subsets of the reals).

Finally, note that this definition of interactive domain closely resembles the notion of the game defined by Ficici (2004). What we are calling entity is there called a behavior, reflecting that work's closer focus on agents selecting behaviors. What we are here calling an interaction is there called an event, and the notion of outcome corresponds to what Ficici calls a measurement. That work should be consulted for a more detailed treatment of interactive domains.

2.2 Co-search and Co-optimization Problems

A function $f: X \rightarrow \mathbb{R}$ gives values to elements of X . However, more information is needed to define a *problem* that can be solved. For instance, one may wish to find all the elements of X that maximize the value of f . Or, one may wish to find only one such element. Or, one may wish to find the elements that minimize f . Notice that for a fixed function f , there are many, distinct ways to decide what makes a “good” element of X . To give a well-defined search or optimization problem, one must specify not just the function f but also one way for deciding which elements of X are to be found.

By analogy, once an interactive domain is defined, one has a way of giving one or more values to interactions of entities, but does not yet have a well-defined problem to solve. The purpose of this section is to detail the kinds of problem that can be defined over interactive domains. These will be called *co-search problems* and *co-optimization problems*. First:

Definition 2 (Co-search Problem) Given an interactive domain, a *co-search problem* over it consists of

- A non-empty subset $I \subset (1, \dots, n)$ of the n domain roles
- A set \mathcal{C} of *potential solutions* aggregated from entities of the domain roles in I
- A *solution concept* that specifies a partitioning of the potential solutions into (actual) solutions and non-solutions. This is represented as a subset $\mathcal{S} \subset \mathcal{C}$ of the potential solutions

□

The last two components of the definition will be examined in more detail.

Potential Solutions: There are two critical points to emphasize:

- In many problems of practical interest, no single entity makes for a sufficient solution. Rock–paper–scissors stands as an intuitive example: none of the entities *rock*, *paper*, or *scissors* is, by itself, a reasonable strategy to play in this game. In such cases, potential solutions are *aggregated* from, meaning built or constructed out of, multiple entities.
- In some problems, one would like potential solutions to either lie in or be aggregated from entities in a single domain role, while in other problems, potential solutions should be aggregates of entities from several domain roles. The subset I is used to distinguish cases like these. If $I = (1)$, solutions are aggregated only from entities playing domain role 1, while if $I = (1, 2, \dots, n)$, solutions are aggregated from entities playing all n roles. One could, of course, have an I that is not all of $(1, \dots, n)$ but contains more than one domain role.

➊ Section 2.3 will give examples of what is meant by saying potential solutions are “aggregated from” entities. While a fully general formalization of this notion is beyond the scope of this chapter, in typical examples, potential solutions are sets of entities, mixtures of (distributions over) entities, tuples of entities, or perhaps combinations of these. (For instance, Nash equilibria are usually pairs of mixtures.) The notion of potential solution here is closely related to the idea of a *configuration* in (Ficici 2004), which should be consulted for more detail; Popovici (2006) discusses the idea of aggregating solutions in more detail as well.

Solution Concepts: The phrase “solution concept” originates in game theory (Osborne and Rubinstein 1994) and is largely synonymous with solution specification or solution definition. The phrase has been widely used in coevolution since being imported into the field by Ficici (2004). While the idea of a solution concept is presented in our abstract, as a subset of \mathcal{C} , in reality, solutions are identified using the metrics of the interactive domain. (What Ficici calls an *intensional* solution concept (Ficici 2004).) That is, it is typical to seek entities or combinations of entities that in some sense optimize the metrics of the interactive domain.

➋ Section 2.4 illustrates the point by describing several examples of solution concepts that have arisen in practice.

A *co-optimization problem* is closely related to a co-search problem. However, instead of a solution concept, a co-optimization problem specifies an order on the potential solutions and implicitly requires that solutions be maximal elements of the order. Specifically:

Definition 3 (Co-optimization Problem) Given an interactive domain, a *co-optimization problem* over it consists of

- A non-empty subset $I \subset (1, \dots, n)$ of the n domain roles;
- A set \mathcal{C} of *potential solutions* built from entities of the domain roles in I ;
- An ordering (which may be a partial order or even a preorder) \leq of \mathcal{C} such that if $c_1, c_2 \in \mathcal{C}$ and $c_1 \leq c_2$, c_2 is interpreted as being no worse a solution than c_1 . (Note that \leq is an ordering on potential solutions, not on numbers. In defining it, it may be the case that lower values from the domain’s metrics are better.) □

A co-optimization problem can be converted into a co-search problem by defining the solution concept $\mathcal{S} \subset \mathcal{C}$ to be the set of maximal elements of \leq . In that sense, co-optimization is a more refined notion than co-search.

As a final bit of terminology, recall that both co-search and co-optimization problems have a subset I of the domain roles that specifies which entities are aggregated into potential solutions. Let \widehat{I} denote the complement of I in $(1, \dots, n)$, so, for instance, if $n = 3$ and $I = (1, 2)$ then $\widehat{I} = (3)$. Then two *problem roles* can be distinguished:

- If $i \in I$, X_i is a *component role* and $x \in X_i$ are *component entities* or *components*
- if $i \in \widehat{I}$, X_i is a *test role* and $x \in X_i$ are *test entities* or *tests*

Note that \widehat{I} may be empty, meaning there is no test role explicitly defined by the problem. However, I cannot be empty by definition, meaning there is always at least one set of entities playing the role of component.

To summarize some of the key concepts relating to entities that have been introduced in this section:

- An interactive domain defines two or more *domain roles* and entities that play each role.
- The notion of type is coarser than that of domain role: several domain roles might correspond to the same type of entity, but each type corresponds to at least one domain role.
- A co-search or co-optimization problem lies at a conceptually higher level, defined over an interactive domain.
- Co-search and co-optimization problems define two *problem roles*, components and tests.
- At the problem level, the component role corresponds to one or more lower-level domain roles. The test role may correspond to zero or more domain roles.
- Since types sit at the domain role level, the relationship between types and problem roles can be complicated. There may be components of different types, tests of different types, components and tests that both have the same type, etc.

☞ [Section 1.2](#), besides distinguishing cooperative and competitive domains, also mentioned the distinction between compositional and test-based problems. Before elaborating on potential solutions in ☞ [Sect. 2.3](#) and solution concepts in ☞ [Sect. 2.4](#), we will define and illustrate these two important classes of co-search and co-optimization problems. Briefly, compositional and test-based problems correspond to the extremes where $|I| = n$ and $|I| = 1$, respectively. The middle ground between these extremes is virtually unexplored.

2.2.1 Compositional Problems

A *compositional problem* is a co-search or co-optimization problem in which all domain roles are used as components to build solutions. That is, $|I| = n$ and, conversely, $|\widehat{I}| = 0$. The idea is that each entity in each domain role is a component. To build potential solutions, one must use entities from each of the domain roles; one does not have a complete potential solution until one has used at least one component from each domain role. An intuitive example is a baseball team: one does not have a baseball team until one has a pitcher, a catcher, outfielders, etc.

Compositional problems have largely been explored under the rubric of cooperative coevolutionary algorithms (CCEAs). Besides theoretical works that study features of algorithm behavior on arbitrary or abstract test problems (Jansen and Wiegand [2003a, b, 2004](#)), or empirical work of algorithm dynamics on simple test problems (Popovici and De Jong [2005a, c](#)), work applying CCEAs to multivariate function optimization or multi-agent learning have also appeared. In multivariate function optimization, one treats each input variable as a distinct domain role, so that each entity in a particular domain role is a potential setting for one of the input variables (Potter and De Jong [1994, 2000](#); Panait et al. [2004](#)). Multi-agent learning applications have treated each domain role as the space of possible behaviors or actions for agents that form a team performing a task together (Parker and Blumenthal [2003](#); Panait et al. [2006c](#)).

2.2.2 Test-Based Problems

A *test-based problem* is a co-search or co-optimization problem in which $|I| = 1$; that is, in which a single domain role contains components, and all other domain roles are tests. Intuitively speaking, the test entities are used to probe or give information about the potential solutions that can be aggregated from the components.

Test-based problems are discussed as such in (De Jong and Pollack [2004](#)) and analyzed in connection with multi-objective optimization in (De Jong and Bucci [2007](#)); however, the idea

is implicit in early work on Pareto coevolution (Noble and Watson 2001; Ficici and Pollack 2001) and is more explicit in later works (De Jong 2004a, c; Monroy et al. 2006). Bucci and Pollack (2002, 2003b) formally analyze test-based problems from the perspective of order-theory, while Bucci and Pollack (2005) and Panait and Luke (2006) treat compositional problems using ideas developed to study test-based problems. De Jong (2005), Jensen (2001), Branke and Rosenbusch (2008), Barbosa (1999), and Stuermer et al. (2009) approach two types of test-based problems not based on Pareto dominance.

In many of these works, the terms *candidate*, *candidate solution*, or *learner* are used to describe what is here described as a component. Likewise, the term *test* is used in those works to denote what is here called an entity playing the test role.

2.3 Potential Solutions in Co-search and Co-optimization Problems

❷ Section 2.2 defined a co-search problem as one that, given an interactive domain, specifies a solution concept as a subset of a set of *potential solutions* that are built from the interactive domain. This section is intended to detail, by example, several common extant ways of creating potential solutions from entities.

2.3.1 Single Entity

The simplest and most obvious set of potential solutions is a set of entities. Consider an interactive domain with n roles and a co-search problem with $I = (1)$, so that the component role is being played by the entities in domain role 1. Then, one set of potential solutions for this problem is the set X_1 of components itself. In this case, the set \mathcal{C} is X_1 , so that a solution concept \mathcal{S} gives a subset of X_1 .

Seminal work by Hillis (1990) and Sims (1994) both use single entities as potential solutions. Hillis' algorithm sought a single sorting network; there was no sense in which two or more sorting networks could be combined. Likewise, Sims' algorithm sought a morphology and behavior for a simulated creature; again, there was no mechanism for combining several creatures into a composite.

Stipulating that single entities serve as solutions is appropriate in certain domains, particularly those involving the design of a complex object (that is, when no clear way of combining entities together is present); or, those in which one expects that a single entity that solves the problem may exist. However, as noted above about rock–paper–scissors, many domains have no single entity that is adequate to solve the problem.

2.3.2 Sets

Consider, for concreteness, that we have an interactive domain with two roles and our co-search problem specifies that $I = (1)$. The entities in X_1 are components, while those in X_2 are tests. In this example, the set \mathcal{C} is the powerset of X_1 , $\mathcal{P}(X_1)$. A solution concept gives a subset of $\mathcal{P}(X_1)$, equivalently one or more subsets of X_1 , where each subset is a solution.

Set-based notions of potential solution have been studied under the umbrella of Pareto coevolution (Ficici and Pollack 2001; Noble and Watson 2001). Treating each test as

an objective to be optimized, the problem-solving goal is to find (an approximation of) the non-dominated front among the components. Therefore, a potential solution is a subset of X_1 , in other words, an element of $\mathcal{C} = \mathcal{P}(X_1)$. The non-dominated front itself is the solution.

When solution concepts are further elaborated in [Sect. 2.4](#), one will see the situation is more subtle; in fact, a set related to, but not quite, the non-dominated front is desirable. However, that discussion will be deferred until then.

2.3.3 Mixtures

Let's maintain the co-search problem of the previous example. However, let's say that a solution is not a subset of X_1 , but a probability distribution over X_1 . Following Vose ([1999](#)), denote the set of these by A^{X_1} . Then another choice for the set of potential solutions \mathcal{C} is A^{X_1} .

Mixture-based solutions are most often discussed in the context of Nash equilibria; the Nash memory ([Ficici and Pollack 2003](#)) and parallel Nash memory ([Oliehoek et al. 2006](#)) are examples of algorithms that treat mixtures as potential solutions.

2.3.4 Compositions in General

Sets and mixtures are both examples of aggregates; that is, potential solutions created by putting together components drawn from one or more of the component roles defined in the problem. Sets and mixtures are particularly simple kinds of aggregates. More complicated compositions are conceivable.

Compositional coevolution in general aims to discover good assemblies. The originally stated aim of cooperative coevolutionary algorithms, from which the more general notion of compositional coevolution sprang, was to attack the problem of evolving complicated objects by explicitly breaking them into parts, evolving the parts separately, and then assembling the parts into a working whole ([Potter and De Jong 2000](#)). The nature of the “coadapted subcomponents” discussed in that work was not strictly defined; hence, the idea is that any subcomponent of any assembly (aggregate) was fair game for the method. Since then, compositional coevolution has been applied to coevolving teams of agents performing a task, for instance, where the composition here is of several different agents collaborating as a team.

In the language developed in this section, agents or coadapted subcomponents are domain entities playing the component role of a compositional problem. A collaboration among entities is an interaction, and the means for evaluating a team or assembly would constitute the metric of the problem. The potential solutions in these cases, then, are the possible tuples over the domain roles; that is, $\mathcal{C} = X_1 \times \dots \times X_n$.

Though the translation into the notion of a co-search problem is less obvious, another important, nontrivial example of composition found in coevolutionary algorithms are in applications of neuro-evolutionary algorithms. The neuro-evolution through augmenting topologies (NEAT) algorithm ([Stanley and Miikkulainen 2002a](#)) has been applied to coevolve robot controllers in a simulated robot duel ([Stanley and Miikkulainen 2002a, b, 2004](#)) as well as players of a variant of the video game Pong ([Monroy et al. 2006](#)). A hallmark of the NEAT algorithm is the separation between components of neural networks, which consist of small assemblies of neurons and associated weighted synapses, and the topology of a

complete network, which functions as a blueprint for how assemblies are put together. A second, important feature of NEAT emphasized in these works is the possibility for complexification or elaboration: since neural network topologies are not limited by NEAT, they can grow to arbitrary complexity, elaborating on previously evolved behaviors. In contradistinction to typical CCEAs, which prespecify the size and complexity of compositions, NEAT permits open-ended complexity increase. (And, one would hope, an increase in capability as well.)

The Symbiogenic Evolutionary Adaptation Model (SEAM) described by Watson (2002) includes a form of variational operator designed to explicitly compose evolving entities. Additionally, SEAM employs a group evolutionary mechanism of composition in conjunction with notions of test-based evolution by using Pareto dominance to determine whether variation is likely to result in productive compositions.

Finally, it is worth pointing out that in general game-theoretic analysis, Nash equilibria are pairs of mixtures of pure strategies. In many cases, only the first mixture in the pair is used to solve a problem; the other is there for testing purposes. However, should one actually need both mixtures in the pair, the set of potential solutions would be $\Lambda^{X_1} \times \Lambda^{X_2}$, which involves two levels of aggregating: first mixing (over X_1 and X_2), then pairing.

2.4 Solution Concepts

This section will detail several solution concepts for both compositional and test-based problems that have been used in coevolutionary algorithms. Recall that a solution concept specifies a subset of the potential solutions, $\mathcal{S} \subset \mathcal{C}$. Each example will detail the interactive domain, the co-search problem including the space of potential solutions, and how solutions are determined from the metric(s) of the domain. Solution concepts for compositional problems are presented first.

2.4.1 Compositional Solution Concepts

Ideal Team

Consider an interactive domain with n domain roles, entity sets X_1, X_2, \dots, X_n and one metric $p : X_1 \times \dots \times X_n \rightarrow \mathbb{R}$. Consider also a co-search problem over this domain with potential solutions drawn from the set of tuples $\mathcal{C} = X_1 \times \dots \times X_n$, so in fact this is a compositional problem. Observe there is a one-to-one correspondence between a potential solution and an interaction. The ideal team solution concept defines as solutions those potential solutions that maximize the value received from the metric

$$\mathcal{S} = \{\bar{x} \in \mathcal{C} \mid \forall \bar{x}' \in \mathcal{C}. p(\bar{x}) \leq p(\bar{x}') \Rightarrow p(\bar{x}) = p(\bar{x}')\} \quad (1)$$

where the shorthand \bar{x} is used to denote an arbitrary tuple in \mathcal{C} . In multi-agent parlance, the teams for which no other teams perform better are ideal teams.

The ideal team is not the only relevant compositional solution concept, and the question has been posed to what extent cooperative coevolution algorithms converge to it (Wiegand 2004). Another solution concept of interest arising from that investigation is *maximizing robustness*. The idea here is that rather than maximizing the outcome of a single potential solution, a solution should be robust in the sense that a “small” change in one of the components results in “small” changes in the composite’s value.

2.4.2 Test-Based Solution Concepts

Unless otherwise specified, the following examples of solution concepts for test-based problems are appropriate for problems of the following form:

- The interactive domain has two roles with entity sets X_1 and X_2 .
- There is a single metric $p : X_1 \times X_2 \rightarrow \mathbb{R}$.
- The co-search problem specifies X_1 as the only component role and X_2 as the only test role.

What varies in these examples is the set of potential solutions and how the subset of solutions is defined. These will be detailed now.

Best Worst Case

Best worst case operates over single-entity potential solutions, meaning $\mathcal{C} = X_1$. This solution concept specifies as solutions those components that maximize the minimum possible outcome over interactions with all tests. (This version has also been called *maximin*. The corresponding *minimax* can similarly be defined.) That is,

$$\mathcal{S} = \left\{ x \in \mathcal{C} \mid \forall x' \in \mathcal{C}. \min_{t \in X_2} p(x, t) \leq \min_{t \in X_2} p(x', t) \Rightarrow \min_{t \in X_2} p(x, t) = \min_{t \in X_2} p(x', t) \right\} \quad (2)$$

This criterion is appropriate in real-world domains where one needs to protect against the worst scenario possible.

Simultaneous Maximization of All Outcomes

Simultaneous maximization of all outcomes requires a solution to be a component that maximizes its outcome over all possible tests simultaneously. That is, $\mathcal{C} = X_1$ is a single entity set of potential solutions, and the solution concept is

$$\mathcal{S} = \{x \in \mathcal{C} \mid \forall x' \in \mathcal{C} \forall t \in X_2. [p(x, t) \leq p(x', t) \Rightarrow p(x, t) = p(x', t)]\} \quad (3)$$

This solution concept has a limited application scope, as for many problems, there does not exist a single potential solution that simultaneously maximizes the outcome against all possible tests.

Maximization of Expected Utility

Maximization of expected utility (MEU) is also relevant when $\mathcal{C} = X_1$. It specifies as solutions those components that maximize the expected score against a randomly selected opponent

$$\mathcal{S} = \{x \in \mathcal{C} \mid \forall x' \in \mathcal{C}. \mathbf{E}(p(x, X_2)) \leq \mathbf{E}(p(x', X_2)) \Rightarrow \mathbf{E}(p(x, X_2)) = \mathbf{E}(p(x', X_2))\} \quad (4)$$

where one is abusing notation and treating X_2 as a uniformly distributed random variable ranging over the set of tests, so that $\mathbf{E}(p(x, X_2))$ is the expected value of $p(x, t)$ when t is selected uniformly randomly from X_2 .

❸ [Equation 4](#) is equivalent to

$$\mathcal{S} = \left\{ x \in \mathcal{C} \mid \forall x' \in \mathcal{C}. \sum_{t \in X_2} p(x, t) \leq \sum_{t \in X_2} p(x', t) \Rightarrow \sum_{t \in X_2} p(x, t) = \sum_{t \in X_2} p(x', t) \right\} \quad (5)$$

when all the sums are defined. That is, maximizing expected utility is equivalent to maximizing the sum of outcome values over all tests when that sum is defined for all the components. Thus, MEU essentially assumes that all tests are of equal importance, which limits its generality.

Nash Equilibrium

The Nash equilibrium solution concept is inspired by game theory (Osborne and Rubinstein 1994) and operates over mixtures of components. When the problem is as before, $\mathcal{C}_1 = \Lambda^{X_1}$. However, deviating slightly from the previous examples, problems with $I = (1, 2)$ will also be considered, so that $\mathcal{C}_2 = \Lambda^{X_1} \times \Lambda^{X_2}$. That is, there are no tests, so in fact \mathcal{C}_2 defines a compositional problem. Furthermore, in both cases it will be assumed that there are two metrics, $p_1 : X_1 \times X_2 \rightarrow \mathbb{R}$ and $p_2 : X_1 \times X_2 \rightarrow \mathbb{R}$ interpreted as giving outcomes to entities in X_1 and X_2 , respectively. In many domains such as those arising from zero sum games, $p_1(x, y) = -p_2(x, y)$ for all $x \in X_1$ and $y \in X_2$.

Consider the case \mathcal{C}_2 first. Let $\alpha \in \Lambda^{X_1}$ and $\beta \in \Lambda^{X_2}$ be two mixtures over X_1 and X_2 , respectively. These can be written as formal sums

$$\alpha = \sum_{x \in X_1} \alpha_x \cdot x \quad (6)$$

and

$$\beta = \sum_{y \in X_2} \beta_y \cdot y \quad (7)$$

where α_x is the probability assigned to the component $x \in X_1$ by the mixture α , and β_y is the probability assigned to the test $y \in X_2$ by β and, since α and β are both distributions, $\sum_{x \in X_1} \alpha_x = 1$ and $\sum_{y \in X_2} \beta_y = 1$. Using this notation, define a function $\mathbf{E}_{p1} : \Lambda^{X_1} \times \Lambda^{X_2} \rightarrow \mathbb{R}$ such that for all $(\alpha, \beta) \in \Lambda^{X_1} \times \Lambda^{X_2}$

$$\mathbf{E}_{p1}(\alpha, \beta) = \sum_{\substack{x \in X_1 \\ y \in X_2}} \alpha_x \cdot \beta_y \cdot p_1(x, y) \quad (8)$$

$\mathbf{E}_{p1}(\alpha, \beta)$ is interpreted as giving the expected outcome that the mixture α receives when interacting with β . $\mathbf{E}_{p2}(\alpha, \beta)$ is defined similarly and gives the expected outcome to β .

A Nash equilibrium is a pair $(\alpha, \beta) \in \Lambda^{X_1} \times \Lambda^{X_2}$ such that neither α nor β can unilaterally change to some other mixture and receive a higher payoff. That is, (α, β) is a Nash equilibrium if the following two conditions hold:

- For all $\alpha' \in \Lambda^{X_1}$, $\mathbf{E}_{p1}(\alpha, \beta) \leq \mathbf{E}_{p1}(\alpha', \beta) \Rightarrow \mathbf{E}_{p1}(\alpha, \beta) = \mathbf{E}_{p1}(\alpha', \beta)$
- For all $\beta' \in \Lambda^{X_2}$, $\mathbf{E}_{p2}(\alpha, \beta) \leq \mathbf{E}_{p2}(\alpha, \beta') \Rightarrow \mathbf{E}_{p2}(\alpha, \beta) = \mathbf{E}_{p2}(\alpha, \beta')$

The Nash equilibrium solution concept for problems with $\mathcal{C}_2 = \Lambda^{X_1} \times \Lambda^{X_2}$ is then

$$\mathcal{S}_2 = \{(\alpha, \beta) \in \mathcal{C}_2 \mid (\alpha, \beta) \text{ is a Nash equilibrium}\} \quad (9)$$

For $\mathcal{C}_1 = \Lambda^{X_1}$, in other words problems in which one only cares about the mixture over components in X_1 , the Nash equilibrium solution concept is

$$\mathcal{S}_1 = \pi_1(\mathcal{S}_2) \quad (10)$$

where π_1 projects a pair (α, β) onto the first coordinate, α .

An attractive feature of the Nash equilibrium as a solution concept is that Nash equilibria have certain “security” guarantees: The expected payoff to α in a Nash equilibrium (α, β) can be no lower than $E_{p1}(\alpha, \beta)$, regardless of the strategy with which it interacts. In a game like $\{\text{rock}, \text{paper}, \text{scissors}\}$, for example, any individual strategy like *rock* will receive a -1 payoff against some opponent (if *paper* plays against *rock*, for example). The mixture $\frac{1}{3} \cdot \text{rock} + \frac{1}{3} \cdot \text{paper} + \frac{1}{3} \cdot \text{scissors}$, by contrast, will never receive an expected payoff lower than 0 against any opponent because $(\frac{1}{3} \cdot \text{rock} + \frac{1}{3} \cdot \text{paper} + \frac{1}{3} \cdot \text{scissors}, \frac{1}{3} \cdot \text{rock} + \frac{1}{3} \cdot \text{paper} + \frac{1}{3} \cdot \text{scissors})$ is a Nash equilibrium for that game and $E_{p1}(\frac{1}{3} \cdot \text{rock} + \frac{1}{3} \cdot \text{paper} + \frac{1}{3} \cdot \text{scissors}, \frac{1}{3} \cdot \text{rock} + \frac{1}{3} \cdot \text{paper} + \frac{1}{3} \cdot \text{scissors}) = 0$. Note that this is a kind of worst-case guarantee for the mixture α that is similar in spirit to that sought in the best worst case solution concept; the primary difference is that the best worst case seeks single components with such a guarantee, while Nash equilibrium seeks a mixture of many components.

Pareto Optimal Set

Multi-objective optimization extends traditional optimization through the introduction of multiple *objectives*. This may be viewed as the use of a function that is vector valued rather than scalar. In Pareto-based solution concepts, every possible test is viewed as an objective to be optimized.

Potential solutions for the Pareto optimal set solution concept are subsets of X_1 ; that is, $\mathcal{C} = \mathcal{P}(X_1)$. Here, the set of solutions will consist of a single member, the non-dominated front, which is defined

$$\mathcal{F} = \{x \in \mathcal{C} \mid \forall x' \in \mathcal{C}. [\forall t \in X_2. [p(x, t) \leq p(x', t)] \Rightarrow \forall t \in X_2. [p(x, t) = p(x', t)]]\} \quad (11)$$

Let the *Pareto covering* order be an order on X_1 defined as follows:

$$x \preceq x' \quad \text{if } \forall t \in X_2. p(x, t) \leq p(x', t) \quad (12)$$

for all x and x' in X_1 . This definition essentially says that the outcome of x' against any test is at least as high as that of x . However, \preceq is not a total order on X_1 , because it is possible that $p(x, t) < p(x', t)$ while $p(x, t') > p(x', t')$ for two tests $t, t' \in X_2$. Furthermore, while \preceq is reflexive and transitive, it need not be a partial order: two distinct components x and x' might receive precisely the same outcomes on all tests, so $x \preceq x'$ and $x' \preceq x$ both hold and antisymmetry fails to hold.

The definition of \mathcal{F} can be simplified using \preceq

$$\mathcal{F} = \{x \in \mathcal{C} \mid \forall x' \in \mathcal{C}. x \prec x' \Rightarrow x' \preceq x\} \quad (13)$$

The Pareto optimal set solution concept is defined as

$$\mathcal{S} = \{\mathcal{F}\} \quad (14)$$

Some remarks:

- There is a formal similarity between \bullet Eq. 3, the simultaneous maximization of all objectives, and the non-dominated front \mathcal{F} defined in \bullet Eq. 11. They differ only in the placement of the quantifier $\forall t \in X_2$. However, while formally similar, these two solution concepts have significantly different interpretations: while \bullet Eq. 13 shows that \mathcal{F} is the set of *maximal* elements of the order \preceq , in fact \bullet Eq. 3 is the set of *maxima* of that order, the difference being that maxima must be larger than all other components across all tests simultaneously. Thus, the non-dominated front puts weaker constraints on its members

than the simultaneous maximization of all objectives, and one would expect the former to be a larger set of components.

- The Pareto optimal set solution concept has only one member, \mathcal{F} , which is itself a set of components. This definition is chosen for consistency with the other solution concepts; each solution concept is a set whose members are solutions. The non-dominated front forms a single, unique solution to a multi-objective problem. A limitation of the Pareto optimal set solution concept is that this set may be very large; while not being covered is a sensible minimum requirement for solutions, for certain problems it may be insufficiently weak, in that it can insufficiently narrow down the set of possible solutions.
- As noted, two components may receive precisely the same outcomes against all possible tests. Thus, while they may be distinct components in the set X_1 , as far as performance against the tests in X_2 goes, they are indistinguishable.

Pareto Optimal [Minimal] Equivalence Set

The indistinguishability of some elements of the non-dominated front entails this set may be too large. One can partition this set in equivalence classes by this property, like so. Say that $x \sim x'$ if $x \preceq x' \wedge x' \preceq x$; that is, x and x' are equivalent if they receive the same outcomes against all tests in X_2 . \sim is an equivalence relation on X_1 . (This is a simple, well-known consequence of \preceq being a preorder.) It is reasonable to suppose that one only needs one representative of each equivalence class under \sim , and this intuition leads to two more solution concepts.

A Pareto optimal equivalence set is a set containing *at least one* element from each equivalence class of the full Pareto optimal set. Note that while there is a single Pareto optimal set, there may be a combinatorial number of Pareto optimal equivalence sets. A Pareto optimal minimal equivalence set contains *exactly one* component from each equivalence class of the full Pareto optimal set. There may be a combinatorial number of Pareto optimal minimal equivalence sets as well.

These two solution concepts typically define a smaller set of potential solutions than the Pareto optimal set. Yet, depending on the characteristics of the problem, such a set can still be very large.

3 Design of Coevolutionary Algorithms

As the previous sections have shown, there is a wide spectrum of problems in interactive domains. While throughout this chapter we discuss generic issues that any algorithm targeted at such co-search problems will have to address, in this section, the main focus is on issues that are specific to approaching these problems via coevolutionary algorithms. Like with any method, application of coevolutionary algorithms to a problem tends to go more smoothly and have more opportunity for success when algorithm engineers *first* go through the process of formalizing the domain and the problem, and *then* design the algorithm.

For domains that are inherently interactive, the formalizing process involves more rationalization than choosing. However, sometimes one may want to reformulate a noninteractive domain into an interactive one. The domains of problems featuring the ideal team solution concept are often the result of such a reformulation. In such cases, many different choices may exist as to how to decompose elements in the original domain, and they may have different effects on problem difficulty.

The design process entails finding useful and productive ways of mapping problem particulars into the algorithmic framework, and heuristic search tends to require some means of making qualitative comparisons and decisions in order to guide the path of the algorithm. There are principles behind, and effects from these decisions. In this section, the choices available to the algorithm designer are discussed, while the biases introduced by these mapping choices are discussed throughout [Sect. 4](#).

Once the engineer identifies the types, domain roles, problem roles, and potential solution set, they must determine how a CoEA can be structured to represent them, and encode data structures within the algorithm to instantiate them in a way that is consistent with the problem's solution concept. Such decisions are considered to relate to *representation*. Additionally, one must decide how to explore the set of interactions, how outcomes from multiple interaction will be aggregated for selection purposes, and how interaction information is communicated throughout various parts of the algorithm. Such decisions are considered to relate to *evaluation*.

3.1 Representation

Successful design and application of any heuristic depends on a number of key representation decisions for how search knowledge is encoded and manipulated. In any evolutionary system, these choices involve questions about how aspects of potential solutions are represented genotypically, modified by genetic operators, and expressed phenotypically.

Coevolution brings additional subtleties to representation issues that are worth special consideration. For one, the relationship between basic terms such as *individuals*, *populations*, and *solutions* can be quite complicated in coevolution. Related to these terms are the foundational, domain-centric terms discussed above such as *test* and *component*, and a well-designed CoEA should consider how these problem-based concepts map to representations used by the search system. Additionally, many modern CoEAs make use of archival and memory mechanisms for a variety of purposes, and it is important to understand how they relate to the above notions. These notions will be discussed in turn and examples of common/possible mappings from problem to algorithm will be provided.

3.1.1 Individuals

In most traditional evolutionary systems, individuals represent potential solutions to some search problem, and the EA manipulates encoded potential solutions by modifying them using variational operators (mutation, crossover) and choosing the better from among them using selection operators (proportionate selection, rank selection, etc.). When optimizing some real-valued function, an individual might be encoded as a vector of real values to be used as arguments for the function, mutations could be accomplished by applying vectors of Gaussian noise, and selection might involve simply choosing those with the highest objective function value. Since the goal of the search is to find an optimal argument vector, one can typically equate potential solution and individual. Even when the EA is searching program spaces, such as in genetic programming, traditional algorithms still make use of individuals who are essentially procedural solutions to the problem.

In coevolution, individuals serve the same mechanistic purpose as in any evolutionary algorithm: they are the fundamental units being manipulated by the search operators

themselves. That is, mutation and crossover modify individuals, and selection chooses among them.

Definition 4 (Individual) An *individual* is a representational unit that is subject to selection and variational operators. \square

But individuals in a CoEA will not always represent potential solutions to the problem being solved. In coevolution, one must think of individuals in terms of how they relate to types, domain roles, and problem roles, *in addition to* traditional issues of how to encode problem aspects. For example, suppose an AI is being developed for controlling an airplane that generalizes over different flight conditions and this is formalized as follows: an interactive domain consists of airplane controllers interacting with different flight conditions/scenarios; the problem is test-based where the potential solutions are controllers and the flight scenarios are tests; and the solution concept is maximum expected utility. One might design a CoEA that maintains two kinds of individuals, corresponding to the two types of the domain, namely individuals representing controllers and individuals representing flight scenarios. But one still has to decide how controllers and scenarios will *actually be encoded*, which will involve additional choices. The consideration of how types, domain roles, and problem roles map to individuals is subtly different from traditional genotype/phenotype decisions.

Most often, individuals represent entities from the domain's types. Thus, for a domain with two symmetric roles, one may have a single kind of individual, and such individuals might participate in interactions in either of the domain's roles. In general, one will have at least as many kinds of individuals as types in the domain. From a problem-role perspective, individuals might represent components of a potential solution or tests helping to judge the quality of potential solutions. Hillis (1990) provides a less common example, where some of the individuals do not correspond to entities, but to sets of entities, namely, those playing the test role. The relationship between individual and solution will be revisited in [Sect. 3.1.4](#) dedicated to solutions.

3.1.2 Populations

Just as with traditional EAs, it is useful to think of populations as simply collections of individuals. Most traditional EAs (excepting island models) have only a single, explicit population, while many CoEAs have multiple populations.

But even in traditional methods, the notion of a population can be a bit murky when dealing with mechanisms such as spatial models, niching, or restrictive mating (Horn 1995; Spears 1994) since stable subsets of individuals in the overall population can arise between which very little genetic material is exchanged. These subsets are sometimes referred to as “populations,” and it is interesting to note that many of these are essentially coevolutionary in nature since fitness can be quite subjective (e.g., niching methods using fitness sharing).

Definition 5 (Population) A *population* is:

1. A set (or multiset) of individuals
2. A subset of individuals isolated from other individuals by some kind of barrier (e.g., inability to interbreed successfully, geographic, etc.) \square

Designing effective CoEAs involves decisions about how aspects of a problem map to populations. The main purpose of the populations is to provide an exploration mechanism for the entity sets of the different types in the domain. Thus, a CoEA will generally maintain at least one population per type and most often a single population per type.

For example, for an ideal team problem in a domain with a fixed number of asymmetric roles (and therefore types), the typical CoEA will maintain one population for each. For a test-based problem in a domain with two asymmetric roles (and therefore types), the typical CoEA will also maintain one population for each type.

For domains with two symmetric roles (thus a single type), the problem definition itself may not distinguish between the component role, and the test role, and the algorithm designer can choose to do the same, by maintaining a single population, or to make the distinction explicit by maintaining two populations. A unique work by Potter (1997) features an ideal team problem in a domain with a variable (unbounded) number of symmetric roles (neural networks with variable number of neurons) approached via a CoEA with a dynamic number of populations, all containing individuals of the same type.

Populations may also be used to represent potential solutions, for example when these are aggregates of entities (and therefore individuals) from one type, as is the case with Pareto optimal solution concepts. (This is analogous to traditional multi-objective optimization, where the population can be used as an approximation of the Pareto-front.)

Finally, yet importantly, individuals in a population, by taking part in interactions, serve the purpose of evaluating individuals in the same or other populations. This is because while a problem definition may specify only some of the domain roles as contributing to the potential solution set, an algorithm needs some criteria based on which to select and promote individuals for the test roles as well.

3.1.3 Archives

Coevolutionary methods often employ another kind of collection, typically referred to as an *archive*. Archives span generations, and thus can be considered a kind of search memory. The purpose of the archives is to help the populations with, or release them from, some of their multiple duties. Archives can allow algorithm designers to separate exploration from evaluation and/or solution representation.

Definition 6 (Archive) An *archive* is a collection of individuals that spans multiple generations of a coevolutionary algorithm. □

Thus, archives often contain the end solution (Rosin and Belew 1997) or actually are the solution, mainly when potential solutions are aggregations of entities (De Jong 2004a, c, 2005; Oliehoek et al. 2006; Ficici and Pollack 2003). So an analogy in traditional evolutionary computing (EC) for this purpose of an archive is the *best-so-far* individual. But they need not only represent solutions, they can and typically do influence the search – a bit like elitism would in a traditional generational EA.

Archives can also serve for evaluation purposes. A simple example of this are *hall-of-fame* methods (Rosin and Belew 1997) where successful individuals discovered during search are added to a hall-of-fame and part of the fitness of new individuals comes from the outcome of interactions with some subset of individuals from that archive.

In domains with multiple types, there might be an archive for each type (in addition to a population for each type). Most archive-based CoEAs involve an `UPDATE` step where individuals in a current population are considered for inclusion in the corresponding archive, and individuals in that archive may be reorganized or removed. There is a certain appeal to this approach because there are often straightforward ways to explicitly implement a particular solution concept by crafting the correct update procedure for an archive.

3.1.4 Solutions

A potential solution can be many different things even as part of the problem specification, the latter being a higher-level notion defined over the low-level elements of an interactive domain. It should therefore not be surprising that, as already seen, a potential solution can map to different things in the algorithm. A potential solution may be a single individual, in which case it may be extracted out of

- Any population (e.g., if approaching a maximum expected utility problem in a domain with two symmetric roles via two populations)
- A specific population (e.g., if approaching a maximum expected utility problem in a domain with two asymmetric roles via two populations)
- An archive (e.g., if using a hall-of-fame approach)

A potential solution may also be a set of individuals, in which case it may be

- The entire contents or a subset of an archive or population (e.g., for CoEAs approaching Pareto optimal solution concepts)
- A collection of individuals, one from each archive/population (e.g., for CoEAs approaching the ideal team solution concept for asymmetric domains)

Further, there may be populations/archives in a CoEA that never contribute any individuals to a potential solution (e.g., populations/archives corresponding to test roles in a test-based problem that are nevertheless used during evaluation).

3.2 Evaluation

Some issues concerning evaluation are pertinent to both single- and multi-population CoEAs. Regardless of whether interactions occur between individuals in the same population or in different populations, decisions need to be made as to what *interactions* should be assessed and how the outcomes of those interactions should be *aggregated* to give individuals fitness. When using multiple populations, the additional issue of *communication* between these populations arises. Each of these three matters will be discussed in turn.

3.2.1 Interactions

The definition of interactions was discussed in the previous section. Here, the focus is on the *selection* of interactions (also referred to as the *interaction method* or, in cooperative domains, *collaboration method*). The simplest choice is to assess all interactions possible, given the

individuals present in the system at evaluation time. This has been referred to as full mixing or complete mixing. While no additional decisions would have to be made, this choice has the disadvantage of being very expensive, as the time cost of the algorithm is counted in interactions assessed. To reduce cost, one must assess only some of all possible interactions. This immediately raises the question “which ones?”

There are two main approaches to choosing a subset of interactions: individual centric and population centric. With the individual-centric approach, one individual at a time is considered, a set of interactions is chosen for that individual to take part in, and after the interactions are assessed, the individual’s fitness is computed. These interactions may be reused (but generally are not) for computing the fitness of the other individuals that took part in them. These other individuals have historically been called *collaborators* in cooperative domains and *opponents* in competitive domains. In this context, the phrase *sample size* denotes the number of interactions used per fitness evaluation. Note that if there is no reuse, the number of interactions an individual takes part in may be greater than the number of interactions used for its evaluation. Thus, while the sample size may be (and usually is) the same for all individuals, the number of interactions that individuals are involved in may vary.

A simple and quite common approach is to use a single interaction per fitness evaluation and have the other individuals in this interaction be the best from their respective populations. When solving ideal team problems, this has been termed *single-best collaboration method* by Wiegand (2004), while for domains considered competitive, it has been referred to as *last elite opponent (LEO) evaluation* (Sims 1994). More generally, it is called the *best-of-generation* interaction scheme.

With the population-centric approach, a *topology* of interactions is picked such that any individual in the population(s) is used at least once, these interactions are assessed and then fitness is computed for all individuals. Tournaments, such as single-elimination or round-robin, are the most common examples for single-population algorithms. Both for single- and for multi-population models, shuffle and pair (also called bipartite pairing) is a population-centric method that simplifies the reuse of assessed interactions (meant to reduce computational time). With the single-elimination tournament, different individuals will participate in a different number of interactions. An approach introduced by Jaśkowski et al. (2008) uses repeated tournaments not to compute fitness for individuals, but to directly select individuals (the winner from each tournament) for breeding.

Information available from previous evaluation rounds may be used to influence how interactions are chosen for the current evaluation round. We call this *fitness bias*. Usually, individual-centric approaches use such biases, while population-centric ones do not. Clearly, to be able to perform such biasing, the algorithm must store some information about previous evaluations. This information usually consists of individuals and their fitness, but can also be more complex in nature (e.g., include other properties of individuals or relationships between individuals). The amount of information can range from remembering the last best individual to remembering all interaction assessments ever performed. With generational CoEAs, intermediary approaches include saving one or a few (usually the best) individuals from each previous generation, saving all individuals in the previous generation, or other memory or archive method (Panait et al. 2006a; De Jong 2004a, c; Ficici and Pollack 2003; Oliehoek et al. 2006).

Additional reviews and comparisons of various methods for selecting interactions can be found in the literature (Angeline and Pollack 1993; Panait and Luke 2002; Sims 1994).

With individual-centric methods, some of the additional choices (in particular the sample size) may be dynamic (i.e., they vary at run-time as a function of time) (Panait and Luke 2005; Panait et al. 2006c) or adaptive (i.e., they vary at run-time as a function of the internal state of the algorithm, e.g., population diversity and operator success) (Panait and Luke 2006; Panait et al. 2006a; Panait 2006).

Additional choices must be made when using spatially embedded CoEAs. These tend to use individual-centric approaches and interactions are localized in space, namely, neighborhood based. The size of the neighborhood corresponds to the sample size, but the shape is an additional decision to be made. Fitness-biased selection of interactions can still be used (generally within the neighborhood).

3.2.2 Aggregation

If an individual participates in a single interaction, then it must obtain a value from it, and that value becomes the individual's fitness. But when an individual participates in multiple interactions and thus obtains multiple values, then a choice must be made about how to aggregate these values.

One approach is to input values from multiple interactions into some computations and output a *single value* per individual (to be used as fitness). The computations can simply use all values obtained by the individual and determine the *best*, the *worst*, or the *average* of those values. A comparison of these three methods can be found in (Wiegand et al. 2001). Other, more complex computations can take into account values from other individuals as well, as is the case for competitive fitness sharing (Rosin and Belew 1995, 1997) or the biasing technique introduced by Panait et al. (2003, 2004). The advantage of the single-value approach is that traditional parent-selection methods can then be used by the algorithm based on single-valued fitness. Unfortunately, different ways of computing a single value have different (and strong) biases, and it is not always straightforward to tell which bias is more or less helpful for the solution concept at hand. In particular, when dealing with the ideal team solution concept, the biases of the averaging method proved harmful (Wiegand 2004) while choosing the best is helpful (Panait 2006). Even so, there has been some amount of controversy over the utility of biases (Bucci and Pollack 2005; Panait and Luke 2006); Bucci (2007) goes so far as to argue that single-valued fitness assessments are to be blamed for a number of pathological algorithm dynamics.

The alternative is to have fitness be a *tuple* of values, usually the values obtained by the individual from multiple interactions. Selecting parents based on such fitnesses requires more specialized methods, in particular, ones akin to multi-objective EAs. The tuples of different individuals of the same role must be somehow comparable, which imposes constraints on the interactions that generated the values in the tuples. The advantage of this approach is that its bias may be more appropriate for solution concepts such as the Pareto optimal set or simultaneous maximization of all outcomes, and it is mostly algorithms targeted at these solution concepts that use tuple fitness (De Jong 2004a, c; Ficici and Pollack 2001). An example using tuple fitness for the ideal team solution concept can be found in (Bucci and Pollack 2005).

3.2.3 Communication

When using a CoEA with multiple populations, in order for individuals in one population to interact with individuals from other populations, the populations must have access to one

another's contents. This is an issue of communication, and thus entails choices typical of any distributed system, such as coordination, flow, and frequency.

In terms of *coordination*, communication can be synchronous or asynchronous. In the *asynchronous* case, the populations evolve at their own pace and communicate with one another through shared memory. They decide independently when to write new information about their state to the shared memory and when to check the memory for new information about the other populations (which may or may not be available). Asynchronous CoEAs are uncommon. In the *synchronous* case, there is a centralized clock that dictates when the populations exchange information.

In terms of *flow* (in Wiegand's (2004) hierarchy of CoEA properties, flow is called *update timing*) the asynchronous model is always *parallel*, in the sense that at any point in time, there may be more than one population running. (When a parallel CoEA is run on a single processor, this translates into the fact that there is no guarantee about the order in which the populations run.) The synchronous model can be either parallel or sequential (also called *serial*). In the *parallel* case, all populations run simultaneously for a certain period of time (dictated by the central clock), after which they all pause and exchange (communicate) information and then they all continue. In the *sequential* case, at any point in time, there is a single population running and populations take turns in a round-robin fashion.

Frequency refers to the number of evaluation–selection–breeding cycles that a population goes through between two communication events. The frequency may be uniform across all populations or it may differ from one population to another.

4 Analysis of Coevolution

Particularly in the last decade, there has been a great deal of activity in analyzing coevolutionary algorithms and their use as co-optimizers. There are two major drivers of this field. One is the fact that most co-optimization problems pose difficulties not encountered in traditional optimization, namely, measuring (and achieving) algorithmic progress and performance. The other is that coevolutionary algorithms as dynamical systems exhibit behaviors not akin to traditional evolutionary algorithms.

The first half of this section clarifies the complex issues pertaining to interactive domains and co-optimization problems and places much extant research in the context of addressing such issues. The second half surveys the wide variety of analytical methods applied to understanding the search and optimization biases of coevolutionary algorithms, as well as the insights that were gained.

4.1 Challenges of Co-optimization: Progress and Performance

For traditional optimization, judging the success of any algorithm attempting to solve a given problem instance is a fairly straightforward matter. There may be different criteria of success, such as the highest quality potential solution(s) found with a given budget of function evaluations or, conversely, what evaluation budget is needed to find potential solutions whose quality is above a certain threshold. Such success metrics also allow for easy comparisons of algorithm performance, even when aggregated over classes of problems.

Additionally, even when concerned with the behavior of a single algorithm on a single problem instance, a straightforward notion of progress through time exists. With each new function evaluation, the algorithm can easily keep track of the best quality potential solution found so far. Even if the quality of the overall best is not known, the algorithm can detect when it gets closer to it. Moreover, should an algorithm actually discover a global optimum, whether or not it is recognized, there is no danger of “losing” it. The best-so-far quality metric is a monotonic function of time. (The potential solution with the optimal quality may change, should the algorithm be deliberately implemented to replace the current best-so-far potential solution with a new one of equal quality.)

All of this is largely possible because the quality of a potential solution can be obtained with a single function evaluation and thus immediately perceived by the algorithm, which in turn allows reliable comparison of any two potential solutions. As trivial as the above statements may appear, they are no longer a given in many co-optimization problems.

Consider first the one area that is most similar to traditional optimization: compositional problems using the ideal team solution concept. The unique feature of these problems is that the interaction set is actually the same as the potential solution set *and* the interaction function serves as the potential-solution quality function. Thus, the quality of a potential solution can be obtained with a single function evaluation and any two potential solutions can reliably be compared. This, of course, is not very surprising since many of these problems are actually obtained via decomposition from traditional optimization problems. Therefore, measuring performance and progress is not an issue.

Nevertheless, approaching these problems via coevolution raises new issues. For example, how does one assign credit to the components of potential solutions that are evolving in different populations? More generally, how do different algorithm design choices affect algorithm performance? Much research around this topic has shown that, even for these most traditional-optimization-similar problems, design heuristics for traditional evolutionary algorithms do not transfer as-is to coevolution (Popovici and De Jong 2004). Still, the ability to easily measure performance and progress greatly facilitates the study of coevolutionary algorithms for ideal team compositional problems.

Note that the equality of the potential solution set and the interaction set is not enough to guarantee ease of performance/progress assessment. Consider compositional problems using the pure Nash equilibria solution concept. This problem is not expressed as a co-optimization problem, but as a generic co-search problem. It is fairly obvious that the single evaluation of the interaction function for this potential solution is not enough to determine whether it constitutes a Nash equilibrium. To determine that, one would need to, in turn, fix all but one component of the potential solution and evaluate interactions corresponding to, in the worst case, the entire set of entities for that component. While this does not mean exploring the entire interaction set, it does mean fully exploring all the component sets, which is to be assumed intractable. A negative decision might be reached sooner than that, but to reach a positive decision exhaustive search must be performed.

For test-based problems, the potential solution set is always different from the interaction set and determining the quality of a potential solution requires evaluating interactions corresponding to entire entity sets (the test sets). Should this be tractable, the problem may be expressed as a traditional optimization problem. We assume that is not the case.

Consider a generic search algorithm that, at every step, evaluates a new interaction and outputs a potential solution. (Algorithms that may not be ready to output a potential solution after every evaluation can be interpreted as outputting their latest output again until ready.)

How can one judge whether the algorithm makes progress toward the solution to the entire problem? How can its output be compared with the output of a different algorithm that has evaluated the same number of interactions? Since determining the true quality of a potential solution is generally computationally intractable for real problems, one is left with attempting to compare different potential solutions based on incomplete information.

The above observations paint a rather bleak view with respect to determining whether an algorithm could tackle one of these problems. However, the matter is not hopeless, though more can be said and done for some problems than for others.

For example, for Pareto dominance solution concepts, it has been shown that for any given set of n component entities (components), an *ideal evaluation set* of at most $n^2 - n$ test entities (tests) exists that results in exactly the same dominance relations among the components as would result from using the set of all possible tests (De Jong and Pollack 2004). Of course, the guaranteed existence of this limited set of tests leaves open the question of how to identify them. However, an operational criterion is available to determine whether any given test should be included in such a limited test set. Specifically, the criterion of whether a test induces a *distinction* between two components, introduced by Ficici and Pollack (2001), can be used for this purpose; see (De Jong and Pollack 2004).

The vast majority of research on these issues has concentrated on progress of (co-optimization) algorithms in individual runs and assessing performance on test problems. Only recently have aggregate performance comparisons between algorithms started receiving attention.

With respect to progress in individual runs, one fact facilitates the analysis: the incomplete information that an algorithm sees, and based on which one should compare different potential solutions outputted by the algorithm, is increasing over time. The remarkable discovery of Ficici (2004) is that some problems (solution concepts) permit the construction of algorithms that can properly leverage this incomplete but increasing information to guarantee that outputted potential solutions have monotonically increasing *global/true* quality over time. Any such algorithm is said to guarantee *global monotonicity* and the said solution concepts are called *globally monotonic*.

Some problems of practical interest have solution concepts that are not globally monotonic. This makes it difficult or even impossible to devise algorithms that guarantee global monotonic progress as described above. Still, for some of these problems, algorithms can be built that guarantee a different form of monotonicity called *local monotonicity*, which entails that the quality of outputted potential solutions with respect to all information seen so far will increase with time.

Both globally and locally monotonic algorithms guarantee convergence to a globally optimal solution, if the interaction space is finite and any point in this space can be generated with nonzero probability at any time.

When neither global nor local monotonicity guarantees can be achieved, some surrogate techniques can be used to instrument what the algorithm is doing, though they do not inform about progress toward the problem-solving goal. Finally, while all of the above assume the intractability of computing global quality, one research approach is to study various co-optimization algorithms on test problems, for which global quality can actually be computed. This metric is not made available to the algorithm, but used externally for instrumentation, and the hope is that the observed results will transfer to real problems.

The remainder of this section reviews global and local monotonicity, surrogate measures of progress, test-bed analytical techniques and aggregate performance comparisons.

4.1.1 Monotonicity

Central to the work on monotonicity is the idea that the solution concept can be interpreted as more general than just a means of partitioning the entire set of potential solutions based on the entire set of interactions. Namely, it can be extended to apply to any context consisting of a subset of interactions and a corresponding subset of potential solutions (i.e., potential solutions that can be built with entities that participated in the given interactions). Thus, it can be viewed as a means for an algorithm to output a potential solution when queried, based on all or some of the entities it has generated and interactions it has assessed. (Conversely, any mechanism for selecting a potential solution to be outputted from the algorithm can be viewed as a solution concept.)

In general, it may be difficult for an algorithm to determine the output of the solution concept when applied to the entire history of entities discovered and interactions assessed if it has discarded some of the entities or some of the interaction outcomes. However, for some solution concepts this is possible. For example, for the best worst case solution concept, an algorithm needs to remember only the worst value seen for any potential solution and not all the interactions it took part in, the other entities involved in those interactions or their outcomes.

One question that arises is whether an algorithm able to report the application of the solution concept to its entire history (whether by means of never discarding any information or by cleverly storing parts or aggregates of this information) can guarantee that the *global* quality of the potential solutions it outputs will never decrease over time, regardless of the means of generating new interactions to be assessed. Ficici (2004) showed that this is possible for some solution concepts, which we call *globally monotonic*, but not for others. Out of the solution concepts presented in [Sect. 2.4](#), the ones proven to be globally monotonic are the Nash equilibrium, the Pareto optimal minimal equivalence set (Ficici 2004), maximization of all outcomes, and ideal team (Service 2009). Solution concepts proven not to be globally monotonic are maximization of expected utility (Ficici 2004), best worst case (Service 2009; Popovici and De Jong 2009), and all Pareto dominance ones besides the minimal equivalence set (Ficici 2004).

For the globally monotonic solution concepts, the challenge from an algorithmic perspective is being able to report the application of the solution concept to the entire history while limiting the amount of history that must be stored. The algorithms mentioned below are in many cases able to discard information without jeopardizing the guarantee of global monotonicity. Yet, all of the globally monotonic algorithms discussed below require unlimited memory.

For the Pareto optimal minimal equivalence set solution concept, De Jong (2004a) introduced an algorithm called *IPCA* (Incremental Pareto-Coevolution Archive) that guarantees global monotonicity (Popovici and De Jong 2009) while discarding information along the way. The key to achieving that lies in a carefully designed archiving mechanism. A variant named the LAyered Pareto Coevolution Archive (LAPCA) (De Jong 2004c) addresses the unbounded memory issue by maintaining a limited number of non-dominated layers. While it no longer provides the monotonicity guarantee, this algorithm achieves good progress on test problems. Similarly, the *Nash memory* algorithm (Ficici and Pollack 2003; Ficici 2004), guarantees global monotonic progress for the solution concept of the Nash equilibrium in symmetric zero-sum domains while discarding information. As before, bounding the memory loses the theoretical monotonicity guarantee but still achieves good progress on test problems. Based on the *Nash memory*, the *parallel Nash memory* algorithm (Oliehoek et al. 2006)

guarantees global monotonic progress for the solution concept of the Nash equilibrium in asymmetric games. For the maximization of all outcomes solution concept, the *covering competitive algorithm* of Rosin (1997) guarantees global monotonic progress while discarding information.

While the guarantee of increasing global quality may not be possible for solution concepts that are not globally monotonic, this does not mean that all hope is lost for problems with such solution concepts. For such problems it may still be possible to devise algorithms that guarantee that the quality of outputted potential solutions *with respect to the interactions seen so far* increases monotonically over time. Solution concepts with this property are called *locally monotonic*.

For example, while the maximization of expected utility (MEU) solution concept introduced in [Sect. 2.4.2](#) is not globally monotonic, a variant of it, namely, maximum utility sum applied to domains with a positive-valued metric, allows algorithms guaranteeing locally monotonic progress (Popovici and De Jong 2009). As the name suggests, the MEU solution concept is an optimization criterion, where the function to be optimized is utility sum. When extended to any context consisting of a subset of interactions and a corresponding subset of potential solutions, the special property this function has (if the metric values are positive) is that the “local” value for a potential solution in some context can only increase when the context is expanded.

Based on this property, for maximum utility sum applied to domains with a binary-valued metric, De Jong (2005) introduced an algorithm called *MaxSolve* that is guaranteed to output the application of the solution concept to the entire history (and therefore an increasing value with respect to an increasing context), while discarding information along the way. This property, coupled with unbounded memory, allows *MaxSolve* to achieve local monotonicity.

As Popovici and De Jong (2009) showed, for the best worst case solution concept, even the local monotonicity guarantee cannot be fully achieved via algorithms that use the solution concept as an output mechanism (and probably not in general).

While monotonicity is an interesting property that has served in clarifying the behavior and goals of coevolutionary solution concepts and algorithms, it should be made clear that guarantees of monotonicity can have limited value for a practitioner. Three important things to keep in mind are that (a) the solution concept is most often a given, not a choice, and for some solution concepts there are no known algorithms with monotonicity guarantees; (b) all algorithms known to have monotonicity guarantees require unbounded memory; and (c) even if the quality of potential solutions can only improve over time, this provides no information about the *rate* at which progress will be achieved. For these reasons, an approach that may turn out to have more practical relevance is to consider the *performance* of coevolutionary algorithms. This topic is treated in [Sect. 4.1.4](#).

4.1.2 Surrogate Progress Metrics

For problems where the above monotonicity guarantees are unobtainable, two questions remain. One is how to design algorithms for tackling these problems. Another is how to instrument any such algorithm. The former is still an open research question. Here, the latter is addressed from the perspective of coevolutionary algorithms. However, while these techniques have been introduced in the context of coevolution, some of them may be adapted to be applicable to generic co-optimization algorithms.

Many techniques have been introduced over the years, and while they cannot tell how the algorithm is doing with respect to the goal, they may still provide useful information about algorithm behavior. The techniques involve computing metrics that are external to the algorithm (i.e., they do not influence its behavior) but rely on its history. They may measure all potential solutions considered by the algorithm or only select those that the algorithm outputs. Measuring all can provide more information, but it may make it difficult to extract the important patterns within and may also pose a challenge for visualization. One must be aware that compressing information (e.g., by means of averaging) may actually eliminate important trends in the data. The trends to look for usually include increase, decrease, stagnation, noise, and repeated values.

The first such technique was introduced by Cliff and Miller (1995) in the form of CIAO plots. The acronym stands for “current individual ancestral opponent.” For a two-population CoEA, a CIAO plot is a matrix in which rows represent generations of one population and columns represent generations of the other population. Every cell represents an interaction between the best individual in each population (as reported by the algorithm) at the corresponding generations. Thus, individuals from later generations of one population interact with individuals from early generations of the other population (ancestors). The cells are color-coded on a gray scale, and can be constructed to reflect success from the perspective of either population.

The “master tournament” metric of Floreano and Nolfi (1997) is basically a compression of the information in CIAO plots. Averages are taken along lines for one population and across columns for the other population.

Both these methods are computationally expensive, as they require the evaluation of n^2 interactions, where n is the number of generations. The master tournament metric makes it easier to identify “broadly successful” individuals, but the averaging it performs may obscure some circularities that can be observed using the CIAO plots. An in-depth critique of CIAO plots is provided in (Cartlidge and Bullock 2004b).

While these metrics were introduced in the context of domains with two asymmetric roles, they are easily applicable to domains with two symmetric roles, whether approached by single-population or two-population CoEAs.

In the context of a domain with two symmetric roles and a two-population CoEA, Stanley and Miikkulainen (2002b) introduced a less costly technique called “dominance tournament.” At each generation, the best individual in each population is determined and the two of them are paired; out of their interaction, the more successful one is designated the generation champion. The dominance property is then defined as follows. The champion from the first generation is automatically considered dominant. In every subsequent generation, the champion is paired only with previous dominant champions and it is itself labeled dominant only if it is more successful than all of them. The method is easily applicable to domains with two symmetric roles and a single-population CoEA. The paper also suggests a (less straightforward) extension to some domains with two asymmetric roles.

CIAO, master tournament, and dominance tournament are all techniques that track only the best of generation individual. This was contrasted by Bader-Natal and Pollack (2004) who introduced a “population-differential” technique monitoring all individuals in each generation. Plots similar to the CIAO plots are produced, but now, each cell is an aggregation over the results of all pair-wise interactions between individuals in the two populations at the generations corresponding to that cell. This is clearly more expensive, and a number of memory policies are introduced for reducing time complexity.

The unifying idea of these techniques is to determine whether an algorithm is making at least some sort of “local” progress away from the starting point.

All the metrics described so far require performing additional evaluations, rather than using the ones already performed by the algorithm. Funes and Pollack (2000) introduced a technique that took the latter approach. Their metric, called “relative strength” is still subjective, as the value it returns for a particular individual depends on the current history of all interactions, and this history grows with time. The metric is based on paired comparison statistics and is applicable to domains with two symmetric roles.

4.1.3 Test-Bed Analysis

A means of judging both an algorithm’s ability to make progress as well as its expected performance on some problem(s) is to test the algorithm on artificial domains for which true quality can be computed. The domains are constructed such that they exhibit properties thought to be present in real domains or such that they expose a range of different behaviors of the algorithm. The hope is that the results observed on the artificial domains will transfer to real domains.

A class of domains introduced to this effect are *number games* (Watson and Pollack 2001). These are domains with two roles, a common entity set consisting of real-valued vectors and a binary-valued interaction function (based on comparisons between vector values). The roles can be interpreted as symmetric or asymmetric. The solution concept is Pareto dominance. What makes these problems easier to analyze is the fact that the interaction function is designed such that a genotype can be used as-is to represent its own true quality. There are a handful of such interaction functions in the literature and many progress-focused algorithm comparisons have been performed using them as a test bed (De Jong 2004a, c, 2005, 2007; Bucci and Pollack 2003a; Funes and Pujals 2005).

Popovici and De Jong (2005b) introduced a set of four domains with two asymmetric roles, a common entity set consisting of single real values and a real-valued interaction function given in closed form. These domains were used to showcase the biases of symmetric last elite opponent evaluation, and how this technique generally does not optimize expected utility. The closed form of the interaction function allowed for easy computation of true quality.

A number of domains of the same kind (two asymmetric roles, real-valued entities, closed-form real-valued interaction function) have been introduced specifically for studying algorithms targeted at the best worse case solution concept (Jensen 2001; Branke and Rosenbusch 2008; Stuermer et al. 2009), which has been shown to be non-monotonic and difficult in terms of achieving even very weak forms of progress (Popovici and De Jong 2009).

Test-bed analysis has also been performed for algorithms targeted at the ideal team solution concept, yet with a different motivation (e.g., studying problem properties and algorithm design choices) since in this case assessing global quality is not an issue. Examples are given in  Sect. 4.2.4.

4.1.4 Comparing Performance

As emphasized throughout the previous section, instrumenting an algorithm from a progress-making perspective or, indeed, designing an algorithm such that it guarantees progress relies

rather heavily on the fact that the amount of information seen by the algorithm increases over time. How an algorithm uses this information can be key to instrumenting/achieving progress. Therefore, the theoretical work on monotonicity has so far had nothing to say about how to compare algorithms since there is no connection between the information that different algorithms see. This line of research provided no generic advice on how to design efficient algorithms.

While test-bed analysis is useful for determining whether an algorithm makes progress or not, when global quality can be computed, one can also use test-beds to compare algorithms based on the expected rate of progress or expected level of solution quality over multiple runs. This kind of performance analysis, especially when backed by dynamics analysis of the kind reviewed in [Sect. 4.2.5](#), has provided insight into the biases of design choices by providing a means of comparison; however, it is unclear how well the results transfer to real-world problems, so the generality of such results is unclear.

From traditional optimization research, the famous no free lunch (NFL) theorem has approached the issue of performance generality (Wolpert and Macready [1997](#); Schumacher et al. [2001](#)). This result has led to a welcome shift in EC research toward identifying classes of problems where NFL does not hold and designing algorithms targeted at a specific class (Igel and Toussaint [2003](#)). This is of particular current interest in co-optimization/co-evolution (Wolpert and Macready [2005](#)) since recent work states the opposite, namely, that free lunches do exist for certain solution concepts.

Wolpert and Macready extended their formalism of traditional optimization algorithms to co-optimization algorithms (albeit without using this terminology) as having two components: a search heuristic and an output selection function. The search heuristic takes as input the sequence of interactions assessed so far and returns a new interaction to be assessed. The output selection function takes the same input and returns a potential solution. The need to explicitly model the output selection function comes from the algorithms' lack of access to a global quality function: in traditional optimization, output selection is based on the quality values seen so far (usually picking the best of them); in co-optimization, what an algorithm sees are values of the interaction function, which provide incomplete information about global quality. The use of archives in CoEAs is often targeted at implementing the output selection function, thus relieving the populations of this duty so they can focus on the search component.

Wolpert and Macready showed that aggregate performance advantages (free lunches) can be obtained both via the output selection function and via the search heuristic. The former means that if the search heuristic is fixed, some output functions perform better than others. The optimal output function is the so-called Bayes output function, which outputs the potential solution with the highest estimated global quality, estimated over all possible problems consistent with the measurements of the interactions seen so far. The latter was showcased in the context of the best worst case solution concept: fixing the output selection function to Bayes, two specific search heuristics were shown to have different average performance.

This line of work was extended by Service and Tauritz ([2008b](#)), which showed that the same two algorithms from Wolpert and Macready ([2005](#)) exhibit different aggregate performance for the maximization of all outcomes solution concept.

Generally, such free lunches are believed to exist in co-optimization whenever the performance of an algorithm depends on information not available in the algorithm's trace of interactions; in other words, it explicitly depends on the interaction function (as opposed to

implicitly, via the values in the trace). Therefore, the ideal team solution concept does not exhibit free lunches since the interaction set is actually the same as the potential solution set and the interaction function serves as the potential solution quality function.

The existence or lack of free lunches can be seen as a property of solution concepts, which has been named “bias” (Service 2009). Since monotonicity is also a solution concept property, the natural question that arises is how these two properties relate to one another. Service (2009) showed they are orthogonal to one another: solution concepts exist in all four classes combining monotonic/non-monotonic with biased/unbiased.

Especially for monotonic and biased solution concepts, the next natural question is whether the algorithms that can achieve monotonicity (known to exist) are also the best performing. This question was investigated by Popovici and De Jong (2009), who showed that the output selection function used by monotonic algorithms is not equivalent to the best-performing Bayes, thus exposing a potential trade-off in algorithm design between monotonicity and performance.

4.2 Analysis of CoEA Biases: A Survey

The previous half of this section discussed the difficulties of measuring and achieving algorithmic progress for co-optimization problems, and reviewed the state of the art in understanding and dealing with these issues. However, when applying coevolutionary algorithms to such problems, an additional concern is understanding and harnessing the biases these algorithms have as dynamical systems. This section surveys the analytical research that contributed such understanding.

4.2.1 Model Analysis

A common algorithm analysis method is to *model* an algorithm mathematically, then to study the properties of that model. The advantage is that certain mathematical facts can sometimes be precisely learned from these models, facts that help to understand system behavior in ways that are simply not possible via traditional approaches. The disadvantage is that the model is *not* a real algorithm, and it is not always clear what can be transferred from model to algorithm. This step is typically bridged by empirical study of some kind.

The simplest way to approach modeling evolutionary computation as a dynamical system is the so-called “infinite population model” (Vose 1999). One assumes that a population is infinitely large and focuses on how the distribution of genotypes within the population changes over time. Questions about the existence (and sometimes the location) of stable, attracting fixed points, or their nature and quality, can sometimes be answered by applying traditional dynamical systems methods to such a model.

Evolutionary game theory (EGT) (Hofbauer and Sigmund 1998; Weibull 1992; Maynard Smith 1982) is an appealing dynamical systems model of biological systems that is well-suited for studying coevolution. In EGT, interactions between genotypes are treated as a *stage game*, and the payoff from that game informs how the distribution is altered for the next play of the game (*replicator dynamics*). Because of its incorporation of game theory, a number of game-theoretic properties of such systems become useful points of consideration (e.g., Nash

equilibria). Additionally, EGT has received a great deal of attention by the economics community (Friedman 1998). Consequently, quite a bit is already known about the dynamical properties of these mathematical models under different conditions.

For the most part, EGT analysis has focused on the dynamics of CoEAs under selection only; however, variational operators in CoEAs can be (and have been) modeled as is typically done in dynamical systems models of traditional EAs, by constructing a matrix that transforms the probability distribution resulting from the selection operator into one that reflects the properties of the population after crossover and mutation are applied, the so-called *mixing matrix* (Vose 1999). To specify this, one must be explicit about representation. Despite these simplifications, some interesting things are known about the system that inform our understanding of CoEAs.

In single population EGT models of CoEAs, for example, stable attracting *polymorphic* equilibria can exist when the underlying stage game is not a constant sum game. That is, aside from the stochastic effects of genetic drift, selection alone can drive the systems to states where the population is a mixture of different kinds of genotypes, and these stable, mixed strategies correspond with a Nash equilibrium of the stage game. Moreover, examining this system using other selection methods has uncovered some fascinating results. Common EC selection methods (e.g., truncation, (μ, λ) , linear rank, Boltzmann) can sometimes lead to systems in which there are stable cycles and even chaotic orbits (Ficici and Pollack 2000b). Indeed, the dynamics of CoEAs can be much more complex than traditional EAs in that stable attractors of infinite population models can be quite unrelated to the specific values in the game payoff matrix itself. Empirical experiments on real algorithms verify that these fundamental dynamical pressures of the selection operator do, in fact, affect how real CoEAs perform on real problems.

Additionally, by considering certain game-theoretic properties of the stage game (a particular variation of the notion of constant-sum), one can show that the behavior of certain single population CoEAs using nonparametric selection operators will, in principle, behave dynamically like a comparable EA on some unknown fitness function (Luke and Wiegand 2003), while this cannot be said for other systems *even when the payoff is fully transitive*. This reinforces the idea that certain co-optimization problems are fundamentally different from traditional optimization problems.

EGT-based models have also been used to study two-population compositional CoEAs, showing that any pure Nash equilibrium of the underlying payoff game is a stable, attracting fixed point. This suggests selection alone can drive compositional CoEAs toward points that are globally very suboptimal in terms of their actual payoff value. Experimentation confirms this is so in real, analogous compositional CoEAs even to the extent that highly inferior local optima draw significantly more populations than do the true global optima. Indeed, complete mixing implies a solution concept wherein “optimality” is defined solely based on how individual strategies do on average over all possible partners. If one is using such methods to try to find a globally maximal payoff value, this can be seen as a kind of pathology (*relative generalization*). This dynamic may well be consistent with obtaining solutions that meet certain specific definitions of *robustness* (Wiegand and Potter 2006).

But most compositional CoEAs use best-of-generation interaction methods, not complete mixing, and Panait et al. (2006b) noted that these more common methods bias compositional coevolutionary search of projections of the payoff space to favor aggregate projections that

suit identifying the global optimum. Further, by incorporating archival notions that help retain *informative* partners in terms of these projection estimates, the optimization potential of compositional CoEAs can be further improved. These analytical lessons have been applied to both real compositional CoEAs, as well as other RL-based co-optimization processes (Panait 2006). Additionally, Vo et al. (2009) showed a certain infinite population EGT model of two-population compositional CoEAs to be equivalent to the distribution model for univariate estimation-of-distribution algorithms, thus arguing for the potential of cross-fertilization between these two subdisciplines of evolutionary computation. This work also provides a generalization of a subset of compositional CoEA models to n -populations.

These studies have shown that interaction and aggregation have profound impacts on the dynamical influences of selection in compositional coevolution. More specifically, the complete mixing interaction pattern may be ill-suited for problems with an ideal team solution concept. Another, altogether different dynamical systems approach by Subbu and Sanderson (2004) provides convergence results for a particular class of distributed compositional CoEAs to ideal team style solutions under conditions where complete mixing is not even possible.

In addition to the infinite population models described above, several works have focused on finite populations. EGT itself has been applied to finite population situations (Maynard Smith 1982; Ficici and Pollack 2000a), but typically under very constrained circumstances (two-strategy games). Outside of using EGT-based methods, there have been attempts to model the dynamics of finite, two-population CoEAs using Markov models (Liekens et al. 2003). While these methods also restrict the size of the problem spaces for obvious reasons, they have important implications for infinite population models in the sense that they clearly demonstrate that the long-term behavior of these systems can differ quite significantly from infinite population models.

4.2.2 Runtime Analysis

EC has made good use of classical algorithm analysis methods to find bounds on the expected number of evaluations necessary before a global optimum has been obtained as a function of the size of the (typically, but not always, combinatorial) genotype space (Oliveto et al. 2007). These methods have the advantage of providing precise and correct performance bounds on real algorithms for real problems, but their chief disadvantage is that it is often difficult to gain crucial insight into the behavior of an algorithm. This concern is typically addressed by selecting problem classes that help identify important properties in the problem and falsify hypotheses regarding how EAs address them.

Indeed, runtime analysis has been quite useful in understanding how simple compositional coevolutionary algorithms approach problems with ideal team solution concepts. A common hypothesis about such algorithms is that they tend to perform better when the representation choices result in a linear separation of problem components with respect to the objective function. Runtime analysis of simple (1 + 1) (Jansen and Wiegand 2003a, b) and steady-state-like (Jansen and Wiegand 2004) variants of compositional CoEAs revealed this hypothesis to be conclusively false: though nonlinear relationships between components can have profound effects on the relative performance differences between a coevolutionary algorithm and a similarly structured EA, separability itself is neither a sufficient nor

necessary property with which to predict problem difficulty (Jansen and Wiegand 2004). Additionally, there exist certain problem classes that essentially *cannot be solved* by a large class of compositional coevolutionary algorithms. Finally, this work suggests that compositional CoEAs optimize by leveraging the decomposition to partition the problem *while* increasing the focus of the explorative effects of the variational operators (so-called *partitioning and focusing* effect).

Runtime analysis of other CoEAs is more challenging and has not yet been done. Fortunately, recent research provides several needed pieces to overcome these challenges. First, there has been a great deal of recent progress in analyzing increasingly more complex multi-objective methods (Laumanns et al. 2004), and much of this may help study CoEAs that employ multi-objective mechanisms (e.g., archives). Second, the formalisms for explicit definition of solution concepts and the guarantee of monotonicity in certain concepts provide clear global goals needed for runtime analysis.

4.2.3 Probabilistic/Convergence Analysis

Another way to investigate algorithms theoretically, is to consider the dynamical behaviors of the real algorithms (as opposed to abstractly modeling them). Typically, such analyses are focused on providing convergence guarantees, but often careful consideration of problem and algorithm properties can provide greater insight.

Schmitt (2003a, b) provides a strong type of convergence analysis. For the maximization of all outcomes solution concept, the proposed algorithm is guaranteed not only to find a solution, but to have its populations converge to containing only genotypes corresponding to the solution(s). Markov chain analysis is used for the proofs. Bounds on convergence speed are not given; however, the work provides some useful general advice for how to apply rates of genetic operators to ensure such convergence.

Additionally, Funes and Pujals (2005) conduct a probability-theory-based investigation into the relationships between problem properties, algorithm properties, and system dynamics. This work focuses on test-based CoEAs, and demonstrates that the interplay of the considered properties cause trajectories through the domain-role sets to either make progress or resemble random-walk behaviors.

4.2.4 Empirical Black-Box Analysis

Analysis of coevolution can be approached empirically by viewing the system as a black box whose inputs are the algorithm and the problem, and the output is observed performance (e.g., quality of potential solution outputted given a certain amount of time). The algorithm and/or the problem are then varied and the output of the system re-observed, with the goal of determining the rules governing the dependency between inputs and outputs. Such studies are performed for problems with computable global quality, such as ideal team problems or test-beds of the kind reviewed in  Sect. 4.1.3.

Two different approaches can be distinguished within the black-box analysis category. One approach focuses on *properties* of the algorithms, of the problems, or of both. When algorithm properties are involved, this approach has been referred to as component analysis

(Wiegand 2004). The other approach varies the algorithm and/or the problem and compares the resulting performance without a clear isolation of the properties responsible for the differences in performance.

This latter approach is reviewed first. Most works introducing new algorithms are of this kind, including some of the early research comparing CoEAs with traditional EAs, both for test-based problems (Hillis 1990; Angeline and Pollack 1993) and for compositional problems (Potter and De Jong 1994). Later on, the approach was used to compare CoEAs among themselves, usually “enhanced” algorithms with basic ones. Examples include works for test-based problems (Ficici and Pollack 2001, 2003; Ficici 2004; De Jong and Pollack 2004; De Jong 2004a, c, 2005) and compositional problems (Bucci and Pollack 2005; Panait et al. 2006a; Panait and Luke 2006; Panait 2006). Some of the algorithms introduced by these works are backed up by theoretical results (De Jong 2004a, 2005; De Jong and Pollack 2004).

Property-focused approaches address problem properties, algorithm properties, or the interactions between them. These cases are discussed in order.

Some of the CoEA-versus-EA comparisons were extended to determine the classes of problems for which one type of algorithm would provide performance advantages over the other. Such work was performed for compositional problems by Potter (1997) and Wiegand and Potter (2006). The scrutinized problem properties were *separability* (Wiegand 2004), *inter-agent epistasis* (Bull 1998), *dimensionality* (here dimensionality refers to the number of roles), *noise*, and *relative sizes of basins of attraction of local optima*.

For test-based problems, empirical black-box analysis was used to investigate problem properties such as *role asymmetry* (Olsson 2001), *intransitivity* (De Jong 2004b), and *dimensionality* (De Jong and Bucci 2006). (Here dimensionality refers to the number of underlying objectives implicitly defined by the test role(s).) These works introduced specialized algorithms intended to target the respective problem property.

Studies focusing only on algorithm properties investigated either the mechanism for *selecting interactions* (Panait et al. 2006c; Panait and Luke 2005; Parker and Blumenthal 2003; Blumenthal and Parker 2004) or the mechanism for *aggregating* the result of those interactions (Panait et al. 2003; Wiegand et al. 2001; Cartlidge and Bullock 2002). All but the last cited work were concerned with compositional problems.

Finally and perhaps most importantly, some black-box empirical studies analyzed the effects on performance of the interdependency between algorithm properties and problem properties. Most studied has been the mechanism for selecting interactions, especially in the context of compositional problems (Potter 1997; Wiegand et al. 2001, 2002; Wiegand 2004; Bull 1997, 2001). The launched hypothesis was that the performance effects of the interaction method are tightly related to the (previously mentioned) problem property separability and the kind of *cross-population epistasis* created when representation choices split up inseparable pieces of the problem. This dependency however proved not to be as straightforward as thought, as it was later shown in (Popovici and De Jong 2005a) via empirical dynamics analysis. For test-based problems, two different methods for selecting interactions were analyzed by Panait and Luke (2002), suggesting that the amount of noise in the problem affects their influence on performance.

For compositional problems, Panait et al. (2004) extended their previous work on the mechanism for aggregating results from multiple interactions by studying how its performance effects are affected by the problem’s local optima and their basins of attraction. Wiegand and Sarma (2004) studied the potential benefits of *spatially distributed schemes for selecting interactions and/or selecting parents* on domains with role asymmetry.

Bull (1998) studied the effects of mutation and crossover in the context of “mixed-payoff” domains Kauffman and Johnson’s (1991) NKC landscapes) and found them to be sensitive to inter-agent epistasis.

4.2.5 Empirical Dynamics Analysis

While black-box analysis can provide some heuristics for improving performance, it cannot explain the causes for the observed dependencies between the inputs and the outputs of a CoEC setup. To understand these causes, one needs to observe the system while running and track some of its time-varying properties. Instead, dynamics analysis is used to explain the connection between algorithm and problem properties on one side and performance on the other side. Individual studies connect different subsets of the pieces, analyzing:

- Dynamics in isolation (Cliff and Miller 1995; Stanley and Miikkulainen 2002b; Bader-Natal and Pollack 2004; Floreano and Nolfi 1997; Axelrod 1989; Cartlidge and Bullock 2004b);
- Problem properties and dynamics (Bull 2005a);
- Problem properties, algorithm properties, and dynamics (Bull 2005b; Kauffman and Johnson 1991);
- Dynamics and performance (Pagie and Mitchell 2002; Juillé and Pollack 1998; Ficici and Pollack 1998; Miller 1996; Funes and Pollack 2000; Paredis 1997);
- Problem properties, dynamics, and performance (Watson and Pollack 2001);
- Algorithm properties, dynamics, and performance (Williams and Mitchell 2005; Pagie and Hogeweg 2000; Rosin and Belew 1995, 1997; Cartlidge and Bullock 2003 2004a; Bucci and Pollack 2003a);
- How the combination of algorithm properties and problem properties influences dynamics and how dynamics influences performance (Popovici 2006).

These analyses used some of the progress metrics described in [Sect. 4.1.2](#), and/or various techniques for tracking genotypic/phenotypic changes. Studies involving the latter were performed for domains and representations that are easily amenable to visualization.

Cliff and Miller (1995) were also the first to use techniques for tracking genotypic changes in order to analyze the run-time behavior (dynamics) of CoEAs. They introduced “elite bitmaps,” “ancestral Hamming plots,” and “consensus distance plots” as tools complementary to CIAO plots. They all work on binary representations. Elite bitmaps simply display the genotype of best-of-generation individuals next to each other in temporal sequence. Some additional processing can reveal interesting patterns. Ancestral Hamming plots display the Hamming distance between elite individuals from different generations. Consensus distance plots monitor the genotypic make up of the whole population through the distribution of Hamming distances from the genotype of each individual to the population’s “consensus sequence.” All three techniques are applicable to EAs in general, not just CoEAs.

Popovici (2006) extensively used best-of-generation trajectory plots for understanding the effects of various CoEA design choices and exposed best-response curves as a problem property that is a strong driver of coevolutionary algorithm behavior.

It is via the empirical dynamics analysis approach that most knowledge about the pros and cons of using CoEAs for co-optimization was generated. And just as traditional canonical

evolutionary algorithms can be used for optimization, yet they are not intrinsically optimizers (De Jong 1992), canonical coevolutionary algorithms may be useful in co-optimization, yet they are not intrinsically co-optimizers.

5 The Future of Coevolution

The bulk of this chapter has focused on how coevolutionary algorithms, co-search problems, and interactive domains have been studied. This section is dedicated to the future of coevolution, including current lines of work, research questions, and results with intriguing but so-far-untapped potential. We end with some concluding remarks.

5.1 Open Issues

Recent research has helped establish a firm, formal foundation for coevolutionary problem solvers, and it has provided some principled ways to think about, design, and apply such systems. Nevertheless, many issues remain quite unresolved. These are grouped into two categories: those relating disparate theoretical analyses and those relating the analytical understanding of CoEAs to their practical application.

5.1.1 Relating Theories

Dynamical systems analysis of compositional coevolution has demonstrated that certain robustness properties in the problem can attract populations (Wiegand and Potter 2006). But there has yet to be any attempt to formalize this idea as a solution concept, and it remains to be seen whether such a concept is monotonic. Similarly, Lothar Schmitt's convergence analysis (Schmitt 2003b) provides useful feedback about how to manage the parameters of operators; however, it makes very specific assumptions about the solution concept, and no work has yet approached the task of generalizing his ideas to include CoEAs as applied to problems with different concepts of solution. Runtime analysis for compositional approaches has yielded precise bounds for those algorithms on certain optimization problems (Jansen and Wiegand 2004), and there has been a lot of success using similar methods to analyze the performance of EAs on multi-objective optimization problems. This suggests it should be possible to apply such analyses to CoEAs for test-based problems, due to their underlying multi-objective nature.

Though in a handbook of natural computing, this chapter has tried to present coevolutionary algorithms in the broader context of co-optimization. As pointed out in [Sect. 4.1](#), some of the difficulties CoEAs face, such as the difficulty to monitor and achieve progress, are specific to the nature of certain co-optimization problems and not the evolutionary aspect of these algorithms. Any other algorithms attempting to solve such problems will have to deal with these issues. Formalizing co-optimization algorithms as having two components, a search heuristic and an output selection function, allows for easy transfer of results pertaining to monotonicity and performance to algorithms using non-evolutionary search heuristics, such as the ones introduced in ([Service and Tauritz 2008a](#)).

Last but not least, many research questions on how algorithms should be designed have been opened by the recent confluence of the two generic co-optimization theories concerning monotonicity and performance (Service 2009; Popovici and De Jong 2009). This is expounded below.

5.1.2 Relating Theory to Practice

As discussed earlier in the chapter, the notion of monotonic solution concept not only provides a way to characterize problems but also allows engineers to construct principled algorithms for which consistent progress toward a solution can be expected (Ficici 2004). Still, on a practical level, several questions remain. Many algorithms that implement monotonic solution concepts have unrealistic memory requirements. Researchers are only beginning to try to understand what the impact of practical limits on mechanisms such as archive size have on performance and theoretical guarantees about progress. Similarly, hidden in the free lunch proofs of Wolpert and Macready (2005) was advice on how to obtain some performance advantage, such as avoiding unnecessary evaluations, exploiting biases introduced by the solution concept, and using a Bayes output selection function. Still, determining how to use this advice in real algorithms for real problems is very much an open research issue. Further, the design choices required by monotonicity can conflict with those required for performance (Popovici and De Jong 2009) and additional research is needed to determine when/if this trade-off can be avoided or at least how to minimize it. Indeed, recent work relating monotonicity, solution concepts, and the NFL suggest this relationship could be quite complex (Service 2009; Popovici and De Jong 2009).

The same types of questions can be raised with respect to methods used for the discovery of informative dimensions of co-optimization problems: Can heuristic methods be developed that can approximate this search process in the general case, and what are the precise trade-offs of such an approximation? Finally, under certain conditions, it is theoretically possible for some CoEAs to prefer components considered later in the run, which in turn will tend to require larger supporting test sets (Bucci 2007). This implies the possibility of a kind of bloating that practitioners may need to address in practical application.

5.2 Discovery of Search Space Structure

De Jong and Pollack (2004) present empirical results suggesting that a Pareto coevolutionary algorithm could find what were dubbed the *underlying objectives* of a problem. These are hypothetical objectives that determine the performance of components without the need to have them interact with all possible tests. De Jong and Pollack (2004) apply a two-population Pareto coevolutionary algorithm, DELPHI, to instances of a class of abstract interactive domains. Figures 13 and 15 of that work suggest that evaluator individuals (what we have called tests) evolve in a way that tracks the underlying objectives of the domain. The results suggest that the algorithm is sensitive to the presence of underlying objectives even though it is not given explicit information about those objectives, exhibiting what has been called an “emergent geometric organization” of test individuals (Bucci 2007). Bucci and Pollack (2003a) make a similar observation, also empirical though using a different algorithm; Fig. 5 of that work suggests a similar sensitivity to underlying objectives. In both cases, clusters

of individuals, rather than single individuals, move along or collect around the known objectives of the domain. The problems considered, namely, numbers games (Watson and Pollack 2001), were designed to have a known and controllable number of objectives, but the algorithms used in these two studies did not rely on that fact. The work therefore raises the question of whether underlying objectives exist in all domains, and whether algorithms can discover them.

A partial answer to this question is found in the notion of *coordinate system* defined in (Bucci et al. 2004). Coordinate systems, which were defined for a class of test-based problems (specifically, problems with a finite number of components and a finite number of binary-outcome tests), can be viewed as a formalization of the empirically observed underlying objectives of De Jong and Pollack (2004). To elaborate, a coordinate system consists of several *axes*. Each axis is a list of tests ordered in such a way that any component can be placed somewhere in the list. A component's placement is such that it does well against all tests before that spot and does poorly against all tests after it. For this reason, an axis can be viewed as measuring some aspect of a component's performance: A component that places high on an axis is “better than” one that sits lower in the sense that it does well against more tests (more of the tests present in the axis, not more tests of the domain as a whole). Formally, an axis corresponds to a numerical function over the components, in other words to an objective function. It can be proven (Bucci et al. 2004) that every domain of the considered class possesses at least one coordinate system, meaning it has a decomposition into a set of axes. In short, every such domain has some set of objective functions associated with it, one for each axis in a coordinate system for the problem.

Besides defining coordinate systems formally, Bucci et al. (2004) give an algorithm that finds a coordinate system for an interactive domain in polynomial time. The algorithm, though fast, is not guaranteed to produce the smallest-possible coordinate system for the domain, however. Finite domains must have a minimal coordinate system, but in general, even finite domains can have distinct coordinate systems of different sizes. The algorithm is not coevolutionary per se, as it examines the outcomes of tests on components. It is therefore applicable to the entire class of test-based problems and agnostic about the specific algorithm used to solve the problem.

The above work leaves open the question of whether underlying objectives or coordinate systems are simply mathematical curiosities with no practical or theoretical utility. The work of De Jong and Bucci (2007) addresses that question in two ways. First, it provides an exact coordinate system extraction algorithm that, unlike the approximate algorithm of Bucci et al. (2004), is slow but is guaranteed to return a minimal-sized coordinate system for a finite interactive domain. (Interactive domains can, in general, have more than one minimal-sized coordinate system. Hence *a* and not *the*.) Second, it applies the exact extraction algorithm to several small instances of the game of Nim, and observes that for all instances tested, the axes of extracted coordinate systems contain significant information about how a strategy performs at the game. Thus, far from being theoretical peculiarities, at least in this case (minimal) coordinate systems intuitively relate to real structure in the domain.

Given this last fact and that certain coevolutionary algorithms seem to be sensitive to the underlying dimensions of a domain, one is led to an intriguing possibility: that appropriately designed coevolutionary algorithms could discover and extract meaningful structure from interactive domains in the process of solving problems over them. Besides solving problems, algorithms might be able to simultaneously output useful knowledge about domains. For complex, ill-understood domains, the knowledge output might be at least as useful as a solution.

5.3 Open-Ended Evolution and Novelty

An important possibility that should not be lost to our solution-based, problem-oriented view is the idea that the goal of evolutionary systems need not necessarily be to find a particular solution (be it a set of points or otherwise) at all. In particular, in cases where a representation space is not explicitly limited, evolutionary systems can be seen as dynamical methods to explore “interesting” spaces. Here “interesting” might correspond with some problem-oriented view or relate to aspects of some simulation that involves the evolutionary process itself, but it may also simply correspond with notions of novelty.

In traditional, non-coevolutionary systems, an objective fitness measure in conjunction with selection methods will tend to drive the systems in particular directions. Explicit construction of fitness functions that encourage some direct notion of novelty can certainly be developed; however, coevolution offers some very natural and interesting possibilities here. Indeed, some of the earliest forms of artificial evolution involved game playing as means of exploring some of basic mechanisms of evolution and self-maintenance themselves (Barricelli 1963).

Many of the concepts discussed above (e.g., *informativeness* and *distinctions*) are very natural measures of novelty, and algorithms that literally function by moving in directions that work to maintain these are compelling for this purpose. Even more compelling is the idea just discussed above: Since CoEAs can be used to discover geometries of comparisons, to construct and report dimensions of informativeness in a space, they are very appealing mechanisms for novelty search in open-ended evolution because they may be capable of providing much more than new, unusual individuals – they may well be able to place such individuals in relationship with things already seen.

6 Concluding Remarks

The great promise of coevolutionary algorithms to find sorting networks, teams, 3-D creatures, game-playing strategies, or other complicated entities given only information about how these interact with other entities is far from realized. However, the theoretical tools and empirical methodologies presented in this chapter help in getting closer to that goal. One noteworthy outcome of theoretical investigations is that free lunch is possible: algorithms that provably perform better than others across all problem instances. This observation is relatively new and unexplored, but represents an exciting direction in coevolutionary algorithms research. It offers the possibility that a coevolutionary algorithm could not only find interesting or capable entities, but do so faster than random search would. We hope that the principled introduction to co-optimization and coevolutionary computation given in this chapter will contribute to the realization of these goals, by helping future efforts leverage the strong foundation laid by prior research.

Abstract

Niching techniques are the extension of standard evolutionary algorithms (EAs) to multimodal domains, in scenarios where the location of multiple optima is targeted and where EAs tend to lose population diversity and converge to a solitary basin of attraction. The development and investigation of EA niching methods have been carried out for several decades, primarily within the branches of genetic algorithms (GAs) and evolution strategies (ES). This research yielded altogether a long list of algorithmic approaches, some of which are bio-inspired by various concepts of organic speciation and ecological niches, while others are more computational-oriented. This chapter will lay the theoretical foundations for niching, from the perspectives of biology as well as optimization, provide a summary of the main contemporary niching techniques within EAs, and discuss the topic of experimental methodology for niching techniques. This will be accompanied by the discussion of specific case-studies, including the employment of the popular covariance matrix adaptation ES within a niching framework, the application to real-world problems, and the treatment of the so-called niche radius problem.

1 Introduction

Evolutionary Algorithms (EAs) have the tendency to lose diversity within their population of feasible solutions and to converge into a single solution (Bäck 1994, 1996; Mahfoud 1995a), even if the search landscape has multiple globally optimal solutions.

Niching methods, the extension of EAs to finding multiple optima in multimodal optimization within one population, address this issue by maintaining the diversity of certain properties within the population. Thus, they aim at obtaining parallel convergence into multiple attraction basins in the multimodal landscape within a single run.

The study of niching is challenging both from the theoretical point of view and from the practical point of view. The theoretical challenge is twofold – maintaining diversity within a population-based stochastic algorithm from the computational perspective, and also gaining an insight into *speciation* theory or *population genetics* from the evolutionary biology perspective. The practical aspect provides a real-world incentive for this problem – there is an increasing interest of the *applied optimization community* in providing decision makers with multiple solutions that ideally represent different conceptual designs, for single-criterion or multi-criterion search spaces (Avigad et al. 2004, 2005). The concept of “*going optimal*” is often extended nowadays into the aim of “*going multi optimal*”: **obtaining optimal results but also providing the decision maker with a variety of different options**. (The *Second Toyota Paradox* (Cristiano et al. 2001), which is often reviewed in management studies, promotes the consideration of multiple candidate solutions during the car production process: “Delaying decisions, communicating ambiguously, and pursuing an excessive number of prototypes, can produce better cars faster and cheaper”).

Among the three conventional streams of EAs (Bäck 1996) – *genetic algorithms* (GAs) (Goldberg 1989), *evolution strategies* (ES) (Beyer and Schwefel 2002), and evolutionary programming (EP) (Fogel 1966) – niching methods have been studied in the past four decades almost exclusively within the framework of GAs. However, niching methods have been mostly

a by-product of studying *population diversity*, and were hardly ever at the front of the evolutionary computation (EC) research as an independent subfield.

This chapter thus aims at achieving three main goals:

1. Laying the theoretical foundations for niching, both from the biological as well as the computational perspectives
2. Providing a summary of the main contemporary niching techniques within evolutionary algorithms
3. Discussing the topic of experimental methodology for niching techniques, and proposing a framework for it

We shall begin by providing the natural computing motivation for niching by means of the biological background for the evolutionary process of *speciation*, given in [Sect. 2](#), where it will also be linked to the domain of function optimization. The important topic of *population diversity* within evolutionary algorithms is discussed in detail in [Sect. 3](#), focusing on the two canonical streams of GAs and ES. This is followed by an overview of the existing niching techniques within EAs, in [Sect. 4](#). A case study of a specific niching technique with the popular covariance matrix adaptation evolution strategy (CMA-ES) receives special attention by means of a detailed description in the end of that section. The topic of experimental methodology for research on niching is discussed in [Sect. 5](#), where proposed synthetic test functions as well as recommended performance criteria are outlined. Niching with the CMA-ES is revisited in that section, as an experimental observation case study. [Section 6](#) is dedicated to a crucial and challenging issue for niching methods, the so-called *niche radius problem*. Finally, [Sect. 7](#) concludes this chapter and proposes directions for future research in this domain.

A Note on the Scope It should be stressed that there exist niching methods in other natural computing frameworks, such as in particle swarm optimization (PSO) or in ant colony optimization (ACO) (for general field reviews see Kennedy and Eberhart ([2001](#)) and Engelbrecht ([2005](#)) for PSO or Dorigo and Stützle ([2004](#)) and Blum ([2005](#)) for ACO). These frameworks exceed the scope of this chapter, which solely focuses on evolutionary algorithms. We refer the reader who wishes to learn about niching techniques in PSO to Brits et al. ([2002](#)) and Parrott and Li ([2006](#)), or to Angus ([2006](#)) in ACO.

A Note on Notation Upon consideration of optimization problems, this chapter will assume *minimization*, without loss of generality, unless specified otherwise.

2 Background: From Speciation to Ecological Optima

This section constitutes the introduction to niching, and thus covers a diverse set of interdisciplinary topics. It will review the *biological* elementary concepts that correspond to the core of niching methods, such as *population diversity* and *speciation*, while mainly relying on Freeman and Herron ([2003](#)). It will then make the linkage to computing, by shifting to the optimization arena and discussing the equivalent to ecological niches: *basins of attraction*.

A Note on Terminology A species is defined as the *smallest evolutionary independent unit*. The term *niche*, however, stems from ecology, and it has several different definitions. It is sometimes referred to as the collective environmental components which are favored by a specific species, but could also be considered as the ecosystem itself which hosts individuals of

various species. Most definitions would typically also consider the *hosting capacity* of the niche, which refers to the limited available resources for sustaining life in its domain. In the context of function optimization, *niche* is associated with a *peak*, or a *basin of attraction*, whereas a *species* corresponds to the subpopulation of individuals occupying that *niche*.

2.1 Preliminary: Organic Evolution and Genetic Drift

Organic evolution can be broken down into four defining fundamental mechanisms: *natural selection*, *mutation*, *migration* or *gene flow*, and *genetic drift*. The latter, which essentially refers to *sampling errors in finite populations*, was overlooked by Darwin, who had not been familiar with Mendelian genetics, and thus did not discuss this effect in his *Origin of Species* (Darwin 1999). We assume that the reader is familiar with the first three fundamental elements, that is, selection–mutation–migration, and would like to elaborate on the drift effect, as it is the least intuitive mechanism among the four aforementioned evolutionary forces. In short, *genetic drift* (Fisher 1922; Wright 1931; Kimura 1983) is a stochastic process in which the diversity is lost in finite populations. A distribution of genetic properties is transferred to the following generation in a limited manner, due to the finite number of generated offspring, or equivalently, the limited statistical sampling of the distribution. As a result, the distribution is likely to approach an *equilibrium distribution*, for example, fixation of specific alleles when subject to equal fitness. This is why *genetic drift* is often considered as a *neutral effect*. The smaller the population, the faster and stronger this effect occurs. An analogy is occasionally drawn between genetic drift to *Brownian motion* of particles in mechanics.

The *genetic drift* effect had been originally recognized by Fisher (1922) (referred to as *random survival*), and was explicitly mentioned by Wright when studying Mendelian populations (Wright 1931). It was, however, revisited and given a new interpretation in the *Neutral Theory of Molecular Evolution* of Kimura (1983). The *neutral theory* suggested that the *random genetic drift* effect is the main driving force within molecular evolution, rather than the *nonrandom natural selection* mechanism. *Natural selection* as well as *genetic drift* are considered nowadays, by the contemporary evolutionary biology community, as the combined driving force of organic evolution. Moreover, the importance of the *neutral theory* is essentially in its being a **null hypothesis model** for the *natural selection theory*, by definition.

2.2 Organic Diversity

Diversity among individuals or populations in nature can be attributed to different evolutionary processes which occur at different levels. We distinguish here between variations that are observed within a single species to a *speciation* process, during which a new species arises, and both of them are reviewed shortly.

2.2.1 Variations Within a Species

Diversity of organisms within a single species stems from a variance at the genotypic level, referred to as *genetic diversity*, or from the existence of a spectrum of phenotypic realizations to a specific genotype. These effects are quantified and are usually associated with *genotypic variance* and *phenotypic variance*, respectively. Several hypotheses explaining *genetic diversity*

have been proposed within the discipline of *population genetics*, including the *neutral evolution theory*. It should be noted that genetic diversity is typically considered to be advantageous for survival, as it may allow better adaptation of the population to environmental changes, such as climate variations, diseases, etc.

Phenotypic variance is measured on a continuous spectrum, also known as quantitative variation. Roughly speaking, the main sources of quantitative variations (Freeman and Herron 2003; Scheiner and Goodnight 1984) are outlined here:

1. Genes have *multiple loci*, and hence are mapped onto a large set of phenotypes.
2. *Environmental effects* have direct influence on natural selection; fitness is time-dependent, and thus phenotypic variations in the outcome of selection are expected to occur.
3. *Phenotypic plasticity* is the amount in which the *genotypic expression* vary in different environments. (Bradshaw (1965) gave the following qualitative definition to phenotypic plasticity: “The amount by which the expressions of individual characteristics of a genotype are changed by different environments is a measure of the plasticity of these characters.”) And it is a direct source of variation at the phenotypic level.
4. The plastic response of the genotype to the environment, that is, the joint effect of genetic and environmental elements, also affects the selection of a specific phenotype, and thus can lead to variations. This effect is known as *genotype–environment interaction* (“G-by-E”).

Thus, *quantitative variations* are mainly caused by genotypic and phenotypic realizations and their interaction with the environment. The ratio between *genetic variance* to total *phenotypic variance* is defined as *heritability* (Wright 1931).

2.2.2 Speciation

Speciation, on the other hand, is the process during which a new species arises. In this case, statistical disassociation, which is the trigger to speciation, originates from gradually decreasing physical linkage.

The essence of the speciation process is **lack of gene flow**, where physical isolation often plays the role of the barrier to gene flow. Lack of gene flow is only one of the necessary conditions for speciation. Another necessary condition for speciation to occur is that the reduction of gene flow will be followed by a phase of **genetic divergence**, by means of *mutation, selection, or drift*. Finally, the completion or elimination of divergence can be assessed via the so-called *secondary contact* phase: interbreeding between the parental populations would possibly fail (offspring is less fit), succeed (offspring is fitter), or have a neutral outcome (offspring has the same fitness). This would correspond, respectively, to increasing, decreasing, or stabilizing the differentiation between the two arising species. Note that the speciation can occur *de facto*, without the actual secondary contact taking place; the latter is for observational assessment purposes.

In organic evolution, four different levels of *speciation* are considered, corresponding to four levels of physical linkage between the subpopulations:

1. **Allopatric speciation** The split in the population occurs only due to complete geographical separation, for example, migration or mountain building. It results in two geographically isolated populations.

2. **Peripatric speciation** Species arise in small populations, which are not geographically separated but rather isolated in practice; the effect occurs mainly due to the *genetic drift* effect.
3. **Parapatric speciation** The geographical separation is limited, with a physical overlap between the two zones where the populations split from each other.
4. **Sympatric speciation** The two diverging populations coexist in the same zone, and thus the speciation is strictly non-geographical. This is observed in nature in parasite populations, that are located in the same zone, but associated with different plant or animal hosts (McPheron et al. 1988).

These four modes of speciation correspond to four levels of geographically decreasing linkages. Generally speaking, *statistical association* of genetic components in nature, such as *loci*, typically results from *physical linkage*. In this case, we claim that statistical disassociation, which is the trigger to speciation, originates from gradually decreasing physical linkage.

In summary, speciation typically occurs throughout three steps:

1. Geographic isolation or reduction of gene flow
2. Genetic divergence (mutation, selection, drift)
3. Secondary contact (observation/assessment)

2.3 “Ecological Optima”: Basins of Attraction

We devote this section to the definition of basins of attraction. The task of defining a *generic basin of attraction* seems to be one of the most difficult problems in the field of *global optimization*, and there have only been few attempts to treat it theoretically. (Intuitively, and strictly metaphorically speaking, we may think of a *region of attraction* of \mathbf{x}_L as the region, where if water is poured, it will reach \mathbf{x}_L . Accordingly, we may then think of the basin of \mathbf{x}_L as the maximal region that will be covered when the cavity at \mathbf{x}_L is filled to the lowest part of its rim (Törn and Zilinskas 1987).)

Rigorously, it is possible to define the basin by means of a *local optimizer*. In particular, consider a gradient descent algorithm starting from \mathbf{x}_0 , which is characterized by the following dynamics:

$$\frac{d\mathbf{x}(t)}{dt} = -\nabla f(\mathbf{x}(t)) \quad (1)$$

with the initial condition $\mathbf{x}(0) = \mathbf{x}_0$. Now, consider the set of points for which the limit exists:

$$\Upsilon = \left\{ \mathbf{x} \in \mathbb{R}^n \mid \mathbf{x}(0) = \mathbf{x} \wedge \mathbf{x}(t) \mid_{t \geq 0} \text{satisfies Eq. 1} \wedge \lim_{t \rightarrow \infty} \mathbf{x}(t) \text{ exists} \right\} \quad (2)$$

Definition 1 The *region of attraction* $A(\mathbf{x}_L)$ of a local minimum, \mathbf{x}_L , is

$$A(\mathbf{x}_L) = \left\{ \mathbf{x} \in \Upsilon \mid \mathbf{x}(0) = \mathbf{x} \wedge \mathbf{x}(t) \mid_{t \geq 0} \text{satisfies Eq. 1} \wedge \lim_{t \rightarrow \infty} \mathbf{x}(t) = \mathbf{x}_L \right\} \quad (3)$$

The *basin* of \mathbf{x}_L is the **maximal level set** that is fully contained in $A(\mathbf{x}_L)$.

In the case of several disconnected local minima with the same function value, it is possible to define the region of attraction as the union of the nonoverlapping connected sets.

2.4 Classification of Optima: The Practical Perspective

On a related note to the theoretical definition of the basin, the practical perspective for the *classification of optima shapes*, also referred to as global topology, is worth mentioning. This topic is strongly related to the emerging subfield of *robustness study* (see, e.g., Tsui 1992), which aims at attaining optima of high quality with large basins (i.e., low partial derivative values in the proximity of the peak). Moreover, yet visited from a different direction, another approach was introduced recently by Lunacek and Whitley for classifying different classes of multimodal landscapes with respect to algorithmic performance (Lunacek and Whitley 2006). The latter defines the *dispersion metric* of a landscape as the degree to which the local optima are globally clustered near one another. Landscapes with low dispersion have their best local optima clustered together in a single *funnel*. (We deliberately avoid the definition of a funnel as it is rather vague. We refer the reader to Doye et al. (2004).) This classification of low dispersion and high dispersion may be associated with the algorithmic trade-off between exploration of the landscape and exploitation of local structures. Upon considering landscapes with multiple funnels, a recent study (Lunacek et al. 2008) investigated the impact of a global structure of two uneven funnels on the evolutionary search. It concluded that EAs tend to converge into the larger funnel, even if it is of suboptimal quality, and thus put their effectiveness in global exploration in multi-funnel landscapes into question.

3 Population Diversity in Evolutionary Algorithms

The term *population diversity* is commonly used in the context of Evolutionary Algorithms, but it rarely refers to a rigorous definition. Essentially, it is associated both with *genetic diversity* as well as with *speciation* – the two different concepts from organic evolution that were discussed in the previous section. This is simply due to the fact that the differences between the two concepts do not have any practical effect on the evolutionary search nor on the goal of maintaining diversity among the evolving candidate solutions. In the well-known trade-off between *exploration* and *exploitation* of the landscape during a search, *maintaining population diversity* is a driving force in the *exploration front*, and thus it is an important component. However, among EC researchers, population diversity is primarily considered as a component due to play a role in the important exploration of the landscape for the sake of obtaining a single solution, while its role in obtaining multiple solutions is typically considered as a secondary one.

Mahfoud's Formalism

Mahfoud constructed a formalism for characterizing *population diversity* in the framework of Evolutionary Algorithms (see Mahfoud 1995a, pp. 50–59). Mahfoud's formal framework was based on the partitioning of the search space into equivalence classes (set to *minima* in the search landscape), a descriptive relation (typically, *genotypic* or *phenotypic* mappings), and the measurement of distance between the current distribution of subpopulations to some predefined *goal distribution*.

Let P be a discrete distribution describing the current partitioning of the population into subpopulations, and let Q be the goal distribution of the population with respect to the defined sites. The formalism focuses in defining the *directed divergence*, or distance

of distribution P to distribution Q . Several well-known metrics follow this formalism by satisfying its various criteria, such as Shannon's information entropy, standard distance metrics, etc. (Mahfoud 1995a).

Diversity Loss

Subject to the complex dynamics of the various forces within an evolutionary algorithm, population diversity is typically lost, and the search is likely to converge into a single basin of attraction in the landscape. *Population diversity loss* within the population of solutions is the fundamental effect which niching methods aim to treat. In fact, from the historical perspective, the quest for diversity-promoting techniques was the main goal within the EC community for some time, and niching methods were merely obtained as *by-products*, so to speak, of that effort.

Due to the fundamental differences between GAs and ES, we choose to describe the effect of population diversity loss for each one of them separately.

3.1 Diversity Loss Within Genetic Algorithms

Mahfoud devoted a large part of his doctoral dissertation to studying population diversity within GAs (Mahfoud 1995a). He concluded that three main components can be attributed to the effect of population diversity loss within GAs.

Selection Pressure The traditional GA applies a probabilistic selection mechanism, namely, the *roulette-wheel selection* (RWS). This mechanism belongs to a broad set of selection mechanisms, which follow the fitness-proportionate selection principle. Selection pressure is thus associated with the first *moment of the selection operator*. It has been demonstrated by Mahfoud (1995a) that the selection pressure, or equivalently the nonzero expectation of the selection operator, prevents the algorithm from converging in parallel into more than a single attractor.

Selection Noise Selection noise is associated with the second *moment of the selection operator*, or its *variance*. Mahfoud (1995a) demonstrated that the high variance of the RWS, as well as of other selection mechanisms, is responsible for the fast convergence of a population into a single attractor, even when there exists a set of equally fit attractors. This effect can be considered as a *genetic drift* in its broad definition, that is, sampling error of a distribution.

Operator Disruption Evolutionary operators in general, and the *mutation* and *recombination* operators in particular, boost the evolution process toward exploration of the search space. In that sense, they have a constructive effect on the process, since they allow locating new and better solutions. However, their action also has a destructive effect. This is due to the fact that, by applying them, good solutions that have been previously located might be lost. Therefore, they may eliminate competition between highly fit individuals, and "assist" some of them to take over. The mutation operator usually has a small effect, since it acts in small steps – low mutation probability in the traditional GA, which means infrequent occurrence of bit flips. Thus, the mutation operator can be considered to have a negligible disruption. The recombination operator, on the other hand, has a more considerable effect. In the GA field, where the *crossover* operator is in use (single-point, two-point or n -point crossovers), the latter has been shown to have a disruptive nature by breaking desired patterns within the population (the well-known *schema theorem* discusses the schema disruption by the crossover operator

and states that schemata with high defining length will most likely be disrupted by the crossover operator; see, for example, Goldberg (1989).

Corollary 1 *The traditional GA, which employs the standard set of operators, is exposed to statistical as well as disruptive effects that are responsible for the loss of population diversity. This outcome is likely to occur due to the first and second moments of the RWS operator, as well as to the disruptive nature of the crossover operator. We conclude that the traditional GA is expected to lose diversity among its candidate solutions.*

3.2 Diversity Loss Within Evolution Strategies

The defining mechanism of ES is strongly dictated by the mutation operator as well as by the deterministic selection operator. As defining operators, they have a direct influence on the diversity property of the population. The recombination operator, nevertheless, does not play a critical role in the ES mechanism.

We attribute two main components to the *population diversity loss* within ES: fast *take-over*, which is associated with the *selection* operator, and *genetic drift* (or *neutrality effect*), which is associated both with the *selection* and the *recombination* operators.

3.2.1 Selective Pressure: Fast Take-Over

Evolution strategies have a strictly deterministic, rank-based approach to selection. In the two traditional approaches (Bäck 1996) – (μ, λ) and $(\mu + \lambda)$ – the best individuals are selected, implying, rather intuitively, high *selective pressure*. Due to the crucial role of the selection operator within the evolution process, its impact within the ES field has been widely investigated.

Goldberg and Deb introduced the important concept of *take-over time* (Deb and Goldberg 1989), which gives a quantitative description of selective pressure **with respect only to the selection operator**.

Definition 2 The *take-over time*, τ^* , is the minimal number of generations until repeated application of the selection operator yields a uniform population filled with copies of the best individual.

The selective pressure has been further investigated by Bäck (1994), who analyzed all the ES selection mechanisms also with respect to take-over times. He concluded that upon employing the typical selection mechanisms, very short *take-over times* are yielded. This result implies that ES are typically subject to high *selective pressures*.

3.2.2 ES Genetic Drift

We consider two different ES neutral effects that could be together ascribed as a general ES genetic drift: *recombination drift*, and *selection drift*. We argue that these two components are responsible for the loss of population diversity within ES.

Recombination Drift

Beyer explored extensively the so-called *mutation-induced speciation by recombination* (MISR) principle (see, e.g., Beyer 1999). According to this important principle, repeated application of the mutation operator, subject to a dominant recombination operator, would lead to a stable distribution of the population, which resembles a species or a cloud of individuals. When fitness-based selection is applied, this cloud is likely to move together toward fitter regions of the landscape. Furthermore, Beyer managed to prove analytically (Beyer 1999) that the MISR principle is indeed universal when finite populations are employed, subject to sampling-based recombination. The latter was achieved by analyzing the ES dynamics without fitness-based selection, deriving the expected population variance, and showing that it is reduced with random sampling in finite populations. This result was also corroborated by numerical simulations. This study provides one with an analytical result that a sampling-based recombination is subject to genetic drift, and leads to loss of population diversity.

Selection Drift

A recent study on the extinction of subpopulations on a simple *bimodal equi-fitness* model investigated the drift effect of the selection operator (Schönemann et al. 2004). It considered the application of *selection* on finite populations, when the fitness values of the different attractors were equal (i.e., eliminating the possibility of a *take-over effect*), and argued that a neutral effect (*drift*) would occur, pushing the population into a single attractor. The latter study, indeed, demonstrated this effect of *selection drift* in ES, which resulted in a convergence to an equilibrium distribution around a single attractor. It was also shown that the time of extinction increases proportionally with μ . The analysis was conducted by means of Markov chain models, supported by statistical simulations.

Corollary 2 *Evolution Strategies that employ finite populations are typically underposed to several effects that are responsible for the loss of population diversity. It has been shown that the standard selection mechanisms may lead to a fast take-over effect. In addition, we argued that both the recombination and the selection operators experience their own drift effects that lead to population diversity loss. We concluded that an evolution strategy with a small population is likely to encounter a rapid effect of diversity loss.*

4 Evolutionary Algorithms Niching Techniques

Despite the fact that the motivation for multimodal optimization is beyond doubt, and the biological inspiration is real, there is no unique definition of the goal statement for *niching techniques*. There have been several attempts to provide a proper definition and functional specification for niching; we review here some of them:

1. Mahfoud (1995a) chose to put emphasis on locating as well as maintaining good optima, and formulated the following:
 - The litmus test for a niching method, therefore, will be whether it possesses the capability to find multiple, final solutions within a reasonable amount of time, and to maintain them for an extended period of time.

2. Beyer et al. (2002) put forward also the actual maintenance of population diversity:
 - *Niching*: process of separation of individuals according to their states in the search space or maintenance of diversity by appropriate techniques, for example, local population models, fitness sharing, or distributed EA.
3. Preuss (2006) considered the two definitions mentioned above, and proposed a third:
 - Niching in EAs is a two-step procedure that (a) concurrently or subsequently distributes individuals onto distinct basins of attraction and (b) facilitates approximation of the corresponding (local) optimizers.

We choose to adopt Preuss' mission statement and define **the challenge in niching as follows:**

- **Attaining the optimal interplay between partitioning the search space into niches occupied by stable subpopulations, by means of population diversity preservation, to exploiting the search in each niche by means of a highly efficient optimizer with local-search capabilities.**

Next, we shall provide an overview of existing niching techniques. Special attention will be given to a specific niching method which is based on a state-of-the-art evolution strategy, the so-called covariance matrix adaptation ES (CMA-ES). The latter is considered to be particularly efficient for high-dimensional continuous optimization, and will be described in greater detail.

4.1 GA Niching Methods

Niching methods within genetic algorithms have been studied during the past few decades, initially triggered by the necessity to promote *population diversity* within EAs. The research has yielded a variety of different methods, which are the vast majority of existing work on niching in general.

The remainder of this section will focus on GA niching techniques, by providing a short survey of the main known methods, with emphasis on the important concepts of *sharing* and *crowding*. This survey is mainly based on Mahfoud (1995a) and Singh and Deb (2006).

4.1.1 Fitness Sharing

The *sharing* concept was one of the pioneering niching approaches. It was first introduced by Holland (1975), and later implemented as a niching technique by Goldberg and Richardson (1987). This strong approach of **considering the fitness as a shared resource** has essentially become an important concept in the broad field of evolutionary algorithms, and laid the foundation for various successful niching techniques for multimodal function optimization, mainly within GAs. A short description of the *fitness sharing* mechanism follows.

The basic idea of *fitness sharing* is to consider the fitness of the landscape as a resource to be shared among the individuals, in order to decrease redundancy in the population. Given a similarity metric of the population, which can be *genotypic* or *phenotypic*, the *sharing function* is defined as follows:

$$sh(d_{i,j}) = \begin{cases} 1 - \left(\frac{d_{i,j}}{\rho}\right)^{\alpha_{sh}} & \text{if } d_{i,j} < \rho \\ 0 & \text{otherwise} \end{cases} \quad (4)$$

where $d_{i,j}$ is the distance between individuals i and j , ρ (traditionally noted as σ_{sh}) is the fixed radius of every niche, and $\alpha_{sh} \geq 1$ is a control parameter, typically set to 1. Using the *sharing function*, the *niche count* is given by

$$m_i = \sum_{j=1}^N sh(d_{i,j}) \quad (5)$$

where N is the number of individuals to be considered in the selection phase.

Let an individual raw fitness be denoted by f_i , then the *shared fitness* is defined by:

$$f_i^{sh} = \frac{f_i}{m_i} \quad (6)$$

assuming that the fitness is *strictly positive* and subject to *maximization*. The evaluation of the shared fitness is followed by the selection phase, which is typically based on the RWS operator (Goldberg 1989); The latter takes into consideration the shared fitness. Thus, the *sharing mechanism* practically penalizes individuals that have similar members within the population via their fitness, and by that it aims at reducing redundancy in the gene pool, especially around the peaks of the fitness landscape.

One important auxiliary component of this approach is the *niche radius*, ρ . Essentially, this approach makes a strong assumption concerning the fitness landscape, stating that the optima are far enough from one another with respect to the *niche radius*, which is estimated for the given problem and remains fixed during the course of evolution. Furthermore, it is important to note that the formulas for determining the value of ρ , which will be given in [Sect. 4.3](#), are dependent on q , the number of peaks of the target function. Hence, a second assumption is that q can be estimated. In practice, an accurate estimation of the expected number of peaks q in a given domain may turn out to be extremely difficult. Moreover, peaks may vary in shape, and this would make the task of determining ρ rather complicated. The aforementioned assumptions pose the so-called *niche radius problem*, to be discussed in [Sect. 6](#).

In the literature, several GA niching *sharing-based* techniques, which implement and extend the basic concept of sharing, can be found (Mahfoud 1995a; Goldberg 1987; Yin and Germany 1993; Jelasity 1998; Miller and Shaw 1996; Petrowski 1996; Cioppa et al. 2004). Furthermore, the concept of sharing was successfully extended to other “yields of interest,” such as *concept sharing* (Avigad et al. 2004).

4.1.2 Dynamic Fitness Sharing

In order to improve the *sharing mechanism*, a dynamic approach was proposed. The *dynamic niche sharing* method (Miller and Shaw 1996), which extended the *fitness sharing* technique, aimed at dynamically recognizing the q peaks of the forming niches, and based on that information, classified the individuals as either members of one of the niches, or as members of the “non-peaks domain.”

Explicitly, let us introduce the *dynamic niche count*:

$$m_i^{\text{dyn}} = \begin{cases} n_j & \text{if individual } i \text{ is within dynamic niche } j \\ m_i & \text{otherwise (non-peak individual)} \end{cases} \quad (7)$$

where n_j is the size of the j th dynamic niche (i.e., the number of individuals which were classified to niche j), and m_i is the standard *niche count*, as defined in [Eq. 5](#).

The shared fitness is then defined as follows:

$$f_i^{\text{dyn}} = \frac{f_i}{m_i^{\text{dyn}}} \quad (8)$$

The identification of the dynamic niches can be carried out by means of a *greedy* approach, as proposed in Miller and Shaw (1996) as the dynamic peak identification (DPI) algorithm (see [Algorithm 1](#)). As in the original *fitness sharing* technique, the *shared fitness evaluation* is followed by the selection phase, typically implemented with the RWS operator. Thus, this technique does not fixate the peak individuals, but rather provides them with an advantage in the selection phase, which is probability-based within GAs.

4.1.3 Clearing

Another variation to the *fitness sharing* technique, called *clearing*, was introduced by Petrowski (1996) at the same time as the *dynamic fitness sharing* (Miller and Shaw 1996). The essence of this mechanism is the “*winner takes it all*” principle, and its idea is to designate a specific number of individuals per niche, referred to as *winners*, which could enjoy the resources of that niche. This is equivalent to the introduction of a “*death penalty*” to the *losers* of the niche, the individuals of each niche that lose the generational competition to the actual peak individuals. Following a *radius-based* procedure of identifying the winners and losers of each niche in each generation, the winners are assigned with their raw-fitness values, whereas all the other individuals are assigned with zero fitness (*maximization* was assumed). This is called the *clearing phase*. The selection phase, typically based on the RWS operator, considers, *de facto*, only the winners of the different niches. The allowed number of winners per niche, also referred to as the *niche capacity*, is a control parameter that reflects the degree of elitism. In any case, as in the previous techniques, the peak individuals are never fixated, and are subject to the probabilistic selection of the GA. This method was shown to outperform the *fitness sharing* technique on a specific set of low-dimensional test problems (Petrowski 1996).

Algorithm 1 Dynamic Peak Identification

```

 input: population Pop, number of niches q, niche radius ρ
1: Sort Pop in increasing fitness order {minimization}
2: i := 1
3: NumPeaks := 0
4: DPS := ∅ {Set of peak elements in population}
5: while NumPeaks ≠ q and i ≤ popSize do
6:   if Pop[i] is not within sphere of radius ρ around peak in DPS then
7:     DPS := DPS ∪ {Pop[i]}
8:     NumPeaks := NumPeaks + 1
9:   end if
10:  i := i + 1
11: end while
output: DPS

```

4.1.4 Crowding

Crowding was one of the pioneering methods in this field, as introduced by De Jong (1975). It considered, and to some extent generalized, *preselection schemes*, which had been investigated in the doctoral dissertation of Cavicchio (1970). The latter had showed that certain preselection schemes boosted the preservation of population diversity. The *crowding* approach aimed at reducing changes in the population distribution between generations, in order to prevent *premature convergence*, by means of *restricted replacement*. Next, we will describe the method in more detail.

Given the traditional GA, a proportion G of the population is selected in each generation via fitness-proportionate selection to undergo variations (i.e., *crossover* and *mutation*) – out of which a part is chosen to die and to be replaced by the new offspring. Each offspring finds the individuals it replaces by taking a random sample of CF (referred to as **crowding factor**) individuals from the population, and replacing the **most similar individual** from the sample. An appropriate *similarity metric* should be chosen.

The crucial point of this niching mechanism is the calculation of the so-called *crowding distance between parents and offspring*, in order to control the *change rate* between generations. A different use of the *crowding distance*, applied among individuals of the same generation and assigned with reversed ranking, is widely encountered in the context of evolutionary multiobjective optimization (EMOA) (Deb 2001; Coello Coello et al. 2007). In the joint context of niching and EMOA see also Deb’s “omni-optimizer” (Deb and Tiwari 2005).

Mahfoud, who analyzed the *crowding* niching technique (1995a), concluded that it was subject to disruptive effects, mainly *drift*, which prevented it from maintaining more than two peaks. He then proposed a mechanism called *deterministic crowding*, as an improvement to the original *crowding* scheme. The proposed procedure applies variation operators to pairs of individuals in order to generate their offspring, which are all then evaluated with respect to the crowding distance, and undergo *replacement selection* (see  [Algorithm 2](#), which assumes *maximization*).

4.1.5 Clustering

The application of *clustering* for niching is very intuitive from the computational perspective, as well as straightforward in its implementation. Yin et al. (1993) proposed a clustering

Algorithm 2 Deterministic Crowding: Replacement Selection (*maximization*)

- 1: Select two parents, p_1 and p_2 , randomly, without replacement
- 2: Generate two variations, c_1 and c_2
- 3: **if** $d(p_1, c_1) + d(p_2, c_2) \leq d(p_1, c_2) + d(p_2, c_1)$ **then**
- 4: **if** $f(c_1) > f(p_1)$ **then** replace p_1 with c_1
- 5: **if** $f(c_2) > f(p_2)$ **then** replace p_2 with c_2
- 6: **else**
- 7: **if** $f(c_2) > f(p_1)$ **then** replace p_1 with c_2
- 8: **if** $f(c_1) > f(p_2)$ **then** replace p_2 with c_1
- 9: **end if**

framework for niching with GAs, which we describe here briefly. A clustering algorithm, such as the *K-Means* algorithm (Haykin 1999), first partitions the population into niches, and then considers the *centroids*, or center points of mass, of the newly partitioned subpopulations.

Let d_{ic} denote the distance between individual i and its *centroid*, and let f_i denote the raw fitness of individual i . Assuming that there are n_c individuals in the niche of individual i , its fitness is defined as:

$$f_i^{\text{Clustering}} = \frac{f_i}{n_c \cdot (1 - (d_{ic}/2d_{\max})^\alpha)} \quad (9)$$

where d_{\max} is the maximal distance allowed between an individual and its niche centroid, and α is a defining parameter. It should be noted that the clustering algorithm uses an additional parameter, d_{\min} , for determining the minimal distance allowed between centroids, playing an equivalent role to the *niche radius* ρ of the *sharing*-based schemes.

This method is often subject to criticism for its strong dependency on a relatively large number of parameters. However, this *clustering* technique has become a popular kernel for niching with EAs, and its application was reported in various studies (see, e.g., Schönemann et al. 2004, Hanagandi and Nikolaou 1998, Branke 2001, Gan and Warwick 2001, Aichholzer et al. 2000, Streichert et al. 2003, and Ando et al. 2005).

4.1.6 The Sequential Niche Technique

A straightforward approach of *iteration* can be used to sequentially locate multiple peaks in the landscape, by means of an *iterative local search* (Ramalhinho-Lourenco et al. 2000). This procedure is blind to any information gathered in previous searches, and sequentially restarts stochastic search processes, hoping to hit a different peak every run. Obviously, it is likely to encounter *redundancy*, and the number of expected iterations is then increased by a factor. A **redundancy factor** can be estimated if the peaks are of equal height (equi-fitness landscape), that is, the probability to converge into any of the q peaks is equal to $1/q$:

$$R = \sum_{i=1}^q \frac{1}{i}$$

For $q > 3$, this can be approximated by:

$$R \approx \gamma + \ln(q) \quad (10)$$

where $\gamma \approx 0.577$ is the Euler–Mascheroni constant. This *redundancy factor* remains reasonably low for any practical value of q , but is expected to considerably increase if all optima are not likely to be found equal.

On a related note, we would like to mention a multirestart with an increasing population size approach, that was developed with the CMA-ES algorithm (Auger and Hansen 2005a). The latter aims at attaining the global minimum, while possibly visiting local minima along the process and restarting the algorithm with a larger population size and a modified initial step-size. It is not defined as a niching technique and does not target optima other than the global minimum, but it can capture suboptimal minima during its search.

Beasley et al. extended the naive *iteration* approach, and developed the so-called *Sequential Niche* technique (Beasley et al. 1993). This method, in contrast to the other niching methods presented earlier, does not modify the genetic operators nor any characteristics of the

traditional GA, but rather creates a general search framework suitable for locating multiple solutions. By means of this method the search process turns into a sequence of independent runs of the traditional GA, where the basic idea is to suppress the fitness function at the observed optimum that was obtained in each run, in order to prevent the search from revisiting that optimum.

In further detail, the traditional GA is run multiple times sequentially: given the best solution of each run, it is first stored as a possible final solution and, second, the fitness function is artificially suppressed in all the points within the neighborhood of that optimum up to a desired radius. This modification is done immediately after each run. Its purpose is to discourage the following runs from revisiting these optima, and by that to encourage the exploration of other areas of the search landscape – aiming at obtaining all its optima. It should be noted that each function modification might yield artificial discontinuities in the fitness landscape. This method focuses only on locating multiple optima of the given search problem, without considering the concepts of parallel evolution and formation of subpopulations. In that sense, it has been claimed that it could not be considered as a niching method, but rather as a modified iterated search.

4.1.7 The Islands Model

This is probably the most intuitive niching approach from the biological perspective, directly inspired by organic evolution. Also referred to as the *regional population model*, this approach (see, e.g., Grosso 1985; Adamidis 1994; Martin et al. 1997) simulates the evolution of subpopulations on remote computational units (independent processors), aiming at achieving a speciation effect by **monitoring the gene flow**. The population is divided into multiple subpopulations, which evolve independently for a fixed number of generations, called *isolation period*. This is followed by a phase of controlled gene flow, or *migration*, when a portion of each subpopulation migrates to other nodes.

The genetic diversity and the amount of information exchange between subpopulations are determined by the following parameters – the number of exchanged individuals, the *migration rate*, the selection method of the individuals for migration (uniformly at random, or elitist fitness-based approach), and the scheme of migration, for example, complete net topology, ring topology, or neighborhood topology.

4.1.8 Other GA-Based Methods

Tagging (see, e.g., Spears 1994 and Deb and Spears 1997) is a mechanism that aims at improving the distance-based methods of *fitness sharing* and *crowding*, by labeling individuals with tag-bits. Rather than carrying out distance calculations, the tag-bits are employed for identifying the subpopulations, enforcing *mating restrictions*, and then implementing the *fitness sharing* mechanism. An individual is classified to a subpopulation by its genetic inheritance, so to speak, which is subject to generational variations, rather than by its actual spatial state. This concept simplifies the classification process, and obviously reduces the computational costs per generation, and at the same time it introduces a new bio-inspired approach into niching: individuals belong to a species because their parents did, and not because they are currently adjacent to a “peak individual,” for instance. This technique was shown in Spears (1994) to be a rather efficient implementation of the *sharing* concept.

A complex subpopulation differentiation model, the so-called **multinational evolutionary algorithm**, was presented by Ursem (1999). This original technique considers a world of “nations,” “governments,” and “politicians,” with dynamics dictated by migration of individuals, merging of subpopulations, and selection. Additionally, it introduces a topology-based auxiliary mechanism of *sampling*, which detects whether feasible solutions share the same basin of attraction. Due to the *curse of dimensionality*, this sampling-based mechanism is expected to lose its efficiency in high-dimensional landscapes.

Stoean et al. (2005) constructed the so-called **elitist generational genetic chromodynamics algorithm**. The idea behind this radius-based technique was the definition of a *mating region*, a *replacement region*, and a *merging region* — with appropriate mating, replacement, and merging radii — which dictates the dynamics of the genetic operations.

4.1.9 Miscellaneous: Mating Schemes

It has been observed that once the niche formation process starts, that is, when the population converges into the multiple basins of the landscape, crossbreeding between different niches is likely to fail in producing good offspring. In biological terms, this is the elimination of the divergence, by means of *hybridization*, in the **secondary contact phase**, as discussed in [Sect. 2.2](#).

Deb and Goldberg (1989) proposed a so-called *mating restriction scheme*, which poses a limitation on the choice of partners in the reproduction phase and prevents recombination between competing niches. They employed a distance measure, subject to a distance threshold, which was set to the niche radius, and showed that it could be used to improve the *fitness sharing* algorithm.

Mahfoud (1995a) proved that the mating restriction scheme of Deb and Goldberg was not sufficient, *per se*, in maintaining the population diversity in GA niching. A different approach of Smith and Bonacina (2003), however, considered an evolutionary computation multi-agent system, as opposed to the traditional *centralized EA*, and did manage to show that the same mating restriction scheme in an agent-based framework was capable of maintaining diversity and converging with stability into the desired peaks.

From the biological perspective, the mating restriction scheme is obviously equivalent to keeping the geographical isolation, or the barrier to gene flow, in order to allow the completion of the speciation phase. As discussed earlier, the geographical element in organic evolution is the crucial component which creates the conditions for speciation, and it is not surprising that artificial niching techniques choose to enforce it, by means of mechanisms such as the niche radius or the mating restriction scheme.

4.2 ES Niching Methods

Researchers in the field of evolution strategies initially showed no particular interest in the topic of niching, leaving it essentially for genetic algorithms. An exception would be the employment of island models. Generally speaking, classical niching schemes such as *fitness sharing*, which redefine the selection mechanism, are likely to interfere with the core of evolution strategies – the *self-adaptation mechanism* – and thus doomed to fail in a straightforward implementation. Any manipulation of the fitness value is usually not suitable for evolution strategies, as in the case of constraints handling: death penalty is typically the chosen

approach for a violation of a constraint in ES, rather than a continuous penalty as used in other EAs, in order to avoid the introduction of disruptive effects to the self-adaptation mechanism (see, e.g., Coello Coello 1999; Kramer and Schwefel 2006). Therefore, niching with evolution strategies would have to be addressed from a different direction. Moreover, the different nature of the ES dynamics, throughout the *deterministic selection* and the *mutation operator*, suggests that an alternative treatment is required here.

There are several, relatively new, niching methods that have been proposed within ES, mostly clustering-based (Schönemann et al. 2004; Aichholzer et al. 2000; Streichert et al. 2003). In addition, niching was also introduced to the mixed-integer ES framework (Li et al. 2008). A different approach, based on derandomized evolution strategies (DES) (for the latter see, e.g., Ostermeier et al. (1993, 1994) and Hansen et al. (1995)), was presented by Shir and Bäck (2008). One of its variants, which employs the popular covariance matrix adaptation evolution strategy (CMA-ES), will receive special attention here, and will be set as a detailed case study of niching techniques, to be outlined in the following section.

4.2.1 Case Study: Niching with CMA-ES

A niching framework for $(1 + \lambda)$, derandomized ES (DES) kernels subject to a fixed niche radius has been introduced recently (see, e.g., Shir and Bäck 2008). Following the *mission statement* presented earlier, the aim was the construction of a generic niching framework, which offers the combination of population diversity preservation and local search capabilities. Thus, DES were considered as an excellent choice for that purpose, as EAs with local search characteristics. Furthermore, DES typically employ small populations, which was shown to be a potential advantage for a niching technique, as it can boost the speciation effect (Shir 2008).

The Covariance Matrix Adaptation Evolution Strategy (CMA-ES)

The CMA-ES (Hansen and Ostermeier 2001), is a DES variant that has been successful in treating correlations among object variables by efficiently learning matching mutation distributions. Explicitly, given an initial search point $\mathbf{x}^{(0)}$, λ offspring are generated by means of normally distributed variations:

$$\mathbf{x}^{(g+1)} \sim \mathcal{N}\left(\langle \mathbf{x} \rangle_W^{(g)}, \sigma^{(g)^2} \mathbf{C}^{(g)}\right) \quad (11)$$

Here, $\mathcal{N}(\mathbf{m}, \mathbf{C})$ denotes a normally distributed random vector with mean \mathbf{m} and a covariance matrix \mathbf{C} . The best μ search points out of these λ offspring undergo weighted recombination and become the parent of the next generation, denoted by $\langle \mathbf{x} \rangle_W$. The covariance matrix \mathbf{C} is initialized as the *unity matrix* and is learned during the course of evolution, based on cumulative information of successful past mutations (the *evolution path*). The global step-size, $\sigma^{(g)}$, is updated based on information extracted from *principal component analysis* of $\mathbf{C}^{(g)}$ (the *conjugate evolution path*). For more details, we refer the reader to Hansen and Ostermeier (2001).

An elitist sibling to the CMA comma strategy was also introduced (Igel et al. 2006), based upon the classical $(1+1)$ -ES (Bäck 1996).

A Detailed Description of the Algorithm

This niching technique is based upon interacting search processes, which simultaneously perform a derandomized $(1, \lambda)$ or $(1 + \lambda)$ search in different locations of the space. In case of

multimodal landscapes these search processes are meant to explore different attractor basins of local optima.

An important point in this approach is to strictly enforce the fixed allocation of the population resources, that is, number of offspring per niche. The idea is thus to prevent a scenario of a take-over, where a subpopulation located at a fitter optimum can generate more offspring. The biological idea behind this fixed allocation of resources stems from the concept of limited *hosting capacities* of given ecological niches, as previously discussed.

The *speciation interaction* occurs every generation when all the offspring are considered together to become niches' representatives for the following iteration, or simply the next search points, based on the rank of their fitness and their location with respect to higher-ranked individuals. The focus here is on a simple framework without recombination ($\mu = 1$).

Given q , the estimated/expected number of peaks, $q + p$ "D-sets" are initialized, where a D-set is defined as the collection of all the dynamically adapted strategy as well as decision parameters of the CMA algorithm, which uniquely define the search at a given point of time. (A D-set originally referred to the *derandomized* set of strategy parameters. When the CMA kernel is in use, it is sometimes referred to in the literature as a CMA-set.) These parameters are the current search point, the covariance matrix, the step-size, as well as other auxiliary parameters. At every point in time the algorithm stores exactly $q + p$ D-sets, which are associated with $q + p$ search points: q for the peaks and p for the "non-peaks domain." The $(q+1)th \dots (q+p)th$ D-sets are associated with individuals, which are randomly re-generated every *epoch*, that is, a cycle of κ generations, as potential candidates for niche formation. This is basically a *quasi-restart* mechanism, which allows new niches to form dynamically. Setting the value of p should reflect the trade-off between applying a wide restart approach for exploring further the search space to exploiting computational resources for the existing niches. In any case, due to the *curse of dimensionality*, p loses its significance as the dimension of the search space increases.

Until the stopping criterion is met, the following procedure takes place. Each search point samples λ offspring, based on its evolving D-set. After the fitness evaluation of the new $\lambda \cdot (q + p)$ individuals, the classification into niches of the entire population is obtained in a *greedy* fashion, by means of the DPI routine (Miller and Shaw 1996) (Algorithm 1). The latter is based on the fixed niche radius ρ . The peaks then become the new search points, while their D-sets are inherited from their parents and updated according to the CMA defining equations.

A pseudocode for a single iteration in this *niching routine* is presented as Algorithm 3.

Natural Interpretation: Alpha-Males Competition

We would like to point out the nature of the subpopulations dynamics in the aforementioned niching scheme. Due to the *greedy* classification to niches, which is carried out every generation, some niches can merge in principle, while all the individuals, except for the *peak individual*, die out in practice. Following the posed principle of fixed resources per niche, only the peak individual will be sampled λ times in the following generation. In socio-biological terms, the peak individual could be then associated with an **alpha-male**, which wins the local competition and gets all the sexual resources of its ecological niche. The algorithm as a whole can be thus considered as a competition between $q + p$ alpha-males, each of which is fighting for one of the available q "computational resources," after winning its local competition at the "ecological optimum" site. The domination battles take place locally every cycle, as dictated by the DPI scheme. An elitist-CMA kernel will allow aging alpha-males to keep participating in the ongoing competitions, whereas a comma strategy will force their replacement by fresh

Algorithm 3 $(1+\lambda)$ -CMA-ES Niching with Fixed Niche Radius (A Single Iteration)

```

1: for  $i = 1 \dots (q + p)$  search points do
2:   Generate  $\lambda$  samples based on the D-set of  $i$ 
3: end for
4: Evaluate fitness of the population
5: Compute the Dynamic Peak Set with the DPI Algorithm
6: for all elements of  $DPS$  do
7:   Set peak as a search point
8:   Inherit the D-set and update it respectively
9: end for
10: if  $N_{DPS}$ =size of  $DPS < q$  then
11:   Generate  $q - N_{DPS}$  new search points, reset D-sets
12: end if
13: if  $gen \bmod \kappa \equiv 0$  then
14:   Reset the  $(q + 1)th \dots (q + p)th$  search points
15: end if

```

blood of new alpha-males. At the global level, the value of p determines the selection pressure of alpha-males; setting $p = 0$ will then eliminate global competition and will grant automatically λ offspring to each alpha-male in the following generation, respectively.

4.3 Niche-Radius Calculation

The original formula for ρ for *phenotypic sharing* in GAs was derived by Deb and Goldberg (1989). Analogously, by considering the decision parameters as the decoded parameter space of the GA, the same formula can be applied, using the Euclidean metric, to ES. Given q , the number of target peaks in the solution space, every niche is considered to be surrounded by an n -dimensional hypersphere with radius ρ , which occupies $\frac{1}{q}$ of the entire volume of the space. The volume of the hypersphere which contains the entire space is

$$V = cr^n \quad (12)$$

where c is a constant, given explicitly by:

$$c = \frac{\pi^{\frac{n}{2}}}{\Gamma(\frac{n}{2} + 1)} \quad (13)$$

with $\Gamma(n)$ as the Gamma function. Given lower and upper bound values $x_{k,\min}$, $x_{k,\max}$ of each coordinate in the decision parameters space, r is defined as follows:

$$r = \frac{1}{2} \sqrt{\sum_{k=1}^n (x_{k,\max} - x_{k,\min})^2} \quad (14)$$

If we divide the volume into q parts, we may write

$$c\rho^n = \frac{1}{q} cr^n \quad (15)$$

which yields

$$\rho = \frac{r}{\sqrt[n]{q}} \quad (16)$$

Hence, by applying this niche radius approach, two assumptions are made:

1. The number of target peaks, q , is given or can be estimated.
2. All peaks are at least at distance 2ρ from each other, where ρ is the fixed radius of every niche.

5 Experimental Methodology

Since the topic of niching has not drawn considerable attention from the mainstream EC community, there have been no constructive attempts to generate a generalized experimental framework, for testing niching methods to be agreed upon. This section will focus on that, and propose an experimental methodology for EA niching algorithms. It will present a suite of synthetic test functions, discuss possible performance criteria, and conclude by revisiting the niching-CMA algorithm and some of its experimental observations.

In the broad context of function optimization, EA niching techniques are obviously within the general framework of stochastic algorithms, and as such should be treated carefully upon reporting their experiments. We recommend following Bartz-Beielstein (2006) when conducting experiments, and especially following the 7-points scheme of Preuss (2007) when reporting them.

5.1 Multimodal Test Functions

The choice of a numerical testbed for evaluating the performance of search or optimization methods is certainly one of the core issues among the scholars in the community of algorithms and operations research.

In a benchmark article, Whitley et al. (1996) criticized the commonly tested artificial landscapes in the evolutionary algorithms community, and offered general guidelines for constructing test problems. A remarkable effort was made almost a decade after that document, when a large group of scholars in the EC community joined their efforts and compiled an agreed test suite of single-objective artificial landscapes (Suganthan et al. 2005), to be tested in an open performance competition reported at the 2005 IEEE Congress on Evolutionary Computation (CEC) (Auger and Hansen 2005b). The latter also included multimodal functions.

The issue of developing a multimodal test suite received even less attention, likely due to historical reasons. Since multimodal domains were mainly treated by GA-based niching methods, their corresponding test suites were limited to low-dimensional continuous landscapes, typically with two decision parameters to be optimized ($n = 2$) (see, e.g., Goldberg and Richardson 1987; Mahfoud 1995a).

When compiling our proposed test suite, we aim at following Whitley's guidelines, and to include some traditional GA-niching test functions as well as functions from the 2005 CEC inventory (Suganthan et al. 2005). Some of the landscapes have symmetric or equal distributions of minima, and some do not. Some of the functions are *separable*, that is, they can be optimized by solving n 1-dimensional problems separately (Whitley et al. 1996), while some of them are non-separable.

Table 1

Test functions to be *minimized* and initialization domains. For some of the non-separable functions, we apply translation and rotation: $\mathbf{y} = \mathcal{O}(\mathbf{x} - \mathbf{r})$ where \mathcal{O} is an orthogonal rotation matrix, and \mathbf{r} is a shifting vector

Separable:			
Name	Function	Init	Niches
\mathcal{M}	$\mathcal{M}(\mathbf{x}) = -\frac{1}{n} \sum_{i=1}^n \sin^\alpha(5\pi x_i)$	$[0, 1]^n$	100
\mathcal{A} [Ackley]	$\mathcal{A}(\mathbf{x}) = -c_1 \cdot \exp\left(-c_2 \sqrt{\frac{1}{n} \sum_{i=1}^n x_i^2}\right) \\ - \exp\left(\frac{1}{n} \sum_{i=1}^n \cos(c_3 x_i)\right) + c_1 + e$	$[-10, 10]^n$	$2n+1$
\mathcal{L}	$\mathcal{L}(\mathbf{x}) = -\prod_{i=1}^n \sin^k(l_1 \pi x_i + l_2) \cdot \exp\left(-l_3 \left(\frac{x_j - l_4}{l_5}\right)^2\right)$	$[0, 1]^n$	$n+1$

We propose for consideration a set of multimodal test functions, as indicated in [Table 1](#). The table summarizes the proposed unconstrained multimodal test functions as well as their initialization intervals and the number of target niches. Next, we provide the reader with an elaborate description of the test functions, corresponding to the notation of [Table 1](#):

- \mathcal{M} is a basic hypergrid multimodal function with uniformly distributed minima of equal function value of -1 . It is meant to test the stability of a particularly large number of niches: in the interval $[0, 1]^n$ it has 5^n minima. We set $\alpha = 6$.
- The well-known Ackley function has one global minimum, regardless of its dimension n , which is surrounded isotropically by $2n$ local minima in the first hypersphere, followed by an exponentially increasing number of minima in successive hyperspheres. Ackley's function has been widely investigated in the context of *evolutionary computation* (see, e.g., Bäck [1996](#)). We set $c_1 = 20$, $c_2 = 0.2$, and $c_3 = 2\pi$.

- \mathcal{L} – also known as $F2$, as originally introduced by Goldberg and Richardson (1987) – is a sinusoid trapped in an exponential envelope. The parameter k determines the sharpness of the peaks in the function landscape; We set it to $k = 6$. \mathcal{L} has one global minimum, regardless of n and k . It has been a popular test function for GA niching methods. We set $l_1 = 5.1$, $l_2 = 0.5$, $l_3 = 4 \cdot \ln(2)$, $l_4 = 0.0667$ and $l_5 = 0.64$.
- The Rastrigin function (Törn and Zilinskas 1987) has one global minimum, surrounded by a large number of local minima arranged in a lattice configuration.

We also propose its shifted-rotated variant (Suganthan et al. 2005), with a linear transformation matrix of condition number 2 as the rotation operator.

- The Griewank function (Törn and Zilinskas 1987) has its global minimum ($f^* = 0$) at the origin, with several thousand local minima in the area of interest. There are four suboptimal minima $f \approx 0.0074$ with $\mathbf{x}^* \approx (\pm\pi, \pm\pi\sqrt{2}, 0, 0, 0, \dots, 0)$.

We also propose its shifted-rotated variant (Suganthan et al. 2005), with a linear transformation matrix of condition number 3 as the rotation operator.

- The Vincent function is a sine function with a decreasing frequency. It has 6^n global minima in the interval $[0.25, 10]^n$.
- The Shekel function, suggested by Törn and Zilinskas (1987), introduces a landscape with a dramatically uneven spread of minima. It has one global minimum, and seven ordered local minima.
- The function after Fletcher and Powell (Bäck 1996) is a non-separable *nonlinear parameter estimation problem*, which has a nonuniform distribution of 2^n minima. It has non-isotropic attractor basins.

5.2 Performance Criteria

The performance criteria of niching methods include numerous possible attractive options and, generally speaking, vary in different experimental reports. The common ground is typically the examination of the population in its final stage, while aiming to observe the algorithm's ability to capture as well as *Maintain* peaks of high-quality. Stability of good niches is thus considered as one of the implicit criteria.

Studies of traditional GA niching methods had been strongly interested in the distribution of the final population compared to a goal-distribution, as formalized by Mahfoud (1995a). While Mahfoud's formalism introduced a generic theoretical tool, being derived from information theory, other studies considered, *de facto*, specific performance calculations. For example, a very popular niching performance measurement, which satisfies Mahfoud formalism's criteria, is the *Chi-square-like performance statistic* (see, e.g., Deb and Goldberg 1989). The latter estimates the deviation of the actual distribution of individuals N_i from an ideal distribution (characterized by mean μ_i and variance σ_i^2) in all the $i = 1 \dots q + 1$ subspaces (q peak subspaces and the non-peak subspace):

$$\chi^2 = \sqrt{\sum_{i=1}^{q+1} \left(\frac{N_i - \mu_i}{\sigma_i} \right)^2} \quad (17)$$

where the ideal-distribution characteristic values are derived per function.

Most of the existing studies have focused on the ability to identify global as well as local optima, and to converge in these directions through time, with no particular interest in the

distribution of the population. One possible performance criterion is often defined as the *success-rate* of the niching process, which refers to the percentage of optima attained by the end of the run with respect to the target peaks, as defined *a priori*. Furthermore, as has been employed in earlier studies of GA niching (Miller and Shaw 1996), another performance criterion is called the *maximum peak ratio* (MPR) statistic. This metric measures the quality as well as the number of optima given as a final result by the evolutionary algorithm. Explicitly, assuming a *minimization problem*, given the fitness values of the subpopulations in the final population $\{\tilde{f}_i\}_{i=1}^q$, and the fitness values of the real optima of the objective function $\{\hat{\mathcal{F}}_i\}_{i=1}^q$, the *maximum peak ratio* is defined as follows:

$$\text{MPR} = \frac{\sum_{i=1}^q \hat{\mathcal{F}}_i}{\sum_{i=1}^q \tilde{f}_i} \quad (18)$$

where all values are assumed to be *strictly positive*. If this is not the case in the original parametrization of the landscape, the latter should be scaled accordingly with an additive constant for the sake of this calculation. Also, given a maximization problem, the MPR is defined as the sum of the obtained optima divided by the sum of the real optima. A drawback of this performance metric is that the real optima need to be known *a priori*. However, for many artificial test problems these can be derived analytically, or tight numerical approximations to them are available. We adopt the MPR performance criterion and recommend it for reporting experimental results of EA niching techniques.

5.2.1 Another Perspective: MPR Versus Time

Although the MPR metric was originally derived to be analyzed by means of its saturation value in order to examine the niches' stability, a new perspective was introduced by Shir and Bäck (2005a). That study investigated the MPR as a function of time, focusing on the early stages of the run, in addition to the saturation value. It was shown experimentally that the time-dependent MPR data fits a theoretical function, the *logistic curve*:

$$y(t) = \frac{a}{1 + \exp\{c(t - T)\}} \quad (19)$$

where a is the saturation value of the curve, T is its time shift, and c (in this context always negative) determines the shape of the exponential rise. This equation, known as the *logistic equation*, describes many processes in nature. All those processes share the same pattern of behavior: growth with *acceleration*, followed by *deceleration* and then a *saturation* phase. In the context of evolutionary niching methods, it was argued (Shir and Bäck 2005a) that the logistic parameters should be interpreted in the following way: T as the *learning period* of the algorithm, and the absolute value of c as its *niching formation acceleration*. a is clearly the MPR saturation value.

5.3 Experimental Observation Examples: Niching-CMA Revisited

We revisit the niching-CMA algorithm with three examples of experimental observations.

5.3.1 MPR Time-Dependent Analysis: Reported Observations

The MPR time-dependent analysis was applied in Shir and Bäck (2005a) to two ES-based niching techniques: niching with the CMA-ES and niching with the Standard-ES according to the Schwefel-approach (Shir and Bäck 2005b). In short, the latter method applies the same niching framework as the niching-CMA (Sect. 4.2.1) except for one conceptual difference: It employs a (μ, λ) strategy in each niche, subject to *restricted mating*. Otherwise, it applies the standard ES operators (Bäck 1996).

We outline some of the conclusions of that study:

1. The **niching formation acceleration**, expressed as the absolute value of c , had larger values for the CMA-ES kernel for all the observed test cases. That implied stronger niching acceleration and faster convergence.
2. A trend concerning the absolute value of c as a function of the dimensionality was observed: The higher the dimensionality of the search space, the lower the absolute value of c , that is, the slower the niching process.
3. The **learning period**, expressed as the value of T in the curve fitting, has negative as well as positive values. Negative values mean that the niches' formation process, expressed as the exponential rise of the MPR, started immediately from generation zero.
4. The averaged **saturation value a** , that is, the MPR saturation value, was larger in all of the test cases for the CMA-ES mechanism. In that respect, the CMA kernel outperformed the standard-ES on the tested landscapes.

That study concluded with the claim that there was a clear *trade-off*. Either a long learning period followed by a high niching acceleration (CMA-ES), or a short learning period followed by a low niching acceleration (Standard-ES). A hypothesis concerning the existence of a general trade-off between the learning period T and the niching acceleration, c , was numerically assessed in a following study (Shir and Bäck 2008). It was shown that this trade-off stands for various DES niching variants on two synthetic landscapes (one separable, one non-separable) in a large spectrum of search space dimensions.

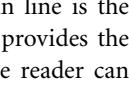

5.3.2 Performance on the Synthetic Multimodal Test-Suite

The proposed CMA-ES niching framework has been successfully applied to a suite of synthetic multimodal *high-dimensional* continuous landscapes, as reported by Shir and Bäck (2008), which in principle followed the recommended test functions proposed earlier in this chapter. That study addressed various *research questions* concerning the generalized DES niching framework, such as *which DES variant captures and maintains most desired optima* (i.e., best saturation MPR values), *what are the differences in the niching formation acceleration among the DES variants*, and others. The CMA-ES kernels were observed to perform very well among the DES variants, with the (1+10) kernel performing best, while typically obtaining most of the desired basins of attraction of the various landscapes at different dimensions. Furthermore, upon carrying out behavioral analysis of the simulations, e.g., MPR analysis, some characteristic patterns for the different algorithmic kernels were revealed. For instance, it was observed that the elitist-CMA has consistently the lowest niching acceleration. A straightforward and rather intuitive explanation for the excellent behavior of the elitist-CMA variant would be its tendency to maintain convergence in any basin of attraction, versus a higher

probability for the comma strategy to escape them. Moreover, another argument for the advantage of an elitist strategy for niching was suggested. The niching problem can be considered as an optimization task with constraints, that is, the formation of niches that restricts competing niches and their optimization routines from exploring the search space freely. It has been suggested in previous studies (see, e.g., Kramer and Schwefel 2006) that ES self-adaptation in constrained problems would tend to fail with a comma strategy, and thus an elitist strategy is preferable for such problems.

We choose to omit here specific details concerning the numerical simulations, and refer the reader to Shir and Bäck (2008) and Shir (2008).

5.3.3 Real-World Application: Quantum Control

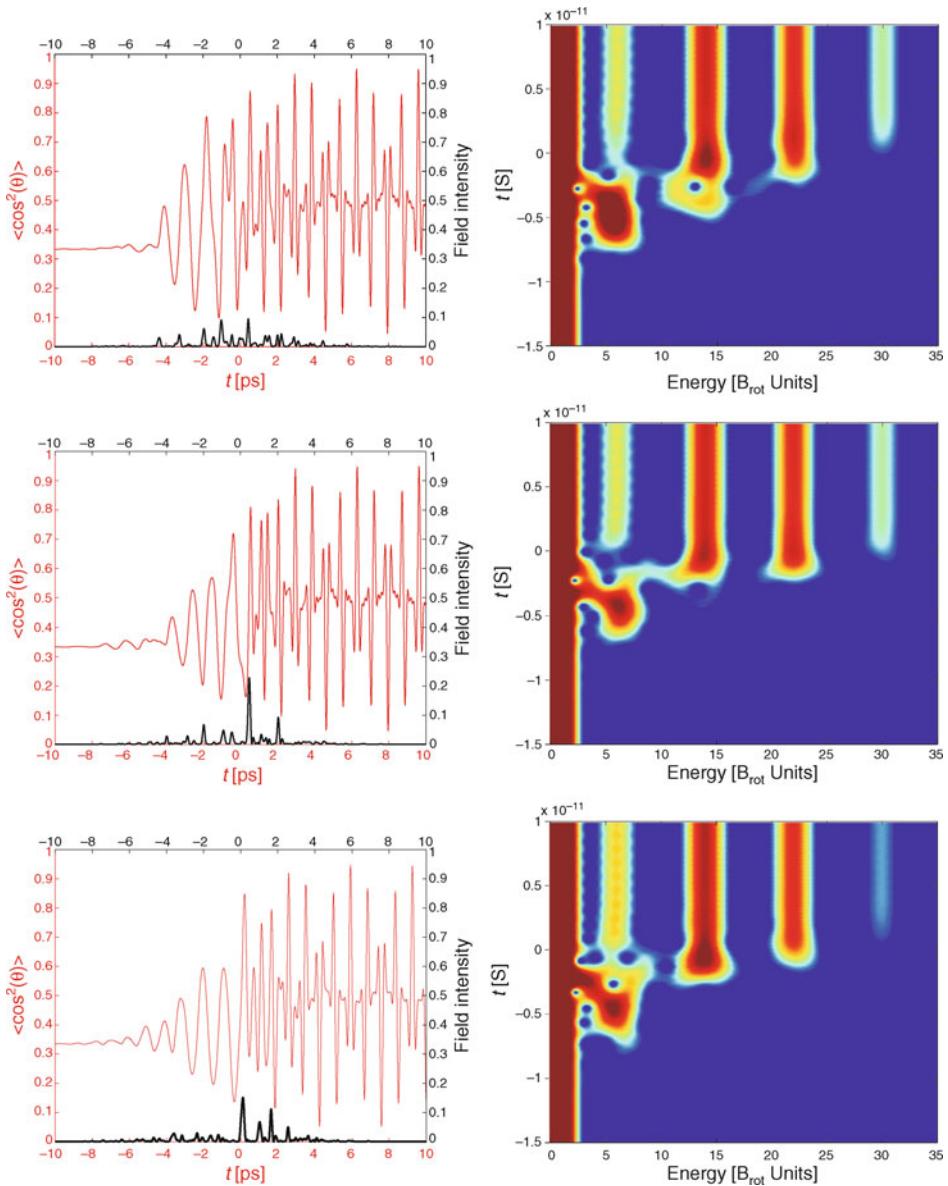

As was, furthermore, reported by Shir and Bäck (2008), the proposed DES niching framework was successfully applied to a real-world landscape from the field of Quantum Control. (Symbolically, this interdisciplinary study forms a *closed natural computing circle*, where biologically oriented investigation of organic evolution and speciation helps to develop methods for solving applications in physics in general, and in quantum control in particular. By our reckoning, this symbolism is even further strengthened upon considering the stochastic nature of evolutionary algorithms. This process can be thus considered as throwing dice in order to solve quantum mechanics, sometimes referred to as the *science of dice*.) Namely, the dynamic molecular alignment problem (for a review see Shir et al. 2008). In short, the goal of this application is the maximization of the alignment of diatomic molecules after the interaction with an electric field arising from a laser source. The black-box noise-free simulator, which is designed in a lab-oriented fashion, provides a reliable physics simulation with a duration of 35 s per trial solution. The 80 object variables constitute a parametrized curve, to be learned, that undergoes spectral transformation for the construction of the electric field. This challenging high-dimensional application required the definition of a tailor-made diversity measure, due to certain invariance properties of the control function that stem from the spectral transformations. The resulting metric employed was the Euclidean distance in the second derivative space of the control function. DES niching variants were shown to perform well, and to obtain different pulse shapes of high quality, representing different conceptual designs. Also in this case, the elitist-CMA kernel was observed to perform best. While referring the reader to Shir and Bäck (2008) and Shir (2008) for more details on this particular study, we would like to conclude with a visualization of the resulting niching process. Three laser-pulse niches, obtained in a typical elitist-CMA run, are plotted for illustration in  Fig. 1 (left column): The thick line describes the attained pulse shape, while the thin line is the molecular reaction, also referred to as the *revival structure*. The right column provides the equivalent quantum pictures, in terms of population of the energy levels: The reader can observe three different modes of quantum energy-level population for the different attained niches.

6 The Niche-Radius Problem

While the motivation and usefulness of niching cast no doubt, the relaxation of assumptions and limitations concerning the hypothetical landscape is much needed if niching methods are

Fig. 1

Experimental results for niching-CMA with a fixed niche-radius on the real-world problem of dynamic molecular alignment (quantum control). *Left column: alignment and revival-structure of the three niches obtained by the (1+10)-CMA. Thin red line: alignment; thick black line: intensity of the laser pulse.* *Right column: Quantum picture of the solutions; a Fourier transform applied to the revival structures of the optimal solutions (the thin red alignment curves).* The values are log scaled, and represent how high the rotational levels of the molecules are populated as a function of time. Note that the quality of the laser pulse cannot be measured in those plots.

to be valid in a broader range of applications. In particular, consider the assumptions made in [Sect. 4.3](#) concerning the fitness landscape, stating that the optima are far enough from one another with respect to the *niche radius*, which is estimated for the given problem and remains fixed during the course of evolution. Most prominently, the niche radius is used in the *sharing function*, which penalizes fitness values of individuals whose distance to other individuals is below that threshold ([Sect. 4.1.1](#)). Obviously, there are landscapes for which this assumption is not applicable, and where this approach is most likely to fail (see [Fig. 2](#) and [3](#) for illustrations). This topic is directly linked to the task of defining a generic basin of attraction, which was discussed in [Sect. 2.3](#).

6.1 Treating the Niche Radius Problem: Existing Work

There were several GA-oriented studies which addressed this so-called *niche radius problem*, aiming to relax the assumption specified earlier, or even to drop it completely. Jelasity (1998) suggested a cooling-based mechanism for the niche-radius, also known as the UEGO, which adapts the global radius as a function of time during the course of evolution. Gan and Warwick (2001) introduced the so-called dynamic niche clustering, to overcome the radius problem by using a clustering mechanism. A complex subpopulation differentiation model, the so-called multinational evolutionary algorithm, was presented by Ursem (1999). It introduces a topology-based auxiliary mechanism of sampling, which detects whether feasible solutions share the same basin of attraction. A recent study by Stoean et al. (2007) considered

Fig. 2

The Shekel function (see, e.g., Törn and Zilinskas 1987) in a 2D decision space: introducing a dramatically uneven spread of optima.

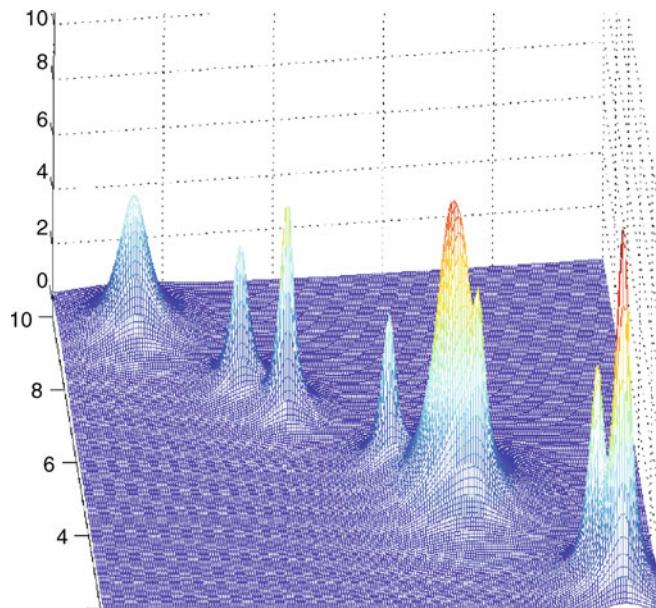

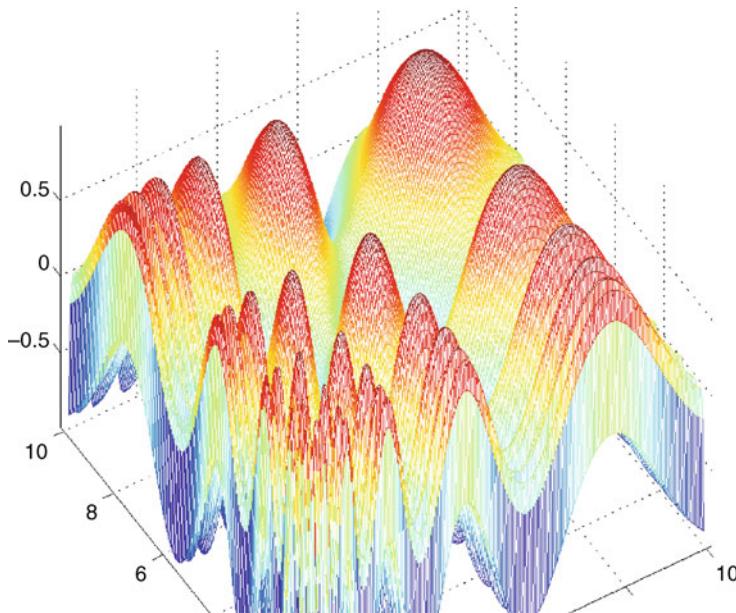

Fig. 3

The Vincent function in a 2D decision space: a sine function with a decreasing frequency.

the hybridization of the latter with a radius-based niching method proposed in Stoean et al. (2005). An iterative statistical-based approach was introduced (Cioppa et al. 2004) for learning the optimal niche radius, without *a priori* knowledge of the landscape. It considers the *fitness sharing* strategy, and optimizes it as a function of the population size and the niche radius, without relaxing the landscape assumption specified earlier – that is, the niches are eventually obtained using a single fixed niche radius. Finally, two ES-based niche-radius adaptation niching algorithms were proposed recently (Shir and Bäck 2006; van der Goes 2008). They both considered individual niche radii for the evolving population members, based upon original learning schemes. While Shir and Bäck (2006) relied on coupling the niche radius to the niche's global step size in combination with a secondary selection scheme, van der Goes et al. (2008) introduced a pure self-adaptive niche-radius approach, independent of any coupling to strategy parameters. The latter considered inner and outer niche counts, and applied the original sharing function for the sake of niches classification. Both approaches were shown to successfully tackle landscapes with challenging distributions as well as shapes of attraction basins.

6.2 Learning Niche Shapes: Exploiting CMA Information

As an extension to the previously discussed niching-CMA case study (Sect. 4.2.1), a self-adaptive niche-shaping approach was derived in a recent study (Shir et al. 2010). The latter introduced the *Mahalanobis distance metric* into the niching mechanism, aiming to allow a

more accurate spatial classification of niches by considering rotatable ellipsoid shapes as classification regions. The shapes of these ellipsoids were obtained from the covariance matrix of the evolving multivariate normal distribution adapted by the CMA mutation scheme, replacing the default classification by means of Euclidean hyperspheres. This approach was implemented in a straightforward manner using the Mahalanobis metric as a replacement for the Euclidean, due to the fact that the former metric, the hyperspheres of which are ellipsoids when viewed in the Euclidean space, is parametrized by a covariance matrix that is obtained without additional cost from the CMA. The proposed approach was tested on high-dimensional artificial landscapes at several levels of difficulty, and was shown to be robust and to achieve satisfying results.  *Figure 4* provides an illustration for the numerical results of this self-adaptive approach. It presents a snapshot gallery of the niching algorithm with the elitist-CMA kernel, employing the Mahalanobis distance, performing on the 2-dimensional Fletcher-Powell landscape.

7 Discussion and Outlook

Niching studies, following somehow various *mission statements*, introduce a large variety of approaches, some of which are more biologically inspired, whereas others are multimodal-optimization oriented. In both cases, those techniques were mainly tested on *low-dimensional synthetic landscapes*, and the application of these methods to real-world landscapes was hardly ever reported to date. We claim that niching methods should be implemented also for attaining multiple solutions in high-dimensional real-world problems, serving decision makers by providing them with the choice of optimal solutions, and representing well evolutionary algorithms in multimodal domains. By our reckoning, the *multimodal front* of real-world applications, that is, multimodal real-world problems, which pose the demand for multiple optimal solutions, should also enjoy the powerful capabilities of evolutionary algorithms, as other fronts do, for example, multi-objective or constrained domains.

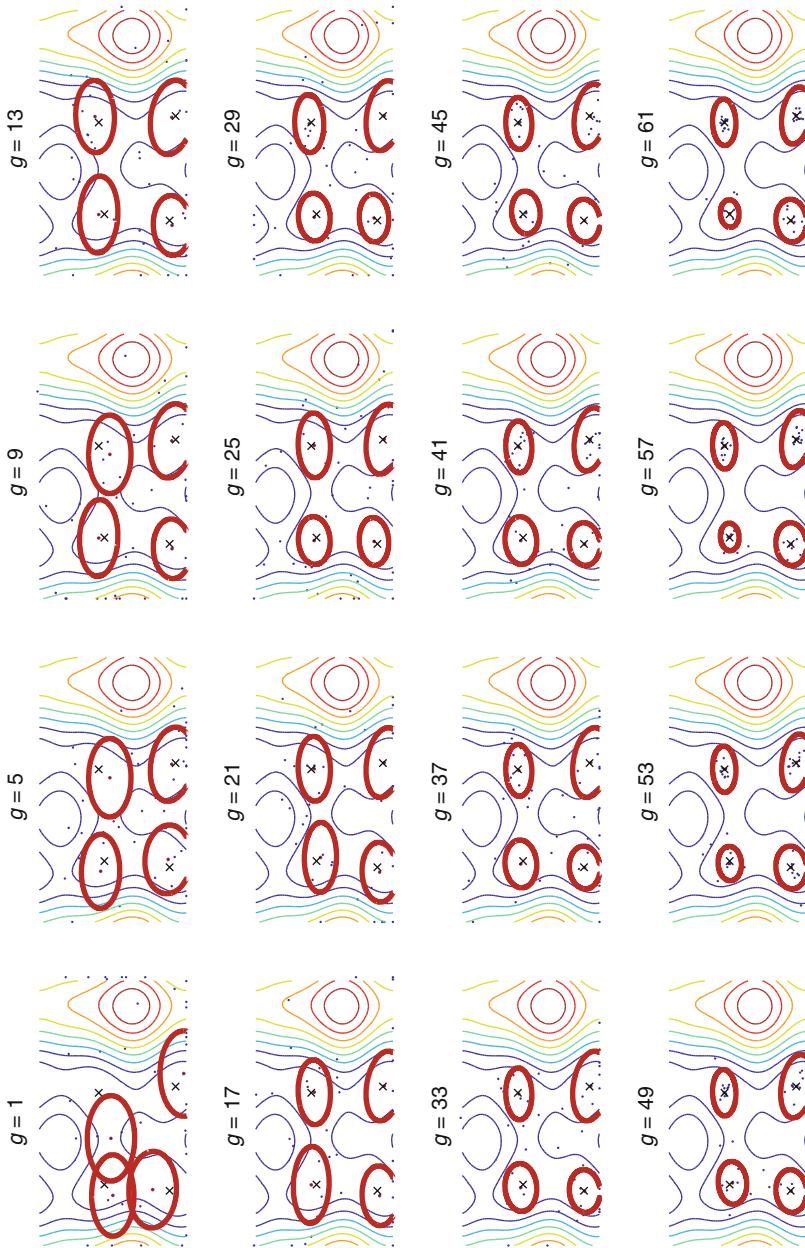

On a different note, Preuss, in an important paper (Preuss 2006), raised the question: “*Under what conditions can niching techniques be faster than iterated local search algorithms?*” Upon considering a simplified model, and assuming the existence of an efficient basin identification method, he managed to show that it does pay off to employ EA niching techniques on landscapes whose basins of attraction vary significantly in size. However, the original question in its general form remained open. Mahfoud (1995b) drew a comparison of *parallel* versus *sequential* niching methods, while considering *fitness sharing*, *deterministic crowding*, *sequential niching*, and *parallel hillclimbing*. Generally speaking, he concluded that parallel niching GAs outperform parallel hillclimbers on a hard set of problems, and that *sequential niching* is always outperformed by the parallel approaches.

Obviously, there is *no free lunch*, and there is no best technique, especially in the domain of multimodal search spaces. In this respect, *local search* capabilities should not be underestimated, and *population diversity preservers* should not be overestimated. We claim that like any other complex component in organic as well as artificial systems, the success of niching is about the subtle interplay between the different, sometime conflicting, driving effects.

In this chapter, we have introduced *niching* as an algorithmic framework following the evolutionary process of *speciation*. Upon providing the practical motivation for such a framework, in terms of conceptual designs for better decision making, we outlined in detail the essential biological background, as well as the computational perspective of multimodal function

Fig. 4

A snapshot gallery: the adaptation of the *classification-ellipses*, subject to the Mahalanobis metric with the updating covariance matrix, in the elitist-CMA strategy for a 2D Fletcher-Powell problem. Images are taken in the box $[-\pi, \pi]^2$. Contours of the landscape are given as the background, where the Xs indicate the real optima, the dots are the evolving individuals, and the ellipses are plotted centered about the peak individual. A snapshot is taken every four generations (i.e., every 160 function evaluations), as indicated by the counter.

optimization. This was followed by a survey of existing EA niching techniques, mainly from the GA field, and a detailed description of a specific case-study technique, based on the CMA-ES. We highlighted the *natural computing* aspects of these techniques, especially the biologically oriented components in each scheme, e.g., hosting capacity, gene flow, alpha-males, etc. We then proposed an experimental framework for testing niching methods, and presented some experimental observations of the CMA-ES case-study technique, including results from a real-world problem. We would like to use this opportunity to encourage other scholars to apply the proposed experimental framework, and at the same time to consider ways to join forces for the construction of a general framework to be agreed upon. Finally, we discussed the important topic of the niche-radius problem, gave an overview of existing methods to treat it, and revisited the CMA-ES case study for an extended self-adaptive scheme, which employs the Mahalanobis metric for obtaining niches with more complex geometrical shapes. We conclude that even though the assumptions made for radius-based niching techniques are problematic, there are good proposed solutions that treat the problem at different levels.

We would like to propose possible directions for future research in this domain:

- Transferring existing niching algorithms into additional real-world applications in general, and into experimental optimization in particular
- Proceeding with the effort to tackle the niche radius problem, in order to develop state-of-the-art niching techniques, which are not subject to the niche radius assumptions
- Extending the study of niching to environments with uncertainty
- Developing theoretical frameworks for the investigation of niching, for example, by means of simplified modeling

Abstract

DNA computing is an area of natural computing based on the idea that molecular biology processes can be used to perform arithmetic and logic operations on information encoded as DNA strands. The first part of this review outlines basic molecular biology notions necessary for understanding DNA computing, recounts the first experimental demonstration of DNA computing (Adleman's 7-vertex Hamiltonian Path Problem), and recounts the milestone wet laboratory experiment that first demonstrated the potential of DNA computing to outperform the computational ability of an unaided human (20 variable instance of 3-SAT).

The second part of the review describes how the properties of DNA-based information, and in particular the Watson–Crick complementarity of DNA single strands, have influenced areas of theoretical computer science such as formal language theory, coding theory, automata theory and combinatorics on words. More precisely, we describe the problem of DNA encodings design, present an analysis of intramolecular bonds, define and characterize languages that avoid certain undesirable intermolecular bonds, and investigate languages whose words avoid even imperfect bindings between their constituent strands. We also present another, vectorial, representation of DNA strands, and two computational models based on this representation: sticker systems and Watson–Crick automata. Lastly, we describe the influence that properties of DNA-based information have had on research in combinatorics on words, by enumerating several natural generalizations of classical concepts of combinatorics of words: pseudopalindromes, pseudoperiodicity, Watson–Crick conjugate and commutative words, involutively bordered words, pseudoknot bordered words. In addition, we outline natural extensions in this context of two of the most fundamental results in combinatorics of words, namely Fine and Wilf's theorem and the Lyndon–Schutzenberger result.

1 Introduction

DNA computing is an area of natural computing based on the idea that molecular biology processes can be used to perform arithmetic and logic operations on information encoded as DNA strands. The aim of this review is twofold. First, the fundamentals of DNA computing, including basics of DNA structure and bio-operations, and two historically important DNA computing experiments, are introduced. Second, some of the ways in which DNA computing research has impacted fields in theoretical computer science are described.

The first part of this chapter outlines basic molecular biology notions necessary for understanding DNA computing (► Sect. 2), recounts the first experimental demonstration of DNA computing (► Sect. 3), as well as the milestone wet laboratory experiment that first demonstrated the potential of DNA computing to outperform the computational ability of an unaided human (► Sect. 4).

The second part of the chapter describes how the properties of DNA-based information, and, in particular, the Watson–Crick (WK) complementarity of DNA single strands have influenced areas of theoretical computer science such as formal language theory, coding theory, automata theory, and combinatorics on words. More precisely, ► Sect. 5 summarizes notions and results in formal language theory and coding theory arising from the problem of design of optimal encodings for DNA computing experiments: ► Section 5.1 describes the problem of DNA encodings design, ► Sect. 5.2 consists of an analysis of intramolecular bonds

(bonds within a given DNA strand), [Sect. 5.3](#) defines and characterizes languages that avoid certain undesirable intermolecular bonds (bonds between two or more DNA strands), and [Sect. 5.4](#) investigates languages whose words avoid even imperfect bindings between their constituent strands.

[Sect. 6](#) contains another representation (vectorial) of DNA strands and two computational models based on this representation: sticker systems and Watson–Crick automata. After a brief description of the representation of DNA partial double strands as two-line vectors, and of the sticking operation that combines them, [Sect. 6.1](#) describes basic sticker systems, sticker systems with complex structures ([Sect. 6.1.1](#)), and observable sticker systems ([Sect. 6.1.2](#)). [Section 6.2](#) investigates the accepting counterpart of the generative sticker systems devices: Watson–Crick automata and their properties.

[Section 7](#) describes the influence that properties of DNA-based information have had on research in combinatorics on words, by enumerating several natural generalizations of classical concepts of combinatorics of words: pseudo-palindromes, pseudo-periodicity, Watson–Crick conjugate and commutative words, involutively bordered words, pseudoknot bordered words. In addition, this section outlines natural extensions in this context of two of the most fundamental results in combinatorics of words, namely Fine and Wilf’s theorem and the Lyndon–Schützenberger result.

[Section 8](#) presents general thoughts on DNA-based information, bioinformation, and biocomputation.

2 A Computer Scientist’s Guide to DNA

In this section, a brief description of the basic molecular biology notions of DNA structure and DNA-based bio-operations used in DNA computing is given. For further details, the reader is referred to Turner et al. (2000); Drlica (1996); Calladine and Drew (1997); Gonick and Wheelis (1991); and Lewin (2007).

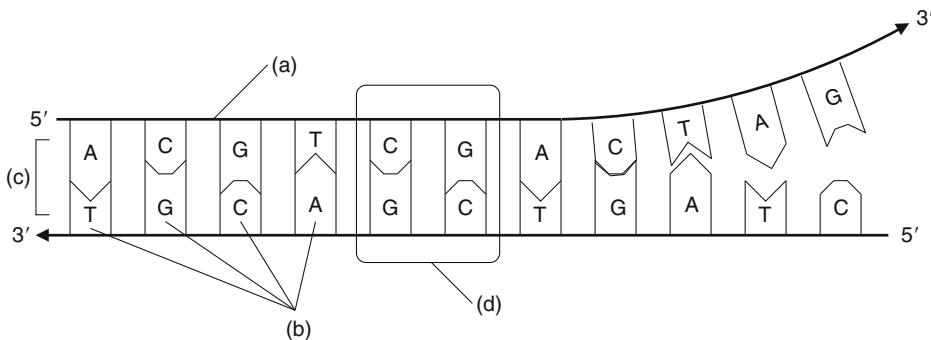

A **DNA (deoxyribonucleic acid)** molecule is a linear polymer. The monomer units of DNA are nucleotides (abbreviated *nt*), and the polymer is known as a “polynucleotide.” There are four different kinds of nucleotides found in DNA, each consisting of a nitrogenous *base* (Adenine, *A*, Cytosine, *C*, Guanine, *G*, or Thymine, *T*), and a sugar-phosphate unit. The abbreviation *N* stands for any nucleotide. The bases are relatively flat molecules and can be divided into purine bases (adenine and guanine) that have two carbon-containing rings in their structure, and smaller pyrimidine bases (cytosine and thymine) that have one carbon-containing ring in their structure.

A sugar-phosphate unit consists of a deoxyribose sugar and one to three phosphate groups. Together, the base and the sugar comprise a *nucleoside*. The sugar-phosphate units are linked together by strong *covalent bonds* to form the backbone of the DNA single strand (ssDNA). A DNA strand consisting of *n* nucleotides is sometimes called an *n-mer*. An *oligonucleotide* is a short DNA single strand, with 20 or fewer nucleotides. Since nucleotides may differ only by their bases, a DNA strand can be viewed simply as a word over the four-letter alphabet $\{A, C, G, T\}$.

A DNA single strand has an orientation, with one end known as the 5' end, and the other end known as the 3' end, based on their chemical properties. By convention, a word over the DNA alphabet represents the corresponding DNA single strand in the 5' to 3' orientation, that is, the word ACGTCGACTAC stands for the DNA single strand 5'-ACGTCGACTAC-3'.

Fig. 1

DNA structure: (a) DNA's sugar-phosphate backbone, (b) DNA bases, (c) Watson–Crick (WK) complementarity between bases A and T of two DNA single strands of opposite orientation, (d) Watson–Crick complementarity between bases C and G of two DNA single strands of opposite orientation.

A crucial feature of DNA single strands is their **Watson–Crick (WK) complementarity**: A (a purine) is complementary to T (a pyrimidine), and G (a purine) is complementary to C (a pyrimidine). Two complementary DNA single strands with opposite orientation bind to each other by weak *hydrogen bonds* between their individual bases as follows: A binds with T through two hydrogen bonds, while G binds with C through three hydrogen bonds. Thus, two Watson–Crick complementary single strands form a stable DNA double strand (dsDNA) resembling a helical ladder, with the two backbones at the outside, and the bases paired by hydrogen bonding and stacked on each other, on the inside. For example, the DNA single strand 5'-ACGTCGACTAC- 3' will bind to the DNA single strand 5'-GTAGTCGACGT-3' to form the 11 base-pair long (abbreviated as 11bp) double strand

$$5' - \text{ACGTCGACTAC} - 3'$$

$$3' - \text{TGCAGCTGATG} - 5'.$$

❷ *Figure 1* schematically illustrates this DNA double strand, omitting the double helix structure, for clarity. If v denotes a DNA single strand over the alphabet $\{A, C, G, T\}$, then by \overline{v} we will denote its Watson–Crick complement.

Another molecule that can be used for computation is *RNA, ribonucleic acid*. RNA is similar to DNA, but differs from it in three main aspects: RNA is usually single-stranded while DNA is usually double-stranded, RNA nucleotides contain the sugar ribose, while DNA nucleotides contain the sugar deoxyribose, and in RNA the base Uracil, U, substitutes for thymine, T, which is present in DNA.

The *genome* of an organism is the totality of its genetic information encoded in DNA. It consists of *chromosomes*, which, in turn, consist of genes. A *gene* is a segment of DNA that holds the information encoding a coherent set of functions necessary to build and maintain cells, and pass genetic traits to offspring. A gene comprises *coding* subsequences (*exons*) that determine what the gene does, and *noncoding* subsequences (*introns*). When a gene is active, the coding and noncoding sequences are copied in a process called *transcription*, producing an RNA copy of the gene's information. This piece of RNA can then direct the *translation* of the catenation of the coding sequences of this gene into *proteins* via the *genetic code*. The genetic

code maps each 3-letter RNA segment (called *codon*) into an amino acid. Several designated triplets, the start codon (*AUG*), and the stop (*UAA*, *UAG*, *UGA*) codons, signal the initiation, respectively, the termination of a translation. There are 20 different standard amino acids. Some of them are encoded by one codon, while others are encoded by several “synonymous” codons. A protein is a sequence over the 20-letter alphabet of amino acids. Proteins are essential parts of organisms and participate in every process within cells having, for example, catalytical, structural, or mechanical functions.

To encode, for example, English text using DNA, one can choose an encoding scheme mapping the Latin alphabet onto strings over $\{A, C, G, T\}$, and proceed to synthesize the obtained information-encoding strings as DNA single strands. In a hypothetical example, one could encode the letters of the English alphabet as $A \rightarrow ACA$, $B \rightarrow ACCA$, $C \rightarrow ACCCA$, $D \rightarrow AC^4A$, etc., wherein the i th letter of the alphabet is represented by AC^iA , that is, a single strand of DNA consisting of i repetitions of C flanked by one A at the beginning and another A at the end. Under this encoding, the text “To be or not to be” becomes the DNA single strand represented by

that can be readily synthesized.

Indeed, **DNA synthesis** is the most basic **bio-operation** used in DNA computing. DNA solid-state synthesis is based on a method by which the initial nucleotide is bound to a solid support, and successive nucleotides are added step by step, from the 3' to the 5' direction, in a reactant solution (☞ Fig. 2).

While the above encoding example is purely hypothetical, DNA strands of lengths of up to 100 nucleotides can be readily synthesized using fully automated *DNA synthesizers*. The result is a small test tube containing a tiny, dry, white mass of indefinite shape containing a homogeneous population of DNA strands that may contain 10^{18} identical molecules of DNA. In bigger quantities, dry DNA resembles tangled, matted white thread.

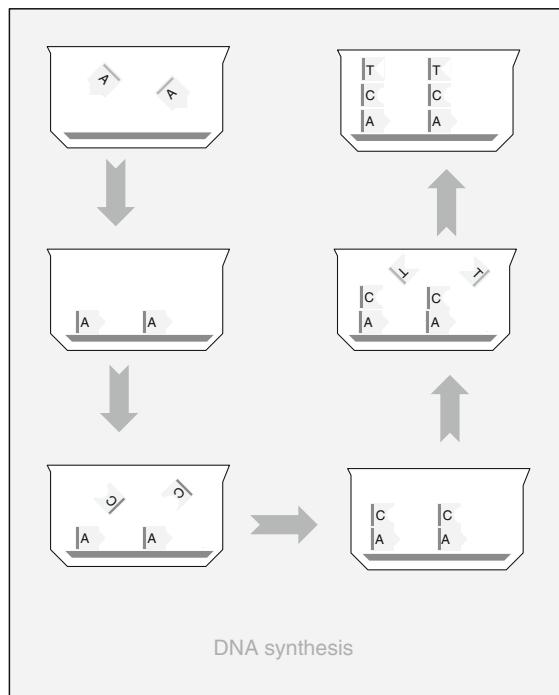

Using this or other DNA synthesis methods, one can envisage encoding any kind of information as DNA strands. There are several reasons to consider such a DNA-based memory as an alternative to all the currently available implementations of memories. The first is the extraordinary information-encoding density that can be achieved by using DNA strands. According to Reif et al. (2002), 1 g of DNA, which contains 2.1×10^{21} DNA nucleotides, can store approximately 4.2×10^{21} bits. Thus, DNA has the potential to store data on the order of 10^{10} more compactly than conventional storage technologies. In addition, the robustness of DNA data ensures the maintenance of the archived information over extensive periods of time (Bancroft et al. 2001; Cox 2001; Smith et al. 2003).

For the purposes of DNA computing, after encoding the input data of a problem on DNA strands, DNA bio-operations can be utilized for computations, see Kari (1997), Păun et al. (1998), and Amos (2005). The bio-operations most commonly used to control DNA computations and DNA robotic operations are described below.

DNA single strands with opposite orientation will join together to form a double helix in a process based on the Watson–Crick complementarity and called **base-pairing** (**annealing**, **hybridization**, **renaturation**), illustrated in ☞ Fig. 3. The reverse process – a double-stranded helix coming apart to yield its two constituent single strands – is called **melting** or **denaturation**. As the name suggests, melting is achieved by raising the temperature, and annealing by lowering it. Each DNA double-strand denaturates at a specific temperature, called its *melting*

Fig. 2

DNA solid-state synthesis. The initial nucleotide is bound to a solid support, and successive nucleotides are added step by step, from the 3' to the 5' direction, in a reactant solution. (From Kari 1997.)

temperature. The melting temperature is defined as the temperature at which half of the DNA strands are double-stranded, and half are single-stranded. It depends on both the length of the DNA sequence, and its specific base-composition (SantaLucia 1998).

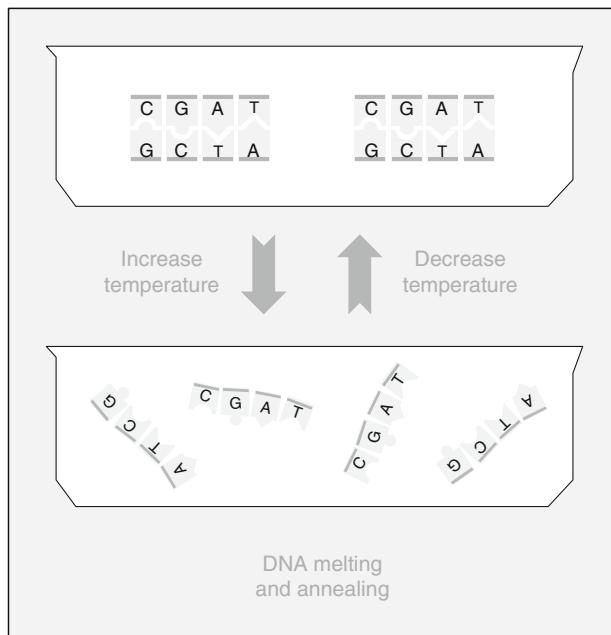

Cutting DNA double strands at specific sites can be accomplished with the aid of specific enzymes, called *restriction enzymes* (*restriction endonucleases*). Each restriction enzyme recognizes a specific short sequence of DNA, known as a *restriction site*. Any double-stranded DNA that contains the restriction site within its sequence is cut by the enzyme at that location, according to a specific pattern. Depending on the enzyme, the cutting operation leaves either two “blunt-ended” DNA double strands or, more often, two DNA strands that are double-stranded but have single-stranded overhangs known as “sticky-ends,” (Fig. 4). Hundreds of restriction enzymes are now known, and a large number are commercially available. They usually recognize sites ranging in size from 4 to 8 bp, the recognition sites are often pseudo-palindromic (see Sect. 7 for a definition of pseudopalindrome).

Another enzyme, called *DNA ligase*, can repair breaks in a double-stranded DNA backbone, and can covalently rejoin annealed complementary ends in the reverse of a restriction enzyme reaction, to create new DNA molecules. The process of thus pasting together compatible DNA strands is called **ligation**.

Separation of DNA strands by size is possible by using a technique called *gel electrophoresis*. The DNA molecules, which are negatively charged, are placed in “wells” situated at one

Fig. 3

Melting (separating DNA double strands into their constituent single strands), and annealing (the reformation of double-stranded DNA from thermally denatured DNA). Raising the temperature causes a DNA double strand to “melt” into its constituent Watson–Crick complementary single strands. Decreasing the temperature has the opposite effect: two DNA single strands that are Watson–Crick complementary will bind to each other to form a DNA double strand. (From Kari 1997.)

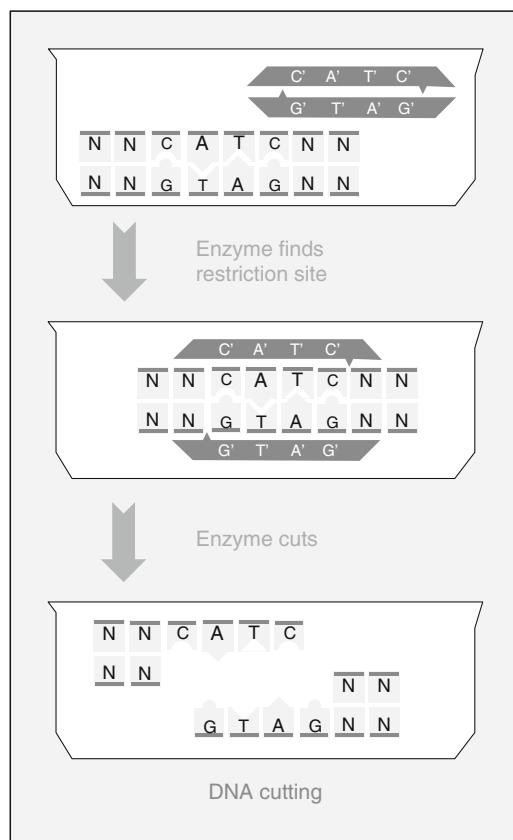

side of an agarose or polyacrylamide gel. Then an electric current is applied to the gel, with the negative pole at the side with the wells, and the positive pole at the opposite side. The DNA molecules will be drawn toward the positive pole, with the larger molecules traveling more slowly through the gel. After a period, the molecules will spread out into distinct bands according to size, **Fig. 5**. The gel method at constant electric field is capable of separating by size DNA molecules as long as 50,000 base pairs, with a resolution of better than 1% the size of the DNA.

Extraction of DNA single strands that contain a target sequence, v , from a heterogeneous solution of DNA single strands, can be accomplished by *affinity purification*, **Fig. 6**. A DNA probe is a single-stranded DNA molecule used in laboratory experiments to detect the presence of a complementary sequence among a mixture of other single-stranded DNA molecules.

The extraction process begins by synthesizing probes, that is, strands \vec{v} , Watson–Crick complementary to v , and attaching them to a solid support, for example, magnetic beads. Then, the heterogeneous solution of DNA strands is passed over the beads. Those strands containing v are “detected” by becoming annealed to \vec{v} , and are thus retained. Strands not containing v pass through without being retained. The solid medium, for example, magnetic

Fig. 4

DNA cutting (digestion) by a restriction enzyme. A hypothetical restriction enzyme (dark gray) recognizes the restriction site CATC on a DNA double-strand (light gray), and cuts the two backbones of the DNA strand, as shown. Under most conditions, Watson–Crick complementarity of four base-pairs is not sufficient to keep the strands together, and the DNA molecule separates into two fragments. The result of the digestion is thus a *CATC*—3' sticky end overhang, and a 3'—*GTAG* sticky end overhang. The reverse process of ligation can restore the original strand by bringing together strands with compatible sticky ends by means of Watson–Crick base-pairing, and using the enzyme ligase that repairs the backbone breaks (nicks) that had been introduced by the restriction endonuclease. (From Kari 1997.)

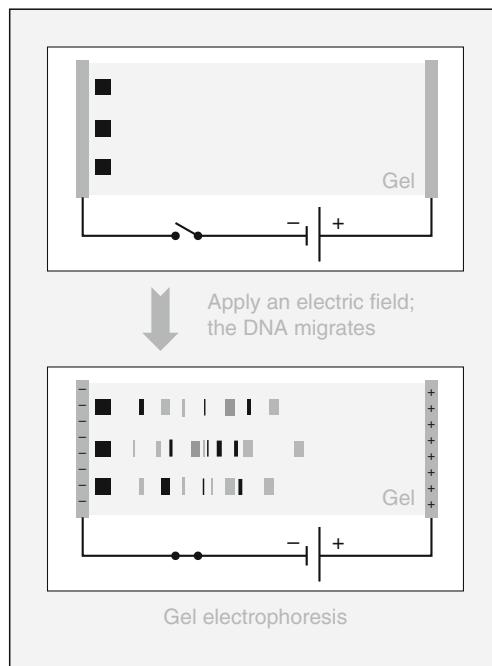

beads, can then be removed from the mixture, washed, and the target DNA molecules can be released from the entrapment.

DNA replication is accomplished by a process called *polymerase chain reaction*, or PCR, that involves the *DNA polymerase* enzyme, [Fig. 7](#).

The PCR replication reaction requires a guiding DNA single strand called *template*, and an oligonucleotide called *primer*, that is annealed to the template. The primer is required to initiate the synthesis reaction of the polymerase enzyme. The DNA polymerase enzyme catalyzes DNA synthesis by successively adding nucleotides to one end of the primer.

Fig. 5

Separation of DNA strands by size (length) by using gel electrophoresis. The DNA samples are placed in *wells* (slots) near one end of the gel slab. The power supply is switched on and the DNA, which is highly negatively charged, is allowed to migrate toward the positive electrode (right side of the gel) in separate *lanes* or *tracks*. DNA fragments will move through the gel at a rate which is dependent on their size and shape. After a while, the DNA molecules spread out into distinct bands and the use of a control “ladder” that contains DNA strands of incremental lengths allows the determination of the lengths of the DNA molecules in the samples. (From Kari 1997.)

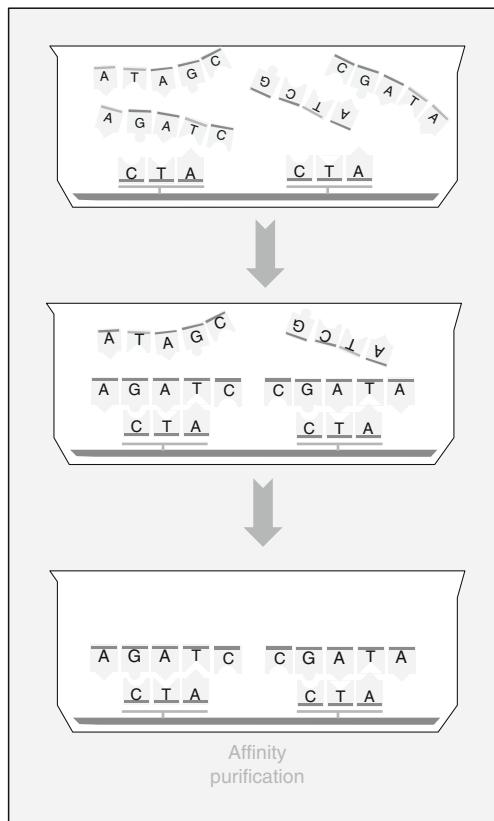

The primer is thus extended at its 3' end, in the direction 5' to 3' only, until the desired strand is obtained that starts with the primer and is complementary to the template. (Note that DNA chemical synthesis and enzymatic DNA replication proceed in opposite directions, namely 3' → 5' and 5' → 3', respectively).

If two primers are used, the result is the exponential multiplication of the subsequence of the template strand that is flanked by the two primers, in a process called *amplification*, schematically explained below. For the purpose of this explanation, if x is a string of letters over the DNA alphabet $\{A, C, G, T\}$, then \bar{x} will denote its simple complement, for example, $AACCTTGG = TTGGAACC$.

One can now assume that one desires to amplify the subsequence between x and y from the DNA double strand ${}^{5'}-\alpha x \beta y \delta-{}^{3'}$, where α, x, β, y , and δ are DNA segments. Then one uses as primers the strand x and the Watson–Crick complement \bar{y}' of y . After heating the solution and thus melting the double-stranded DNA into its two constituent strands, the solution is cooled and the Watson–Crick complement of y anneals to the “top” strand, while x anneals to the “bottom” strand. The polymerase enzyme extends the 3' ends of both primers into the 5' to 3'

Fig. 6

Extraction of strands that contain a target sequence, $v = 5' - GAT - 3'$, by affinity purification. (The 3nt pattern GAT is for illustration purposes only, in practice a longer DNA subsequence would be needed for the process of extraction to work.) The Watson–Crick complement of v , namely $3' - CTA - 5'$, is attached to a solid support, for example, magnetic beads. The heterogeneous solution of DNA strands is poured over. The DNA strands that contain the target sequence v as a subsequence will attach to the complement of the target by virtue of Watson–Crick complementarity. Washing off the solution will result in retaining the beads with the attached DNA strands containing the target sequence. (From Kari 1997.)

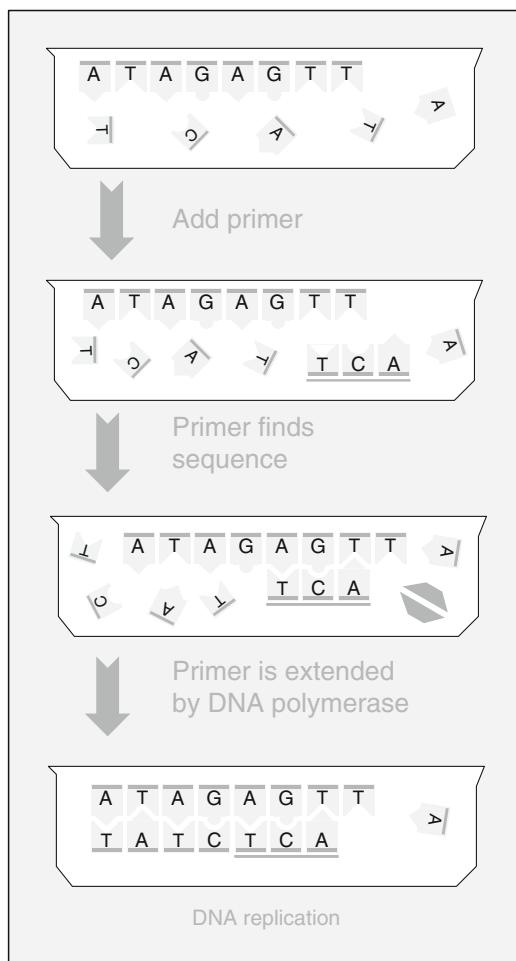

direction, producing partially double-stranded molecules $5' - \alpha x \beta y \delta - 3'$ and $5' - x \beta y \delta - 3'$. In a similar fashion, the next heating–cooling cycle will result in the production of the additional strands $5' - x \beta y - 3'$ and $3' - \bar{x} \bar{\beta} \bar{y} - 5'$. These strands are Watson–Crick complementary and will, from now on, be produced in excess of the other strands, since both are replicated during each cycle. At the end, an order of 2^n copies of the desired subsequences flanked by x and y will be present in solution, where n is the number of the heating–cooling cycles, typically 20 to 30.

A biocomputation consists of a succession of *bio-operations* (Daley and Kari 2002), such as the ones described in this section. The DNA strands representing the output of the biocomputation can then be **sequenced (read out)** using an automated sequencer. One sequencing method uses special chemically modified nucleotides (dideoxyribonucleoside

Fig. 7

DNA strand replication using one primer and the enzyme DNA polymerase. Given a template DNA strand 5' – ATAGAGTT – 3' to replicate, first a primer 3' – TCA – 5' (a short DNA sequence, usually 10–15 nt long, that is complementary to a portion of the template) is added to the solution. DNA polymerase (dark gray) extends the primer in the 5' to 3' direction, until the template becomes fully double stranded. Repeating the process by heating the solution to denature the double-strands and then cooling it to allow annealing of the primer, will thus lead to producing many copies of the portion of the complement of the template strand that starts with the primer. The idea is used in polymerase chain reaction (PCR) that uses two primers, DNA polymerase, dNTPs, and thermal cycling to produce exponentially many copies of the subsequence of a template strand that is flanked by the primers. dNTP, *deoxyribonucleoside triphosphate*, stands for any of the nucleotides dATP, dTTP, dCTP, and dGTP. Each nucleotide consists of a base, plus sugar (which together form a *nucleoside*), plus triphosphate. dNTPs are the building blocks from which the DNA polymerases synthesizes a new DNA strand. (From Kari 1997.)

triphosphates – ddNTPs), that act as “chain terminators” during PCR, as follows. A sequencing primer is annealed to the DNA template that one wishes to read. A DNA polymerase then extends the primer. The extension reaction is split into four tubes, each containing a different chain terminator nucleotide, mixed with standard nucleotides. For example, tube C would contain chemically modified C (ddCTP), as well as the standard nucleotides (dATP, dGTP, dCTP, and dTTP). Extension of the primer by the polymerase then produces all prefixes ending in G of the complement of the original strand. A separation of these strands by length using gel electrophoresis allows the determination of the position of all Gs (complements of Cs). Combining the results obtained in this way for all four nucleotides allows the reconstruction of the original sequence.

Some of the novel features of DNA-encoded information and bio-operations have been used for the first time for computational purposes in the breakthrough proof-of-principle experiment in DNA computing reported by Adleman in 1994.

3 The First DNA Computing Experiment

The practical possibilities of encoding information in a DNA sequence and of performing simple bio-operations were used by Leonard Adleman in 1994 (Adleman 1994) to perform the first experimental DNA computation that solved a seven-vertex instance of an NP-complete problem, namely the directed Hamiltonian path problem (HPP).

A directed graph G with designated vertices v_{start} and v_{end} is said to have a Hamiltonian path if and only if there exists a sequence of compatible directed edges e_1, e_2, \dots, e_z (i.e., a directed path) that begins at v_{start} , ends at v_{end} and enters every other vertex exactly once.

The following (nondeterministic) algorithm solves the problem:

Input. A directed graph G with n vertices and designated vertices v_{start} and v_{end} .

Step 1. Generate random paths through the graph.

Step 2. Keep only those paths that begin with v_{start} and end with v_{end} .

Step 3. Keep only those paths that enter exactly n vertices.

Step 4. Keep only those paths that enter all of the vertices of the graph at least once.

Output. If any paths remain, output “YES”; otherwise output “NO.”

Below, we describe Adleman’s bio-algorithm which solves the seven-vertex instance of the HPP illustrated in Fig. 8, where $v_{\text{start}} = 0$ and $v_{\text{end}} = 6$.

To encode the *input* to the problem, that is the vertices and directed edges of the graph, each vertex of the graph was encoded into a carefully chosen 20-mer single strand of DNA. Then, for each oriented edge of the graph, a DNA sequence was designed and synthesized, consisting of the second half of the sequence encoding the source vertex and the first half of the sequence encoding the target vertex. Exceptions were the edges that started with v_{start} , and the ones that ended in v_{end} , for which the DNA encoding consisted of the full sequence of the source vertex followed by the first half of the target vertex, respectively, the second half of the source vertex followed by the full sequence of the target vertex.

For example, the DNA sequences for the vertex 3 and the oriented edges $2 \rightarrow 3$ and $3 \rightarrow 4$ were encoded respectively as

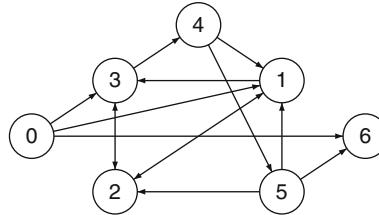

$$O_3 = 5' - \text{GCTATTGAGCTTAAAGCTA} - 3'$$

$$O_{2 \rightarrow 3} = 5' - \text{GTATATCCGAGCTATTGAG} - 3'$$

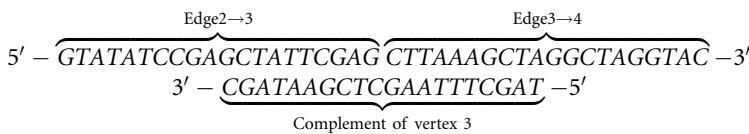

$$O_{3 \rightarrow 4} = 5' - \text{CTTAAAGCTAGGCTAGGTAC} - 3'.$$

Fig. 8

The seven-vertex instance of the Hamiltonian path problem (HPP) solved by Adleman, who used solely molecular biology tools to obtain the answer. This was the first ever experimental evidence that DNA computing is possible. (From Adleman 1994.)

To implement *Step 1*, one mixed together in a test tube multiple copies of each of the encodings of the Watson–Crick complements $\overrightarrow{O_i}$ of all the vertices, together with the encodings for all the directed edges, for a ligation reaction. The complements of the vertices served as splints and brought together sequences associated to compatible edges. For example, the edges $O_{2 \rightarrow 3}$ and $O_{3 \rightarrow 4}$ were brought together by the Watson–Crick complement $\overrightarrow{O_3}$ as follows:

Hence, the Watson–Crick complementarity and the combined ligation reaction resulted in the formation of DNA molecules encoding random paths through the graph. Out of these, the next steps had to find and discard the paths that were not Hamiltonian.

To implement *Step 2* (keep only paths that start with v_{start} and end with v_{end}), the product of *Step 1* was amplified by PCR with primers O_0 and $\overrightarrow{O_6}$. Thus, only those molecules encoding paths that begin with the start vertex 0 and end with the end vertex 6 were amplified.

For implementing *Step 3* (keep only paths of the correct length), gel electrophoresis was used, allowing separation of DNA strands by length. Since any Hamiltonian path, if it exists, has to pass through all the seven vertices of the graph, only DNA double strands of length $7 \times 20 = 140$ were retained.

Step 4 (keep only paths that pass through each vertex at least once) was accomplished by iteratively using affinity purification. After generating single-stranded DNA from the double-stranded product of the preceding step, one attached a sequence $\overrightarrow{O_i}$ to magnetic beads, and the heterogeneous solution of “candidate paths” was passed over the beads. Those strands containing O_i annealed to the complementary sequence and were hence retained. These strands represented paths that pass through the vertex i . This process was repeated successively with $\overrightarrow{O_1}$, $\overrightarrow{O_2}$, $\overrightarrow{O_3}$, $\overrightarrow{O_4}$, and $\overrightarrow{O_5}$.

To obtain the *Output* (are there any paths left?), the presence of a molecule encoding a Hamiltonian path was checked. This was done by amplifying the result of *Step 4* by PCR with primers O_0 and $\overrightarrow{O_6}$, and then reading out the DNA sequence of the amplified molecules. Note that the final PCR was not required for computational purposes: First, it was employed to make sure that, after several filtering steps, the amount of DNA was above the detection threshold, and second to verify the correctness of the answer.

The entire computation required approximately 7 days of wet lab work, and was carried out in approximately 1/50 of a teaspoon of solution (Adleman 1998). It was the first proof-of-concept experiment that DNA computation was possible. From a practical point of view, Adleman's approach had both advantages and disadvantages. On one hand, *Step 1*, which is the cause of the time-complexity exponential blowup in the classical electronic implementation of the algorithm, took only one time-step in Adleman's bio-algorithm. On the other hand, the amount of space needed for the generation of the full solution space grows exponentially relative to the problem size. Indeed, a scaled-up input of size $n = 200$ for the HPP would require, in this brute force approach, an amount of DNA whose weight would be greater than that of the Earth (Hartmanis 1995).

The construction of a DNA pool that contains the full-solution space has been avoided in subsequent bio-algorithms proposed for solving HPP. For example, in Morimoto et al. (1997) a bio-algorithm was proposed that stepwise generated only the possible paths. In this approach, all paths were stepwise extended from v_{start} to v_{end} as follows. After letting many molecules representing v_{start} attach to a surface, $n + 1$ repetitions of the following step found the Hamiltonian path: "Extend each path by one adjacent vertex; Remove paths which contain the same vertex twice." In addition to being space and time efficient (each extension step could be as quick as 30 min), this bio-algorithm avoided the laborious step of separation of strands by length.

4 Beyond Unaided Human Computation

We present another significant milestone in DNA computing research, the first experiment that demonstrated that DNA computing devices can exceed the computational power of an unaided human. Indeed, in 2002, an experiment was reported (Braich et al. 2002), that solved a 20-variable instance of the NP-complete 3-SAT problem, wherein the answer to the problem was found after an exhaustive search of more than 1 million (2^{20}) possible solution candidates.

The input to a 3-SAT problem is a Boolean formula in three-conjunctive-normal-form (3-CNF), that is, a Boolean formula that consists of conjunctions of disjunctive clauses, where each disjunctive clause is the disjunction of at most three literals (a literal is either a Boolean variable or its negation). This formula is called *satisfiable* if there exists a truth value assignment to its variables that satisfies it, that is, that makes the whole formula true. Thus, the output to the 3-SAT problem is "yes" if such a satisfying truth value assignment exists, and "no" otherwise.

The input formula for this experiment was the 20-variable, 24-clause, 3-CNF formula:

$$\begin{aligned} \Phi = & (\overline{x_3} \vee \overline{x_{16}} \vee x_{18}) \wedge (x_5 \vee x_{12} \vee \overline{x_9}) \wedge (\overline{x_{13}} \vee \overline{x_2} \vee x_{20}) \wedge (x_{12} \vee \overline{x_9} \vee \overline{x_5}) \\ & \wedge (x_{19} \vee \overline{x_4} \vee x_6) \wedge (x_9 \vee x_{12} \vee \overline{x_5}) \wedge (\overline{x_1} \vee x_4 \vee \overline{x_{11}}) \wedge (x_{13} \vee \overline{x_2} \vee \overline{x_{19}}) \\ & \wedge (x_5 \vee x_{17} \vee x_9) \wedge (x_{15} \vee x_9 \vee \overline{x_{17}}) \wedge (\overline{x_5} \vee \overline{x_9} \vee \overline{x_{12}}) \wedge (x_6 \vee x_{11} \vee x_4) \\ & \wedge (\overline{x_{15}} \vee \overline{x_{17}} \vee x_7) \wedge (\overline{x_6} \vee x_{19} \vee x_{13}) \wedge (\overline{x_{12}} \vee \overline{x_9} \vee x_5) \wedge (x_{12} \vee x_1 \vee x_{14}) \\ & \wedge (x_{20} \vee x_3 \vee x_2) \wedge (x_{10} \vee \overline{x_7} \vee \overline{x_8}) \wedge (\overline{x_5} \vee x_9 \vee \overline{x_{12}}) \wedge (x_{18} \vee \overline{x_{20}} \vee x_3) \\ & \wedge (\overline{x_{10}} \vee \overline{x_{18}} \vee \overline{x_{16}}) \wedge (x_1 \vee \overline{x_{11}} \vee \overline{x_{14}}) \wedge (x_8 \vee \overline{x_7} \vee \overline{x_{15}}) \wedge (\overline{x_8} \vee x_{16} \vee \overline{x_{10}}) \end{aligned}$$

where, for a Boolean variable x_i , $\overline{x_i}$ denotes the negation of x_i , $1 \leq i \leq 20$. The formula Φ was designed so as to have a unique satisfying truth assignment, namely $x_1 = F$, $x_2 = T$, $x_3 = F$, $x_4 = F$,

$x_5 = F, x_6 = F, x_7 = T, x_8 = T, x_9 = F, x_{10} = T, x_{11} = T, x_{12} = T, x_{13} = F, x_{14} = F, x_{15} = T, x_{16} = T, x_{17} = T, x_{18} = F, x_{19} = F, x_{20} = F$.

The DNA computing experiment that solved the problem (Braich et al. 2002), was based on the following nondeterministic algorithm.

Input: A Boolean formula Φ in 3-CNF.

Step 1: Generate the set of all possible truth value assignments.

Step 2: Remove the set of truth value assignments that make the first clause false.

Step 3: Repeat Step 2 for all the clauses of the input formula.

Output: The remaining (if any) truth value assignments.

To implement this algorithm, the input data was encoded as follows. Every variable $x_k, k = 1, \dots, 20$, was associated with two distinct 15-mer DNA single strands. One of them, denoted by X_k^T , represented true (T), while the second, denoted by X_k^F , represented false (F).

Below are some examples of the particular 15-mer sequences – none of which contained the nucleotide G – synthesized and used in the experiment:

$$X_2^T = \text{ATT TCC AAC ATA CTC}, \quad X_2^F = \text{AAA CCT AAT ACT CCT},$$

$$X_3^T = \text{TCA TCC TCT AAC ATA}, \quad X_3^F = \text{CCC TAT TAA TCA ATC}.$$

Using these 15-mer encodings for the two truth values of all the 20 variables, the library consisting of all possible 2^{20} truth assignments was assembled using the mix-and-match combinatorial synthesis technique of Faulhammer et al. (2000). In brief, oligonucleotides for X_{20}^T and X_{20}^F were synthesized separately, then mixed together. The mixture was divided in half and the result put in two separate test tubes. The synthesis was restarted separately, with sequences X_{19}^T and X_{19}^F , respectively. In principle, the process can be repeated until the desired library is obtained. In practice, two half-length libraries were created separately, and then linked together using a polymerase-chain extension similar to that in Stemmer et al. (1995). Each *library strand* encoding a truth assignment was thus represented by a 300-mer DNA strand consisting of the ordered catenation of twenty 15-mer value sequence, one for each variable, as follows:

$$X_1 X_2 \dots X_{20}, \text{ where } \alpha_i \in \{X_i^T, X_i^F\}, 1 \leq i \leq 20$$

The biocomputation *wet-ware* essentially consisted of a glass module filled with a gel containing the library, as well as 24 glass *clause modules*, one for each of the 24 clauses of the formula. Each clause module was filled with gel containing probes (immobilized DNA single strands) designed to bind only library strands encoding truth assignments satisfying that clause.

The strands were moved between the modules with the aid of gel electrophoresis, that is, by applying an electric current that resulted in the migration of the negatively charged DNA strands through the gel.

The protocol started with the library passing through the first clause module, wherein library strands containing the truth assignments satisfying the first clause (i.e., library strands containing sequences X_3^F , or X_{16}^F , or X_{18}^T) were captured by the immobilized probes, while library strands that did not satisfy the first clause (i.e., library strands containing sequences X_3^T , and X_{16}^T , and X_{18}^F) continued into a buffer reservoir. The captured strands were then released by raising the temperature, and used as input to the second clause module, etc. At the end, only the strand representing the truth assignment that satisfied all 24 clauses remained.

The output strand was PCR amplified with primer pairs corresponding to all four possible true–false combinations of assignments for the first and last variable x_1 and x_{20} . None except

the primer pair $(X_1^F, \overrightarrow{X_{20}^F})$ showed any bands, thus indicating two truth values of the satisfying assignment, namely $x_1 = F$ and $x_{20} = F$. The process was repeated for each of the variable pairs (x_1, x_k) , $2 \leq k \leq 19$, and, based on the lengths of the bands observed, value assignments were given to the variables. These experimentally derived values corresponded to the unique satisfying assignment for the formula Φ , concluding thus the experiment.

One of the remarkable features of this benchmark DNA computing experiment was that the sole bio-operation that was used (except during input and output) was Watson–Crick complementarity-based annealing and melting.

Generally, it is believed that DNA computers that use a brute-force search algorithm for SAT are limited to 60 to 70 variables (Lipton 1995). Several other algorithms that do not use brute force, such as the breadth-first search algorithm (Yoshida and Suyama 2000), and random walk algorithms (Liu et al. 2005; Diaz et al. 2001) have been proposed. With the breadth-first search algorithm, the capacity of a DNA computer can be theoretically increased to about 120 variables (Yoshida and Suyama 2000). A recent example of this approach that avoids the generation of the full solution space is a solution to the SAT problem using a DNA computing algorithm based on ligase chain reaction (LCR) (Wang et al. 2008). This bio-algorithm can solve an n -variable m -clause SAT problem in m steps, and the computation time required is $O(3m + n)$. Instead of generating the full-solution DNA library, this bio-algorithm starts with an empty test tube and then generates solutions that partially satisfy the SAT formula. These partial solutions are then extended step by step by the ligation of new variables using DNA ligase. Correct strands are amplified and false strands are pruned by a ligase chain reaction (LCR) as soon as they fail to satisfy the conditions.

The two DNA computing experiments described in [Sects. 3](#) and [4](#) are historically significant instances belonging to a vast and impressive array of often astonishing DNA computing experiments, with potential applications to, for example, nanorobotics, nanocomputing, bioengineering, bio-nanotechnology, and micromedicine. Several of these significant experiments are described in the chapters [Molecular Computing Machineries — Computing Models and Wet Implementations](#), [Bacterial Computing and Molecular Communication](#), [DNA Memory](#), and [Engineering Natural Computation by Autonomous DNA-Based Biomolecular Devices](#) of this handbook.

5 DNA Complementarity and Formal Language Theory

The preceding two sections described two milestone DNA computing experiments whose main “computational engine” was the Watson–Crick complementarity between DNA strands. Watson–Crick complementarity can now be studied from a theoretical point of view, and the impact this notion has had on theoretical computer science will be described. This section focuses mainly on the formal language theoretical and coding theoretical approach to DNA-encoded information, and highlights some of the theoretical concepts and results that emerged from these studies.

The idea of formalizing and investigating DNA or RNA molecules and their interactions by using the apparatus of formal language theory is a natural one. Indeed, even though the processes involving DNA molecules are driven by complex biochemical reactions, the primary information is encoded in DNA sequences. Therefore, even without the inclusion of all the thermodynamic parameters that operate during DNA–DNA interactions, formal language theory and coding theory are capable of providing a uniform and powerful framework for an effective study of DNA-encoded information.

To briefly describe the problem of encoding information as DNA strands for DNA computing experiments, one of the main differences between electronic information and DNA-encoded information is that the former has a fixed address and is reusable, while the latter is not. More precisely, DNA strands float freely in solution in a test tube and, if one of the input strands for a bio-operation has become involved in another, unprogrammed, hybridization, that input strand is unavailable for the bio-operation at hand, compromising thus the final result of the experiment. Thus, a considerable effort has been dedicated to finding “optimal” DNA sequences for encoding the information on DNA so as to prevent undesirable interactions and favor only the desirable programmed ones.

Standard biological methods evaluating and predicting hybridization between DNA molecules conditions rely on thermodynamical parameters such as the free energy ΔG (intuitively, the energy needed to melt DNA bonds), and the melting temperature of DNA molecules. For the calculation of these quantities, not only the WK complementarity between single bases is important, but also the WK complementarity (or lack thereof) of their neighboring bases with their counterparts: the *nearest-neighbor model* (SantaLucia 1998) has been frequently used for this purpose. However, in many natural processes, the WK complementarity alone plays a crucial role. Furthermore, together with various similarity metrics, the WK complementarity has been often used to obtain an approximate characterization of DNA hybridization interactions.

This section is devoted to describing methods of discrete mathematics and formal language theory that allow for rapid and mathematically elegant characterization of (partially) complementary DNA molecules, their sets, and set-properties relevant for potential cross-hybridizations. For other approaches to this problem and to the problem of design of molecules for DNA computing, the reader is referred to the chapter [DNA Memory](#) in this book. The section is organized as follows. [Section 5.1](#) describes the problem of optimal encoding of information for DNA computing experiments that was the initial motivation for this research, and also introduces the basic definitions and notation. [Section 5.2](#) describes the problem of intramolecular hybridization (hybridization within one molecule, resulting, e.g., in hairpin formation) and results related to hairpin languages and hairpin-free languages. [Section 5.3](#) describes the problem of intermolecular hybridization (interaction between two or more DNA molecules) and the theoretical concepts and results motivated by this problem. [Section 5.4](#) investigates properties of languages that guarantee that even undesirable imperfect bonds between DNA strands are avoided.

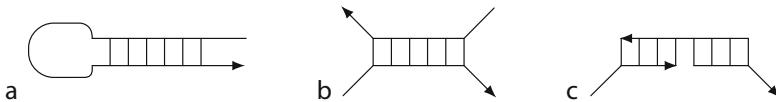

5.1 DNA Encoding: Problem Setting and Notation

In the process of designing DNA computational experiments, as well as in many general laboratory techniques, special attention is paid to the design of an initial set of “good” DNA strands. Mauri and Ferretti (2004), Sager and Stefanovic (2006), and others distinguish two elementary subproblems of the encoding sequence design:

- *Positive* design problem: Design a set of input DNA molecules such that there is a sequence of reactions that produces the correct result.
- *Negative* design problem: Design a set of input DNA molecules that do not interact in undesirable ways, that is, do not produce incorrect outputs, and/or do not consume molecules necessary for other, programmed, interactions.

Fig. 9

Types of undesired (a) intramolecular and (b), (c) intermolecular hybridizations.

The positive design problem is usually highly related to a specific experiment and it is reported to be hard to find a general framework for its solution. In contrast, the negative design problem can be solved on a general basis by construction of a library of molecules that do not allow for undesired mutual hybridizations. According to Sager and Stefanovic (2006), the following conditions must be guaranteed: (1) no strand forms any undesired secondary structure such as hairpin loops (Fig. 9a), (2) no string in the library hybridizes with any string in the library, and (3) no string in the library hybridizes with the complement of any string in the library (Fig. 9b or c). Many laboratory techniques stress the importance of a unified framework for the negative design. An example is the multiplex PCR in which a set of PCR primers is used simultaneously in a single test tube and mutual bonds between primers must be prevented.

A related issue often studied together with the problem of unwanted hybridization is the uniqueness of the oligonucleotides used in experiments. More precisely, one requires that individual oligonucleotides in a mixture differ substantially from each other such that they (and eventually also longer sequences produced by their catenation) can be easily distinguished. Such a property in the mathematical sense is typical for *codes*, hence many authors adopted this naming convention for sets of oligonucleotides, usually of a fixed length, whose elements are then called *DNA codewords*.

A wide spectrum of methods devoted to the DNA encoding design exists. Thermodynamical methods such as those in Deaton et al. (2003), and Dirks and Pierce (2004) provide the most precise results but are computationally the most expensive. Experimental studies trying to construct DNA codes in vitro with the help of the PCR operation can be found, for example, in Chen et al. (2006), and Deaton et al. (2006). An opposite approach relying solely on the WK complementarity allows for fastest but least-precise methods (see, e.g., Head (2000), Jonoska and Mahalingam (2004), and Kari et al. (2005b)). Approximation methods trying to capture key aspects of the nearest neighbor thermodynamic model represent an intermediate step between these two methodologies. Various discrete metrics based often on Hamming or Levenshtein distance have been studied, for example, in Dyachkov et al. (2006, 2008), and Garzon et al. (1997, 2006). The reader is referred to monographs Amos (2005), Ignatova et al. (2008), and Păun et al. (1998) for an overview.

In the sequel, we focus on the characterization of DNA hybridization and unwanted bonds by means of the concepts of formal language and coding theory. Simple examples of construction of DNA codes are also given.

To describe DNA bonds formally, we represent the single-stranded DNA molecules by strings over the *DNA alphabet* $\Delta = \{A, C, T, G\}$, and their mutual reactions can be reduced to formal manipulation of these strings. Therefore, some formal language prerequisites are necessary. For further details the reader is referred to Hopcroft and Ullman (1979), Choffrut and Karhumäki (1997), and Salomaa (1973).

An *alphabet* is a finite and nonempty set of symbols. In the sequel a fixed non-singleton alphabet Σ shall be used as a generalization of the natural DNA alphabet Δ . The set of all words

over Σ is denoted by Σ^* . This set includes the *empty word* λ . The length of a word $w \in \Sigma^*$ is denoted by $|w|$. For an $x \in \Sigma^+$, $|w|_x$ denotes the number of occurrences of x within w . For a nonnegative integer n and a word w , we use w^n to denote the word that consists of n concatenated copies of w . A word v is a *subword* of w if $w = xvy$ for some words x and y . In this case, if $|x| + |y| > 0$ then v is a *proper subword*. By $\text{Sub}(w)$ we denote the set of all subwords of w . For a positive integer k , we use $\text{Sub}_k(w)$ to denote the set of subwords of length k of w . We say that $u \in \Sigma^*$ is a prefix of a word $v \in \Sigma^*$, and denote it by $u \leq v$, if $v = ut$ for some $t \in \Sigma^*$. Two words u, v are said to be *prefix comparable*, denoted by $u \sim_p v$ if one of them is a prefix of the other. In a similar manner, u is said to be a suffix of v if $v = su$ for some $s \in \Sigma^*$. By $\text{Pref}(u)$ ($\text{Suff}(u)$), we denote the sets of all prefixes (respectively suffixes) of u .

The relation of *embedding order* over words is defined as follows: $u \leq_e w$ iff

$$u = u_1 u_2 \cdots u_n, \quad w = v_1 v_2 v_3 \cdots v_n v_n v_{n+1}$$

for some integer n with $u_i v_j \in \Sigma^*$.

A language L is a set of words, or equivalently a subset of Σ^* . A language is said to be λ -free if it does not contain the empty word. If n is a nonnegative integer, we write L^n for the language consisting of all words of the form $w_1 \dots w_n$ such that each w_i is in L , and $L^{\geq n}$ for the language consisting of all catenations of at least n words from L . We also write L^* for the language $L^0 \cup L^1 \cup L^2 \cup \dots$, and L^+ for the language $L^* \setminus \{\lambda\}$. The set $\text{Sub}(L) = \bigcup_{w \in L} \text{Sub}(w)$ we call the set of all subwords of L . The families of regular, linear, context-free, and recursively enumerable languages are denoted by REG, LIN, CF, and RE, respectively.

Many approaches to the construction of DNA encoding are based on the assumption that the set of molecules in a test tube (*tube language*) L is equal to, or a subset of, K^+ , where K is a finite language whose elements are called *codewords*. In general, K might contain codewords of different lengths. In many cases, however, the set K consists of words of a certain fixed length l . In this case, we shall refer to K as a *code of length l*.

A mapping $\alpha : \Sigma^* \rightarrow \Sigma^*$ is called a *morphism* (*antimorphism*) of Σ^* if $\alpha(uv) = \alpha(u)\alpha(v)$ (respectively $\alpha(uv) = \alpha(v)\alpha(u)$) for all $u, v \in \Sigma^*$. Note that a morphism or an antimorphism of Σ^* are completely defined if we define their values on the letters of Σ .

If for a morphism α , $\alpha(a) \neq \lambda$ for each $a \in V$, then α is said to be λ -*free*. A *projection* associated to Σ is a morphism $pr_\Sigma : (V \cup \Sigma)^* \rightarrow \Sigma^*$ such that $pr_\Sigma(a) = a$ for all $a \in \Sigma$ and $pr_\Sigma(b) = \lambda$ otherwise. A morphism $h : V^* \rightarrow \Sigma^*$ is called a *coding* if $h(a) \in \Sigma$ for all $a \in V$ and *weak coding* if $h(a) \in \Sigma \cup \{\lambda\}$ for all $a \in V$. For a family of languages FL , one can denote by $\text{Cod}(FL)$ (respectively $\text{wcod}(FL)$) the family of languages of the form $h(L)$, for $L \in FL$ and h a coding (respectively weak coding).

The *equality set* of two morphisms $h_1, h_2 : V^* \rightarrow \Sigma^*$ is defined as

$$\text{EQ}(h_1, h_2) = \{w \in V^* \mid h_1(w) = h_2(w)\}$$

An *involution* $\theta : \Sigma \rightarrow \Sigma$ of Σ is a mapping such that θ^2 is equal to the identity mapping, that is, $\theta(\theta(x)) = x$ for all $x \in \Sigma$. It follows then that an involution θ is bijective and $\theta = \theta^{-1}$. The identity mapping is a trivial example of an involution. An involution of Σ can be extended to either a morphism or an antimorphism of Σ^* . For example, if the identity of Σ is extended to a morphism of Σ^* , we obtain the identity involution of Σ^* . However, if the identity of Σ is extended to an antimorphism of Σ^* we obtain instead the mirror-image involution of Σ^* that maps each word u into u^R where

$$u = a_1 a_2 \dots a_k, \quad u^R = a_k \dots a_2 a_1, \quad a_i \in \Sigma, \quad 1 \leq i \leq k$$

A word w that is equal to its reverse w^R is called a *palindrome*. If we consider the DNA alphabet Δ , then the mapping $\tau : \Delta \rightarrow \Delta$ defined by $\tau(A) = T, \tau(T) = A, \tau(C) = G, \tau(G) = C$ can be extended in the usual way to an antimorphism of Δ^* that is also an involution of Δ^* . This involution formalizes the notion of Watson–Crick complementarity and will therefore be called the *DNA involution* (Kari et al. 2002).

5.2 Intramolecular Bond (Hairpin) Analysis

In this section, we focus on mathematical properties of DNA hairpins and their importance in DNA encodings. A *DNA hairpin* is a particular type of DNA secondary structure illustrated in [Fig. 10](#).

Hairpin-like secondary structures play an important role in insertion/deletion operations with DNA. Hairpin-freeness is crucial in the design of primers for the PCR reaction. Among numerous applications of hairpins in DNA computing only the Whiplash PCR computing techniques (Rose et al. 2002) and the DNA RAM (see the chapter [DNA Memory](#) in this handbook) are mentioned. The reader is referred, for example, to Kijima and Kobayashi (2006), Kobayashi (2005), and Mauri and Ferretti (2004) for a characterization and design of tube languages with or without hairpins. Coding properties of hairpin-free languages were studied in Jonoska et al. (2002) and Jonoska and Mahalingam (2004). A language-theoretical characterization of hairpins and hairpin languages was given in Păun et al (2001). Hairpins have also been studied in the context of bio-operations occurring in single-celled organisms. For example, the operation of hairpin inversion was defined as one of the three molecular operations that accomplish gene assembly in ciliates (Daley et al. 2003, 2004; Ehrenfeucht et al. 2004). Applications of hairpin structures in biocomputing and bio-nanotechnology are discussed in the chapter [Molecular Computing Machineries — Computing Models and Wet Implementations](#) in this handbook.

The following definition formally specifies hairpin as a structure described in [Fig. 10](#), whose stem consists of at least k base pairs. This condition is motivated by the fact that a hairpin with shorter stem is less stable. An oligonucleotide that does not satisfy this condition is said to be hairpin-free.

Definition 1 (Jonoska et al. 2002; Kari et al. 2006) Let θ be a (morphic or antimorphic) involution of Σ^* and k be a positive integer. A word $u \in \Sigma^*$ is said to be θ - k -hairpin-free or simply $hp(\theta, k)$ -free if $u = xvy\theta(v)z$ for some $x, v, y, z \in \Sigma^*$ implies $|v| < k$.

We denote by $hpf(\theta, k)$ the set of all $hp(\theta, k)$ -free words in Σ^* . The complement of $hpf(\theta, k)$ is the set of all hairpin-forming words over Σ and is denoted by $hp(\theta, k) = \Sigma^* \setminus hpf(\theta, k)$. Observe that $hp(\theta, k+1) \subseteq hp(\theta, k)$ for all $k > 0$. A language L is said to be θ - k -hairpin-free or simply $hp(\theta, k)$ -free if $L \subseteq hpf(\theta, k)$.

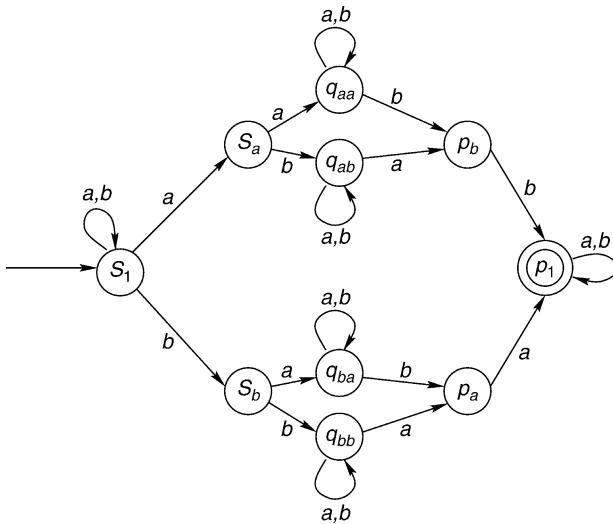

[Fig. 10](#)

A single-stranded DNA molecule forming a hairpin loop.

Fig. 11

An NFA accepting the language $hp(\theta, 2)$ over the alphabet $\{a, b\}$, where the antimorphism is defined as $\theta(a) = b$ and $\theta(b) = a$.

Example 1 Let $\theta = \tau$, the DNA involution over Δ^* . Then

$$hpf(\theta, 1) = \{A, C\}^* \cup \{A, G\}^* \cup \{T, C\}^* \cup \{T, G\}^*$$

In the version of Definition 1 given in Jonoska et al. (2002), a θ - k -hairpin-free language was called θ -subword- k -code. The authors focused on their coding properties and relations to other types of codes. A restriction on the length of the loop of a hairpin was also considered: $1 \leq |y| \leq m$ for some $m \geq 1$. Most of the results mentioned in this section remain valid if this additional restriction is considered.

Theorem 1 (Păun et al. 2001) *The languages $hp(\theta, k)$ and $hpf(\theta, k)$, $k \geq 1$, are regular.*

Figure 11 illustrates a nondeterministic finite automaton (NFA) accepting the language $hp(\theta, 2)$ over the alphabet $\{a, b\}$ where $\theta(a) = b$ and $\theta(b) = a$. Given the above characterization of $hp(\theta, k)$ and $hpf(\theta, k)$, the following result is rather immediate.

Theorem 2 (Kari et al. 2006) *The following problem is decidable in linear (or cubic, respectively) time with respect to (w.r.t.) $|M|$:*

Input: A nondeterministic regular (pushdown, respectively) automaton M
Output: Yes/No depending on whether $L(M)$ is $hp(\theta, k)$ -free

The *maximality problem* of hairpin-free languages is stated as follows: can a given language $L \subseteq \Sigma^*$, satisfying a certain property (e.g., to be a hairpin-free language), be still extended without loss of this property? Formally, a language $L \subseteq \Sigma^*$ satisfying a property \mathcal{P} is said to be

maximal with respect to \mathcal{P} iff $L \cup \{w\}$ does not satisfy \mathcal{P} for any $w \in M \setminus L$, where M is a fixed library of available strands.

Theorem 3 (Kari et al. 2006) *The following problem is decidable in time $\Theta(|M_1| \cdot |M_2|)$ (or $\Theta(|M_1| \cdot |M_2|^3)$, respectively):*

Input: A positive integer k , a deterministic finite (pushdown, respectively) automaton M_1 accepting a $hp(\theta, k)$ -free language, and an NFA M_2

Output: Yes/No depending on whether there is a word $w \in L(M_2) \setminus L(M_1)$ such that $L(M_1) \cup \{w\}$ is $hp(\theta, k)$ -free

For hairpin-free languages, it is relatively straightforward to solve the *optimal negative design problem*: to construct a set of hairpin-free DNA words of a given size, where the words can be chosen from a certain library. All the hairpin-free sets are subsets of $hpf(\theta, k)$. For example, if the length of the desired DNA words equals a constant ℓ , the optimal hairpin-free set is simply $hpf(\theta, k) \cap \Sigma^\ell$. Due to Theorem 1, the set $hpf(\theta, k)$ is regular and hence can be accepted by a finite automaton. The size of the automaton, however, grows exponentially with respect to k .

Theorem 4 (Kari et al. 2006) *Consider the DNA alphabet $\Delta = \{A, C, T, G\}$ and the DNA involution τ .*

- (i) *The size of a minimal NFA accepting $hp(\tau, k)$ is at most 15×4^k . The number of its states is between 4^k and 3×4^k .*
- (ii) *The number of states of either a minimal deterministic finite automaton (DFA) or an NFA accepting $hpf(\tau, k)$ is between $2^{2^{k-1}}$ and $2^{3 \times 2^k}$.*

The reader is referred to Kari et al. (2006) for a generalization of the above theorem for the case of an arbitrary alphabet and arbitrary involution. The construction of the automaton is illustrated in Fig. 11 for the case of alphabet $\{a, b\}$ and an antimorphism θ , where $\theta(a) = b$ and $\theta(b) = a$.

Problems analogous to Theorems 1–4 have been studied also in the case of *scattered hairpins* and *hairpin frames* that represent more complex but rather common types of intramolecular hybridization. The definition of scattered hairpins covers structures like the one described in Fig. 12.

Definition 2 (Kari et al. 2006) *Let θ be an involution of Σ^* and let k be a positive integer. A word $u = wy$, for $u, w, y \in \Sigma^*$, is θ - k -scattered-hairpin-free or simply $shp(\theta, k)$ -free if for all $t \in \Sigma^*$, $t \leq_e w$, $\theta(t) \leq_e y$ implies $|t| < k$.*

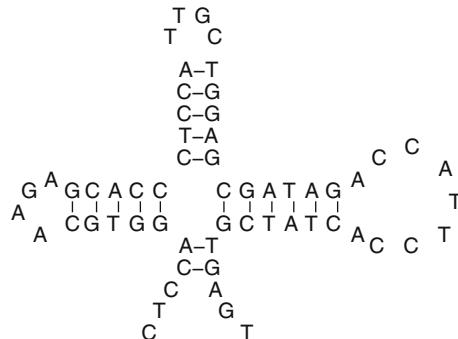

Fig. 12

An example of a scattered hairpin – a word in $shp(\tau, 11)$.

Fig. 13

An example of a hairpin frame.

Similarly, the following definition of hairpin frames characterizes secondary structures containing several complementary sequences such as that in Fig. 13.

Definition 3 (Kari et al. 2006) The pair $(v, \theta(v))$ in a word u of the form $u = xvy\theta(v)z$, for $x, v, y, z \in \Sigma^*$, is called an hp-pair of u . The sequence of hp-pairs $(v_1, \theta(v_1)), (v_2, \theta(v_2)), \dots, (v_j, \theta(v_j))$ of the word u in the form:

$$u = x_1 v_1 y_1 \theta(v_1) z_1 x_2 v_2 y_2 \theta(v_2) z_2 \cdots x_j v_j y_j \theta(v_j) z_j$$

is called an hp-frame of degree j of u or simply an $\text{hp}(j)$ -frame of u .

Several other studies have been published, focusing on formal-language aspects of the hairpin formation. A complete characterization of the syntactic monoid of the language consisting of all hairpin-free words over a given alphabet was given in Kari et al. (2007). Manea et al. (2009) described formal language operations of hairpin completion and reduction and studied their closure and other mathematical properties. DNA trajectories – a new formal tool for description of scattered hairpins – were presented in Domaratzki (2007), where also complexity of the set of hairpin-free words described by a set of DNA trajectories and closure properties of hairpin language classes were studied. Hairpin finite automata with the ability to apply the hairpin inversion operation to the remaining part of the input were introduced in Bordihn et al. (2007). The authors studied the power of hairpin-inspired operations and the resulting language classes. Finally, Kari and Seki (2009) focused on a related secondary structure based on intramolecular bonds – *pseudoknots* (see also Dirks and Pierce (2004) for more information on pseudoknots). The authors provided mathematical formalization of pseudoknots and obtained several properties of pseudoknot-bordered and -unbordered words.

5.3 How to Avoid DNA Intermolecular Bonds

In this section, several properties of a tube language $L \subseteq \Sigma^+$, which prohibit various types of undesired hybridizations between two DNA strands, are formally characterized. Many authors

assume, for simplicity, that hybridization occurs only between those parts of single-stranded DNA molecules that are perfectly complementary. The following language properties have been considered in Hussini et al. (2003) and Kari et al. (2002, 2003).

- (A) **θ -Nonoverlapping:** $L \cap \theta(L) = \emptyset$
- (B) **θ -Compliant:** $\forall w \in L, x, y \in \Sigma^*, w, x\theta(w)y \in L \Rightarrow xy = \lambda$
- (C) **θ -p-Compliant:** $\forall w \in L, y \in \Sigma^*, w, \theta(w)y \in L \Rightarrow y = \lambda$
- (D) **θ -s-Compliant:** $\forall w \in L, y \in \Sigma^*, w, y\theta(w) \in L \Rightarrow y = \lambda$
- (E) **Strictly θ -compliant:** both θ -compliant and θ -nonoverlapping
- (F) **θ -Free:** $L^2 \cap \Sigma^+ \theta(L) \Sigma^+ = \emptyset$
- (G) **θ -Sticky-free:** $\forall w \in \Sigma^+, x, y \in \Sigma^*, wx, y\theta(w) \in L \Rightarrow xy = \lambda$
- (H) **θ -3'-Overhang-free:** $\forall w \in \Sigma^+, x, y \in \Sigma^*, wx, \theta(w)y \in L \Rightarrow xy = \lambda$
- (I) **θ -5'-Overhang-free:** $\forall w \in \Sigma^+, x, y \in \Sigma^*, xw, y\theta(w) \in L \Rightarrow xy = \lambda$
- (J) **θ -Overhang-free:** both θ -3'-overhang-free and θ -5'-overhang-free

For convenience, we agree to say that a language L containing the empty word has one of the above properties if $L \setminus \{\lambda\}$ has that property. Observe that (F) avoids situations like Fig. 9c, while other properties exclude special cases of Fig. 9b.

In Jonoska and Mahalingam (2004), a θ -nonoverlapping language was said to be *strictly θ* . Generally, if any other property holds in conjunction with (A), we add the qualifier *strictly*. This notation has already been used for the property (E). Both *strict* and *non-strict* properties turn out to be useful in certain situations.

For example, a common way to check for the presence of a certain single-stranded molecule w is to add to the solution its complement $\tau(w)$, and use enzymes to destroy any molecules that are not fully double stranded. Simultaneously, we want to prevent all other hybridizations except w and $\tau(w)$. This condition is equivalent to testing whether the whole solution, including w and $\tau(w)$, is non-strictly bond-free (exact matches are allowed).

Further properties have been defined in Jonoska and Mahalingam (2004) for a language L . Observe that the property (K) below avoids bonds like those in Fig. 9a, with a restricted length of the loop part:

- (K) **$\theta(k, m_1, m_2)$ -Subword compliant:** $\forall u \in \Sigma^k, \Sigma^* u \Sigma^m \theta(u) \Sigma^* \cap L = \emptyset$ for $k > 0, m_1 \leq m \leq m_2$
- (L) **θ -k-Code:** $\text{Sub}_k(L) \cap \text{Sub}_k(\theta(L)) = \emptyset, k > 0$

The property (L) was also considered implicitly in Baum (1998) and Feldkamp et al. (2002). In particular, Baum (1998) considered tube languages of the form $(sZ)^+$ satisfying (L), where s is a fixed word of length k and Z is a code of length k – the notation sZ represents the set of all words sz such that z is in Z .

The following property was defined for $\theta = I$, the identity relation, in Head (2000). A language L is called

- (M) **solid** if
 1. $\forall x, y, u \in \Sigma^*, u, xuy \in L \Rightarrow xy = \lambda$ and
 2. $\forall x, y \in \Sigma^*, u \in \Sigma^+, xu, uy \in L \Rightarrow xy = \lambda$

L is *solid relative* to a language $M \subseteq \Sigma^*$ if 1 and 2 above must hold only when there are $p, q \in \Sigma^*$ such that $pxuyq \in M$. L is called *comma-free* if it is solid relative to L^* . Solid languages were also used in Kari et al. (2003) as a tool for constructing error-detecting tube languages that were invariant under bio-operations.

Fig. 14

Classes of tube languages free of certain types of undesired hybridization.

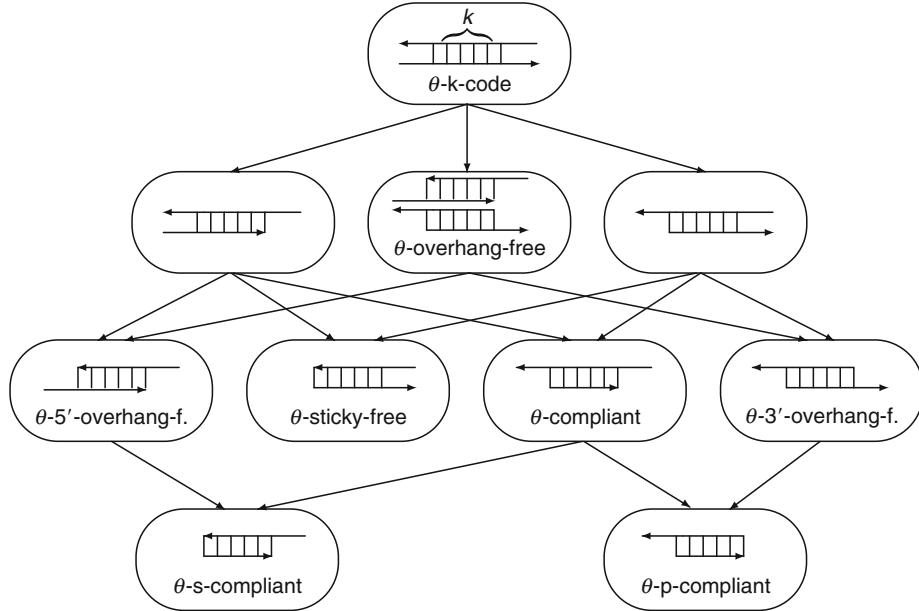

Figure 14 shows the hierarchy of some of the above language properties. Arrows stand for inclusion relations among language classes satisfying these properties.

Example 2 (Kari et al. 2005b) Consider the language $L = \{A^nT^n \mid n \geq 1\} \subset \Delta^+$, and the DNA involution τ . Observe that $\tau(L) = L$. We can deduce that L is:

- Neither τ -nonoverlapping, nor τ - k -code for any $k \geq 1$
- Not τ -compliant, as for $w = A^nT^n$, $x = A$, $y = T$ we have $w, xt(w)y \in L$
- τ - p -Compliant, as $w, \theta(w)y \in L$ implies $w = A^nT^n$, $y = \lambda$; similarly, L is τ - s -compliant
- Not τ -free, as $A^nT^nA^mT^m$, $n, m > 1$, is both in L^2 and in $\Delta^+L\Delta^+$
- Not τ -sticky-free, as for $w = y = A^n$. $x = T^n$ we have $wx, \tau(w)y \in L$
- τ - $3'$ -Overhang-free, as $wx, \tau(w)y \in L$ implies $w = A^nT^n$, $x = T^{n-m}$, $y = T^{m-n}$ and hence $xy = \lambda$; similarly, L is τ - $5'$ -overhang-free and hence τ -overhang-free
- Not $\theta(k, m_1, m_2)$ -subword compliant for any k, m_1, m_2

For further details and relations between the above listed DNA language properties the reader is referred to Jonoska and Mahalingam (2004) and Kari et al. (2003, 2005b).

To establish a common framework allowing us to handle various types of unwanted hybridization in a uniform way, it is necessary to introduce the generalizing concept of word operations on trajectories. Consider a *trajectory alphabet* $V = \{0, 1\}$ and assume $V \cap \Sigma = \emptyset$. We call any string $t \in V^*$ a *trajectory*. A trajectory is essentially a syntactical condition that specifies how a binary word operation is applied to the letters of its two operands. Let $t \in V^*$ be a trajectory and let α, β be two words over Σ .

Definition 4 (Mateescu et al. 1998) The shuffle of α with β on a (fixed) trajectory t , denoted by $\alpha \sqcup \sqcup_t \beta$, is the following binary word operation:

$$\alpha \sqcup \sqcup_t \beta = \{ \alpha_1 \beta_1 \dots \alpha_k \beta_k \mid \alpha = \alpha_1 \dots \alpha_k, \beta = \beta_1 \dots \beta_k, t = 0^{i_1} 1^{j_1} \dots 0^{i_k} 1^{j_k}, \\ \text{where } |\alpha_m| = i_m \text{ and } |\beta_m| = j_m \text{ for all } m, 1 \leq m \leq k \}.$$

Example 3 Let $\alpha = a_1 a_2 \dots a_8$, $\beta = b_1 b_2 \dots b_5$ and assume that $t = 0^3 1^2 0^3 1 0 1 0 1$. The shuffle of α and β on the trajectory t is:

$$\alpha \sqcup \sqcup_t \beta = \{ a_1 a_2 a_3 b_1 b_2 a_4 a_5 a_6 b_3 a_7 b_4 a_8 b_5 \}$$

Observe that the result of the operation is generally a set of words, though in the case of shuffle on trajectory it is always a singleton or the empty set. Notice also that $\alpha \sqcup \sqcup_t \beta = \emptyset$ if $|\alpha| \neq |t|_0$ or $|\beta| \neq |t|_1$.

A set of trajectories is any set $T \subseteq V^*$. The shuffle of α with β on the set T , denoted by $\alpha \sqcup \sqcup_T \beta$, is

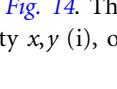

$$\alpha \sqcup \sqcup_T \beta = \bigcup_{t \in T} \alpha \sqcup \sqcup_t \beta \quad (1)$$

The shuffle on (sets of) trajectories generalizes several traditional word operations. Let, for example, $T = 0^* 1^*$. Then $\sqcup \sqcup_T = \cdot$, the operation of catenation.

To characterize the properties of tube languages described above, we define formally a *property* \mathcal{P} as a mapping $\mathcal{P} : 2^{\Sigma^*} \rightarrow \{\text{true, false}\}$. We say that a language L has (or satisfies) the property \mathcal{P} if $\mathcal{P}(L) = \text{true}$. The next definition introduces a general concept of *bond-free property* that covers surprisingly many types of undesired bonds studied in the literature.

Definition 5 (Kari et al. 2005b) Consider a language property \mathcal{P} . Let there be binary word operations \diamond_{lo} , \diamond_{up} and an involution θ such that for an arbitrary $L \subseteq \Sigma^*$, $\mathcal{P}(L) = \text{true}$ iff

- (i) $\forall w \in \Sigma^+, x, y \in \Sigma^* ((w \diamond_{\text{lo}} x) \cap L \neq \emptyset, (\theta(w) \diamond_{\text{up}} y) \cap L \neq \emptyset) \Rightarrow xy = \lambda$, then \mathcal{P} is called a bond-free property (of degree 2)
- (ii) $\forall w, x, y \in \Sigma^* ((w \diamond_{\text{lo}} x) \cap L \neq \emptyset, (\theta(w) \diamond_{\text{up}} y) \cap L \neq \emptyset) \Rightarrow w = \lambda$, then \mathcal{P} is called a strictly bond-free property (of degree 2)

If not stated otherwise, we assume in the sequel that $\diamond_{\text{lo}} = \sqcup \sqcup_{T_{\text{lo}}}$ and $\diamond_{\text{up}} = \sqcup \sqcup_{T_{\text{up}}}$ for some sets of trajectories $T_{\text{lo}}, T_{\text{up}}$. Intuitively, w and $\theta(w)$ represent two complementary oligonucleotides. Then $w \sqcup \sqcup_{T_{\text{lo}}} x$ and $\theta(w) \sqcup \sqcup_{T_{\text{up}}} y$ represent two DNA single strands, which could form a double-stranded DNA molecule with blunt ends, depicted in  Fig. 14. The bond-free property \mathcal{P} guarantees that $w \sqcup \sqcup_{T_{\text{lo}}} x$ and $\theta(w) \sqcup \sqcup_{T_{\text{up}}} y$ with nonempty x, y (i), or w (ii), cannot simultaneously exist in L .

Theorem 5 (Kari et al. 2005b)

- (i) The language properties (B), (C), (D), (G), (H), (I), (M.1), (M.2) are bond-free properties.
- (ii) The language properties (A), strictly (B)–(D), strictly (G)–(I), (L), strictly (L) are strictly bond-free properties.

Moreover, in both cases, the associated sets of trajectories $T_{\text{lo}}, T_{\text{up}}$ are regular.

Proof Let θ be an antimorphism and let the sets of trajectories $T_{\text{lo}}, T_{\text{up}}$ corresponding to the listed bond-free properties be

- (A) $T_{\text{lo}} = T_{\text{up}} = 0^+$
- (B) $T_{\text{lo}} = 0^+, T_{\text{up}} = 1^*0^+1^*$
- (C) $T_{\text{lo}} = 0^+, T_{\text{up}} = 0^+1^*$
- (D) $T_{\text{lo}} = 0^+, T_{\text{up}} = 1^*0^+$
- (G) $T_{\text{lo}} = 0^+1^*, T_{\text{up}} = 1^*0^+$
- (H) $T_{\text{lo}} = 0^+1^*, T_{\text{up}} = 0^+1^*$
- (I) $T_{\text{lo}} = 1^*0^+, T_{\text{up}} = 1^*0^+$
- (L) $T_{\text{lo}} = T_{\text{up}} = 1^*0^k1^*$
- (L) strictly: $T_{\text{lo}} = T_{\text{up}} = 1^*0^k1^* \cup 0^+$

If θ is a morphism, one can similarly define

- (M.1) $T_{\text{lo}} = 0^*, T_{\text{up}} = 1^*0^*1^*$
- (M.2) $T_{\text{lo}} = 1^*0^+, T_{\text{up}} = 0^+1^*$

Consider, for example, the property (H), θ -3'-overhang-freedom. Then $w \sqcup \sqcup_{T_{\text{lo}}} x = \{wx\}$ and $\theta(w) \sqcup \sqcup_{T_{\text{up}}} y = \{\theta(w)y\}$. The relations in [Definition 5](#) (i) take the form $wx \in L, \theta(w)y \in L$ that corresponds to the definition of (H) above. The proofs of the other mentioned properties are analogous.

Observe that $T_{\text{lo}}, T_{\text{up}}$ for a certain property correspond to the “shape” of the bonds prohibited in languages satisfying the property. The above theorem allows for a general characterization of bond-free properties via a solution of an *unique* language inequation in Kari et al. ([2005b](#)). As a consequence, the following result can be obtained.

Theorem 6 (Kari et al. [2005b](#)) *Let \mathcal{P} be a (strictly) bond-free property associated with regular sets of trajectories $T_{\text{lo}}, T_{\text{up}}$. Then the following problem is decidable in quadratic time with respect to $|A|$:*

Input: an NFA A

Output: Yes/No depending on whether $L(A)$ satisfies \mathcal{P}

By [Theorem 5](#), the above result applies to the properties (A) – (D), (G) – (J), (M), strictly (B) – strictly (D), strictly (G) – strictly (J), (L), strictly (L), in the case of regular languages, on one hand. On the other hand, for a given context-free language L it is undecidable whether it satisfies certain bond-free properties, for example, (B) and (F).

Theorem 7 (Hussini et al. [2003](#)) *The following problem is undecidable.*

Input: A bond-free property \mathcal{P} associated with regular sets of trajectories $T_{\text{lo}}, T_{\text{up}}$, and a context-free language L

Output: Yes/No depending on whether $\mathcal{P}(L) = \text{true}$

An important problem studied in the literature is the *optimal negative design problem*: How to construct a non-crosshybridizing set (i.e., a set of single-stranded molecules which do not mutually hybridize) of a certain required size, given a fixed library of available molecules. In general, even to decide whether such a *finite* set exists is an NP-complete problem and its equivalence with the maximal independent set problem can be easily shown

(Deaton et al. 2003). Various heuristics were used to find a nearly optimal solution (Phan and Garzon 2008). Here we focus on a similar but in some cases easier *maximality problem* defined formally in [Sect. 5.2](#).

Theorem 8 (Kari et al. 2005b) *Let $M \subseteq \Sigma^+$ be a regular set of words, and $L \subseteq M$ a regular language satisfying a bond-free property \mathcal{P} .*

- (a) *Let θ be an antimorphism and let \mathcal{P} be one of the properties (B), (C), (D), (G), strictly (B) – strictly (D), strictly (G), (L), strictly (L), or*
- (b) *Let θ be a morphism and let \mathcal{P} be one of the properties (B), (C), (D), (H), (I), strictly (B) – strictly (D), strictly (H), strictly (I), (L), strictly (L).*

Then there is an algorithm deciding whether there is a $w \in M \setminus L$ such that $L \cup \{w\}$ satisfies \mathcal{P} .

Algorithms deciding the maximality of these properties can require an exponential time with respect to the size of an NFA accepting L . The same holds when we want to construct a maximal regular set of DNA strands satisfying these bond-free properties. In two important cases, however, a polynomial time can be achieved (Kari et al. 2005b): (1) for maximality of *regular* nonoverlapping sets satisfying the property (A), and (2) for maximality of *finite θ -compliant* sets satisfying the property (B).

5.4 Preventing Imperfect DNA–DNA Bonds

In [Sects. 5.2](#) and [5.3](#), properties of DNA codes are presented based on the assumption that hybridization binds only two perfectly WK complementary single-stranded DNA molecules. In reality, however, thermodynamical laws allow for hybridization also in cases of some “roughly” complementary molecules with certain irregularities in the WK complementarity sense. This section describes properties of languages that ensure that even such imperfect bindings can be described and eventually prevented.

As already mentioned, the negative design problem is rather computationally expensive when using thermodynamical methods. Various approximative methods using discrete similarity metrics have been therefore studied. In Marathe et al. (2001) and Tulpan et al. (2003), the authors considered codes K of length k satisfying the following property ($H(u, v)$ is the Hamming distance, i.e., the number of mismatches at corresponding positions, between words u and v of the same length).

X[d, k]: If u and v are any codewords in K then $H(u, \tau(v)) > d$.

In fact the above property is studied in conjunction with the uniqueness property $H(K) > d$ – here $H(K)$ is the smallest Hamming distance between any two different words in K .

Garzon et al. (1997) introduced the H -measure based on Hamming distance for two words x and y of length k and explained how this measure can be used to encode instances of the HPP. This measure was also used in Garzon et al. (2006) to search optimal codes for DNA computing using the shuffle operation on DNA strands. A similar measure was defined in Arita (2004) and Arita and Kobayashi (2002) extending the work of Frutos et al. (1997) and was applied to codes of length k whose words can be concatenated in arbitrary ways. Thus, the tube language here was $L = K^+$. The code K satisfied certain uniqueness conditions. In particular, the tube language $L = K^+$ satisfied the following property.

Y[d, k]: If x is a subword of L of length k and v is a codeword in K then $H(x, \tau(v)) > d$.

This property was considered also in Reif et al. (2002) for tube languages of the form $K_1 K_2 \dots K_m$ where each K_i is a certain code of length k .

Finally, Kari et al. (2005a) introduced the following property of a tube language L , motivated by the fact that the above defined properties \mathbf{X} , \mathbf{Y} still allow for certain types of undesired bonds between DNA codewords.

$\mathbf{Z}[d,k]$: If x and y are any subwords of L of length k then $H(x, \tau(y)) > d$.

The reader can observe that the property \mathbf{X} is a generalization of (A) from the previous section. Similarly, \mathbf{Y} is a generalization of (B) and \mathbf{Z} generalizes (L). Note that any set L satisfying property $\mathbf{Z}[d,k]$ also satisfies $\mathbf{Y}[d,k]$. Further relations among different bond-free properties using similarity measures were studied in Kari et al. (2005a).

The choice of the Hamming distance in the condition $H(x, \tau(y)) \leq d$ for *similarity* between words is a very natural one and has attracted a lot of interest in the literature. One might argue, however, that parts of two DNA molecules could form a stable bond even if they have different lengths. In Fig. 15, for example, the bound parts of the two molecules have lengths 10 and 9. Such hybridizations (and even more complex ones) were addressed in Andronescu et al. (2003). Based on this observation, the condition for two subwords x and y to bind together should be

$$|x|, |y| \geq k \quad \text{and} \quad \text{Lev}(x, \tau(y)) \leq d$$

The symbol $\text{Lev}(u, v)$ denotes the *Levenshtein distance* between the words u and v – this is the smallest number of substitutions, insertions, and deletions of symbols required to transform u into v .

To establish a general framework that would cover both the similarity measure H , Lev and possibly also others, Kari et al. (2005a) considered a general binary relation γ on words over Σ , that is, a subset of $\Sigma^* \times \Sigma^*$. The expression “ (u, v) is in γ ” can be rephrased as “ $\gamma(u, v)$ is true” when γ is viewed as a logic predicate. A binary relation is called *rational* if it can be realized by a finite transducer.

Definition 6 (Kari et al. 2005a) A binary relation sim is called a *similarity relation* with parameters (t, l) , where t and l are nonnegative integers, if the following conditions are satisfied.

- (i) If $\text{sim}(u, v)$ is true then $\text{abs}(|u| - |v|) \leq t$, where abs is the absolute value function.
- (ii) If $\text{sim}(u, v)$ is true and $|u|, |v| > l$ then there are proper subwords x and y of u and v , respectively, such that $\text{sim}(x, y)$ is true.

We can interpret the above conditions as follows: (1) the lengths of two similar words cannot be too different and (2) if two words are similar and long enough, then they contain two similar proper subwords.

The notation $H_{d,k}$ shall be used for the relation “ $|u|, |v| \geq k$ and $H(u, v) \leq d$ ”, and $\text{Lev}_{d,k}$ for “ $|u|, |v| \geq k$ and $\text{Lev}(u, v) \leq d$ ”. It is evident that the $H_{d,k}$ is an example of a rational similarity

Fig. 15

Two DNA molecules in which the parts 5' – AAGCGTTCGA – 3' and 5' – TCGGACGTT – 3' bind together although these parts have different lengths.

relation with parameters $(0, k)$. It is also easy to show that $Lev_{d,k}$ is a rational similarity relation as well, with parameters $(d, d + k)$.

Based on the above definition, for any similarity relation $\text{sim}(\cdot, \cdot)$ between words and for every involution θ , we define the following property of a language L with strong mathematical properties.

P[θ , sim]: If x and y are any nonempty subwords of L then $\text{sim}(x, \theta(y))$ is false.

Any language satisfying **P[θ , sim]** is called a (θ, sim) -bond-free language. Although this property seems to be quite general and covering many possible situations, it can be shown that it is only a special case of the strict bond-freeness defined in [Sect. 5.3](#).

Theorem 9 (Kari et al. 2005a) **P[θ , sim]** is a strictly bond-free property.

Proof The mappings sim_L and sim_R are defined as follows:

$$\begin{aligned}\text{sim}_L(y) &= \{x \in \Sigma^* \mid \text{sim}(x, y)\} \\ \text{sim}_R(x) &= \{y \in \Sigma^* \mid \text{sim}(x, y)\}\end{aligned}$$

Recall that a language L is (θ, sim) -bond-free iff

$$\begin{aligned}\forall x_1, y_1, x_2, y_2 \in \Sigma^*, w_1, w_2 \in \Sigma^+ \\ (x_1 w_1 y_1, x_2 w_2 y_2 \in L) \Rightarrow \text{not sim}(w_1, \theta(w_2)) \quad \text{iff} \\ \forall x_1, y_1, x_2, y_2 \in \Sigma^*, w_1, w_2 \in \Sigma^+ \\ (x_1 w_1 y_1, x_2 \theta(w_2) y_2 \in L) \Rightarrow \text{not sim}(w_1, w_2) \quad \text{iff} \\ \forall x_1, w_1, y_1, x_2, w_2, y_2 \in \Sigma^* \\ (x_1 w_1 y_1, x_2 \theta(w_2) y_2 \in L, w_2 \in \text{sim}_R(w_1)) \Rightarrow (w_1 = \lambda \text{ or } w_2 = \lambda) \quad \text{iff} \\ \forall x_1, y_1, x_2, y_2, w \in \Sigma^* \\ (\{x_1 w y_1\} \cap L \neq \emptyset, \{x_2\} \cdot \theta(\text{sim}_R(w) \cap \Sigma^+) \cdot \{y_2\} \cap L \neq \emptyset) \Rightarrow w = \lambda \quad \text{iff} \\ \forall x, y, w \in \Sigma^* \\ (w \sqcup_T x \cap L \neq \emptyset, \theta(\text{sim}_R(w)) \sqcup_T y \cap L \neq \emptyset) \Rightarrow w = \lambda\end{aligned}$$

where $T = 1^* 0^+ 1^*$.

Therefore, an expression corresponding to the definition of strictly bond-free property has been obtained. Notice that results analogous to [Theorem 9](#) could be proved also for the properties $X[d,k]$, $Y[d,k]$, and $Z[d,k]$. Observe, furthermore, that the operation on words w and y defined as $\theta(\text{sim}_R(w)) \sqcup_T y$ is “almost” \sqcup_T , and hence some results from [Sect. 5.3](#) are applicable in the case of (θ, sim) -bond-free languages, provided that the relation sim is “reasonable.”

Theorem 10 (Kari et al. 2005a) Let sim be a rational relation. The following problem is decidable in quadratic time with respect to $|A|$.

Input: An NFA A

Output: YES/NO, depending on whether $L(A)$ is a (θ, sim) -bond-free language

For the case where sim is one of the similarity relations $H_{d,k}$ or $Lev_{d,k}$ the algorithm runs at time $\mathcal{O}(dk|A|^2)$ (or $\mathcal{O}(dk^2|A|^2)$, respectively). The (θ, sim) -bond-freeness remains decidable

even in the case of context-free tube languages, although the existence of a polynomial-time algorithm cannot be guaranteed.

Two problems related to the design of large sets of bond-free molecules, the *optimal negative design problem* and the *maximality problem* have been addressed, too. Both were formally specified in previous sections. The optimal negative design problem remains NP complete even for *finite* tube languages in the case of various similarity metrics. The problem of maximality of *regular* (θ, sim) -bond-free languages has been shown decidable in Kari et al. (2005a), although the existence of a polynomial-time algorithm cannot be generally guaranteed. However, rather surprisingly, in the important Hamming case such an algorithm exists. One can consider languages that are subsets of $(\Sigma^k)^+$, for some positive integer k . We call such languages *k-block languages*. Naturally, any regular k -block language can be represented by a special type of lazy DFA (Wood 1987), which we call a *k-block DFA*.

Theorem 11 (Kari et al. 2005a) *Let d be fixed to be either 0 or 1. The following problem is computable in a polynomial time.*

Input: k -block DFA A such that $L(A)$ is a $(\theta, H_{d,k})$ -bond-free subset of $(\Sigma^k)^+$

Output: YES/NO, depending on whether the language $L(A)$ is maximal with that property.

Moreover, if $L(A)$ is not maximal, output a minimal-length word $w \in (\Sigma^k)^+ \setminus L(A)$ such that $L(A) \cup \{w\}$ is a $(\theta, H_{d,k})$ -bond-free subset of $(\Sigma^k)^+$.

In particular, the time complexity $t(|A|)$ is bounded as follows:

$$t(|A|) = \begin{cases} O(k|A|^3), & \text{if } k \text{ is odd and } d = 0 \\ O(|A|^6), & \text{if } k \text{ is even and } d = 0 \\ O(k^3|A|^6), & \text{if } d = 1 \end{cases}$$

The concept of (θ, sim) -bond-free languages is quite general and could cover also subtler similarity measures than the Hamming or Levenshtein distance. Consider the original nearest-neighbor thermodynamical approach to the hybridization problem (SantaLucia 1998). The calculation of ΔG_{\min} , the minimum free energy among the free energies of all possible secondary substructures that may be formed by the examined DNA sequences, is frequently used to determine the most likely secondary structure that will actually form. Assume secondary substructures of a size limited from above (say, of at most 25 bp), which is reasonable from the practical point of view. One can consider two DNA sequences *similar* if and only if they contain subsequences satisfying the condition $\Delta G_{\min} \geq B$, where B is a threshold value for hybridization energy (the “all or nothing” hybridization model). Such a similarity relation obviously fulfills the conditions of \blacktriangleright Definition 6 and, furthermore, it is rational (even finite). Therefore, for a fixed value of B , the hybridization analysis can possibly benefit from the above mentioned results and rapid algorithms.

We conclude with two examples of a construction of DNA codes in the Hamming case. The first example is based on the method of *k-templates* proposed originally in Arita and Kobayashi (2002). This method allows us to produce codes that are subsets of $(\Sigma^k)^+$.

Theorem 12 (Kari et al. 2005a) *Let I be a nonempty subset of $\{1, \dots, k\}$ of cardinality $m = \lfloor k/2 \rfloor + 1 + \lfloor (d + (k \bmod 2))/2 \rfloor$. Then the language K^+ is $(\tau, H_{d,k})$ -bond-free, where*

$$K = \{v \in \Sigma^k \mid \text{if } i \in I \text{ then } v[i] \in \{A, C\}\}$$

Observe that the size of the code K is $2^m 4^{k-m}$. An advantage of the method of [Theorem 12](#) is that we can construct $(\tau, H_{d,k})$ -bond-free languages with a large ratio d/k .

Another method is based on the operation of *subword closure* K^\otimes of a set $K \subseteq \Sigma^k$

$$K^\otimes = \{w \in \Sigma^* \mid |w| \geq k, \text{Sub}_k(w) \subseteq K\}$$

Denote further $K^\oplus \stackrel{\text{def}}{=} K^\otimes \cap (\Sigma^k)^+$. The following theorem characterizes all maximal $(\tau, H_{d,k})$ -bond-free subsets of $(\Sigma^k)^+$ and $\Sigma^k \Sigma^*$.

Theorem 13 (Kari et al. 2005a) *The class of all maximal $(\tau, H_{d,k})$ -bond-free subsets of $(\Sigma^k)^+$ is finite and equal to*

$$\{K^\oplus \mid K \text{ is a maximal } (\tau, H_{d,k})\text{-bond-free subset of } \Sigma^k\}.$$

The above theorem holds also for subsets of $\Sigma^k \Sigma^*$ if one replaces K^\oplus with K^\otimes . As a consequence, if one constructs a maximal finite subset K of Σ^k satisfying $\tau(K) \cap H_d(K) = \emptyset$, then the language K^\oplus is a maximal $(\tau, H_{d,k})$ -bond-free subset of $(\Sigma^k)^+$. Another implication of [Theorem 13](#) is that all maximal $(\tau, H_{d,k})$ -bond-free subsets of $(\Sigma^k)^+$ or $\Sigma^k \Sigma^*$ are regular.

To conclude, in [Sect. 5](#) several basic types of DNA interaction based on Watson–Crick complementarity are characterized, using the apparatus of formal language and automata theory. Besides its value as a contribution to theoretical computer science, the main application of this research is the description and construction of sets of DNA molecules (called also DNA codes) that are free of certain types of unwanted binding interactions. These codes are especially useful in DNA computing and many other laboratory techniques, which assume that an undesirable hybridization between DNA molecules does not occur. It has been shown that a uniform mathematical characterization exists for many types of DNA bonds, both perfect and imperfect with respect to the WK complementarity principle. This characterization, in turn, implies the existence of effective algorithms for manipulation and construction of these DNA codes.

6 Vectorial Models of DNA-Based Information

In [Sect. 5](#), we saw that formal language theory is a natural tool for modeling, analyzing, and designing “good” DNA codewords that control DNA strand inter- and intramolecular interactions based on Watson–Crick complementarity. This was achieved by formalizing a DNA single-strand in the 5'- 3' orientation as a linear word over the DNA alphabet {A, C, G, T}. A limitation of this representation of DNA single strand as words is that it does not model double-stranded DNA molecules, partially double-stranded DNA molecules (such as DNA strands with sticky ends), or interactions between DNA single strands that may lead to double strands.

This section offers an alternative natural way of representing DNA strands, namely as vectors. A (single, partially double-stranded, or fully double-stranded) DNA molecule is modeled namely by a vector whose first component is a word over the DNA alphabet representing the “top” strand, and the second component is a word over the DNA alphabet representing the “bottom” strand. Using this representation, one can naturally model the operations of annealing and ligation.

We now introduce two computational models that use this representation of DNA strands: a language generating device called *sticker system* ([Sect. 6.1](#)) (Freund et al. 1999; Kari et al.

1998; Păun and Rozenberg 1998), and its automata counterpart, *Watson–Crick automata* (Sect. 6.2) (Freund et al. 1999). A summary of essential results on these topics can be found in Păun et al. (1998).

We start by introducing a vectorial formalism of the notions of DNA single strand, double strand, and partial double strand, as well of the bio-operations of annealing (hybridization) and ligation. Other notions and notations that are used here were defined in Sect. 5.1.

The notion of Watson–Crick complementarity is formalized by a symmetric relation. A relation $\rho \subseteq \Sigma \times \Sigma$ is said to be *symmetric* if for any $a, b \in \Sigma$, $(a, b) \in \rho$ implies $(b, a) \in \rho$. In order to define a symmetric relation ρ , it suffices to specify one of (a, b) and (b, a) as long as we explicitly note that ρ is symmetric.

DNA strands are modeled by 2×1 vectors, wherein the first row corresponds to the “top” DNA strand and the second row corresponds to the “bottom” DNA strand. In this formalism, DNA double strands are modeled as 2×1 vectors in square brackets where the top word is in relation ρ with the bottom word, while DNA single strands are modeled as 2×1 vectors in round brackets where one of the rows is the empty word. More concretely, we write $\begin{bmatrix} a \\ b \end{bmatrix}_\rho$ if two letters a, b are in the relation ρ . Whenever ρ is clear from context, the subscript ρ is omitted. We now define an alphabet of double-stranded columns

$$\Sigma_d = \left[\begin{array}{c} \Sigma \\ \Sigma \end{array} \right]_\rho \cup \left(\begin{array}{c} \Sigma \\ \lambda \end{array} \right) \cup \left(\begin{array}{c} \lambda \\ \Sigma \end{array} \right)$$

where $\left[\begin{array}{c} \Sigma \\ \Sigma \end{array} \right]_\rho = \left\{ \begin{bmatrix} a \\ b \end{bmatrix} \middle| a, b \in \Sigma, (a, b) \in \rho \right\}$, $\left(\begin{array}{c} \Sigma \\ \lambda \end{array} \right) = \left\{ \begin{pmatrix} a \\ \lambda \end{pmatrix} \middle| a \in \Sigma \right\}$, and $\left(\begin{array}{c} \lambda \\ \Sigma \end{array} \right) = \left\{ \begin{pmatrix} \lambda \\ b \end{pmatrix} \middle| b \in \Sigma \right\}$.

The *Watson–Crick domain* associated to Σ and ρ is the set $\text{WK}_\rho(\Sigma)$ defined as $\text{WK}_\rho(\Sigma) = \left[\begin{array}{c} \Sigma \\ \Sigma \end{array} \right]_\rho^*$. An element $\begin{bmatrix} a_1 \\ b_1 \end{bmatrix} \begin{bmatrix} a_2 \\ b_2 \end{bmatrix} \dots \begin{bmatrix} a_n \\ b_n \end{bmatrix} \in \text{WK}_\rho(\Sigma)$ can be written as $\begin{bmatrix} a_1 a_2 \dots a_n \\ b_1 b_2 \dots b_n \end{bmatrix}$ succinctly. Note that $\begin{pmatrix} w_1 \\ w_2 \end{pmatrix}$ means no more than a pair of words w_1, w_2 , whereas $\begin{bmatrix} w_1 \\ w_2 \end{bmatrix}$ imposes that $|w_1| = |w_2|$ and their corresponding letters are complementary in the sense of the relation ρ . Elements of $\text{WK}_\rho(\Sigma)$ are called *complete double-stranded sequences* or *molecules*. Moreover, we denote $\text{WK}_\rho^+(\Sigma) = \text{WK}_\rho(\Sigma) \setminus \{(\lambda, \lambda)\}$.

Note that elements of $\text{WK}_\rho(\Sigma)$ are fully double-stranded. In most DNA computing experiments, for example, Adleman’s first experiment, partially double-stranded DNA, that is, DNA strands with sticky ends, are essential. To introduce sticky ends in the model, let $S(\Sigma) = \left(\begin{array}{c} \lambda \\ \Sigma^* \end{array} \right) \cup \left(\begin{array}{c} \Sigma^* \\ \lambda \end{array} \right)$ be the set of sticky ends. Then we define a set $W_\rho(\Sigma)$ whose elements are molecules with sticky ends at both sides as $W_\rho(\Sigma) = L_\rho(\Sigma) \cup R_\rho(\Sigma) \cup LR_\rho(\Sigma)$, where

$$L_\rho(\Sigma) = S(\Sigma) \text{WK}_\rho(\Sigma)$$

$$R_\rho(\Sigma) = \text{WK}_\rho(\Sigma) S(\Sigma)$$

$$LR_\rho(\Sigma) = S(\Sigma) \text{WK}_\rho^+(\Sigma) S(\Sigma)$$

Note that unlike an element in $L_\rho(\Sigma)$ or $R_\rho(\Sigma)$, elements of $LR_\rho(\Sigma)$ must have at least one “column” $\begin{bmatrix} a \\ b \end{bmatrix}$. Any element of $W_\rho(\Sigma)$ with at least a position $\begin{bmatrix} a \\ b \end{bmatrix}$, $a \neq \lambda$, $b \neq \lambda$, is called a *well-started (double stranded) sequence*. Thus, $LR_\rho(\Sigma)$ is equivalent to the set of all well-started sequences.

Annealing and ligation of DNA molecules can be modeled as a partial operation among elements of $W_\rho(\Sigma)$. A well-started molecule can be prolonged to the right or to the left with another molecule, provided that their sticky ends match. We define “sticking y to the right of x ” operation, denoted by $\mu_r(x, y)$. In a symmetric way, $\mu_\ell(y, x)$ (sticking y to the left of x) is defined. Let $x \in LR_\rho(\Sigma)$ and $y \in W_\rho(\Sigma)$. Being well-started, $x = x_1x_2x_3$ for some $x_1, x_3 \in S(\Sigma)$, $x_2 \in WK_\rho^+(\Sigma)$. Then $\mu_r(x, y)$ is defined as follows (also see Fig. 16):

Case A If y is single-stranded, that is, $y \in S(\Sigma)$, we have the following cases: for $r, p \geq 0$,

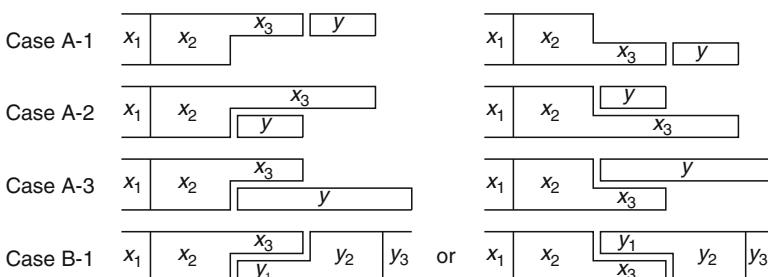

1. If $x_3 = \begin{pmatrix} a_1 \cdots a_r \\ \lambda \end{pmatrix}$ and $y = \begin{pmatrix} a_{r+1} \cdots a_{r+p} \\ \lambda \end{pmatrix}$, then $\mu_r(x, y) = x_1x_2 \begin{pmatrix} a_1 \cdots a_r \\ a_{r+1} \cdots a_{r+p} \end{pmatrix}$.
2. If $x_3 = \begin{pmatrix} a_1 \cdots a_r \\ \lambda \end{pmatrix} \begin{pmatrix} a_{r+1} \cdots a_{r+p} \\ \lambda \end{pmatrix}$, $y = \begin{pmatrix} \lambda \\ b_1 \cdots b_r \end{pmatrix}$, and $(a_i, b_i) \in \rho$ for $1 \leq i \leq r$, then $\mu_r(x, y) = x_1x_2 \begin{pmatrix} a_1 \cdots a_r \\ b_1 \cdots b_r \end{pmatrix} \begin{pmatrix} a_{r+1} \cdots a_{r+p} \\ \lambda \end{pmatrix}$.
3. If $x_3 = \begin{pmatrix} a_1 \cdots a_r \\ \lambda \end{pmatrix}$, $y = \begin{pmatrix} \lambda \\ b_1 \cdots b_r \end{pmatrix} \begin{pmatrix} \lambda \\ b_{r+1} \cdots b_{r+p} \end{pmatrix}$, and $(a_i, b_i) \in \rho$ for $1 \leq i \leq r$, then $\mu_r(x, y) = x_1x_2 \begin{pmatrix} a_1 \cdots a_r \\ b_1 \cdots b_r \end{pmatrix} \begin{pmatrix} \lambda \\ b_{r+1} \cdots b_{r+p} \end{pmatrix}$.
4. The counterparts of cases A1 – A3 where the roles of upper and lower strands are reversed.

Case B If y is well-started (partially double-stranded), that is, $y = y_1y_2y_3$ for some $y_1, y_3 \in S(\Sigma)$ and $y_2 \in WK_\rho^+(\Sigma)$: for $r \geq 0$,

1. If $x_3 = \begin{pmatrix} a_1 \cdots a_r \\ \lambda \end{pmatrix}$, $y_1 = \begin{pmatrix} \lambda \\ b_1 \cdots b_r \end{pmatrix}$, and $(a_i, b_i) \in \rho$ for $1 \leq i \leq r$, then $\mu_r(x, y) = x_1x_2 \begin{pmatrix} a_1 \cdots a_r \\ b_1 \cdots b_r \end{pmatrix} y_2y_3$.
2. The counterpart of case B1 when the roles of upper and lower strands are reversed.

Fig. 16

Sticking operations: Prolongation of a well-started molecule to the right.

If none of these cases applies, $\mu_r(x, y)$ is undefined. Note that in all cases, r can be 0, that is, the system is allowed to prolong the blunt ends of molecules. Moreover, we have $\mu_r\left(x, \binom{\lambda}{\lambda}\right) = \mu_\ell\left(\binom{\lambda}{\lambda}, x\right) = x$ for any $x \in LR_\rho(\Sigma)$.

Note also that this vectorial model of DNA molecules allows – unlike its linear counterpart presented in the previous section – the differentiation between single-stranded DNA molecules, double-stranded DNA molecules, and DNA molecules with sticky ends, as well as for modeling of DNA–DNA interactions such as annealing and ligation.

6.1 Sticker Systems

Sticker systems are formal models of molecular interactions occurring in DNA computing, based on the sticking operation. Several variants of sticker systems have been defined in the literature. In this section, the simple regular sticker system, which is the most realistic variant but which is weak in terms of generating capacity, is described. We also introduce two practical ways to strengthen this variant: by using some complex DNA structures (☞ Sect. 6.1.1), and by observing the sticker system externally (☞ Sect. 6.1.2). Both enhance the computational power of the sticker system to Turing universality.

A sticker system prolongs given well-started DNA molecules, both to the left and to the right, by using the sticking operation, so as to turn them into complete double-stranded molecules. This system is an appropriate model of molecular interaction occurring, for example, in Adleman’s 1994 experiment, and was proposed under the name *bidirectional sticker system* (Freund et al. 1998).

A (bidirectional) *sticker system over a relation* ρ is a 4-tuple $\gamma = (\Sigma, \rho, A, P)$, where Σ is an alphabet endowed with the symmetric relation $\rho \subseteq \Sigma \times \Sigma$, $A \subseteq LR_\rho(\Sigma)$ is a finite subset of well-started sequences (axioms), and P is a finite subset of $W_\rho(\Sigma) \times W_\rho(\Sigma)$. Starting from an axiom in A , the system prolongs it with using a pair in P as follows:

$$x \Rightarrow_\gamma w \text{ iff } w = \mu_r(\mu_\ell(y, x), z) \text{ for some } (y, z) \in P$$

In other words, $x \Rightarrow_\gamma w$ iff sticking y to the left and z to the right of x results in w . The reflexive and transitive closure of \Rightarrow_γ is denoted by \Rightarrow_γ^* . A sequence $x_1 \Rightarrow_\gamma x_2 \Rightarrow_\gamma \dots \Rightarrow_\gamma x_k$, $x_1 \in A$, is called a *computation* in γ (of length $k - 1$). A computation as above is *complete* if $x_k \in WK_\rho^+(\Sigma)$.

The set of all molecules over Σ generated by complete computations in γ is defined as $LM(\gamma) = \{w \in WK_\rho^+(\Sigma) \mid x \Rightarrow_\gamma^* w, x \in A\}$. We can also consider the sticker systems as a generator of languages of strings rather than double-stranded molecules. To this aim, the following language is associated with $LM(\gamma)$

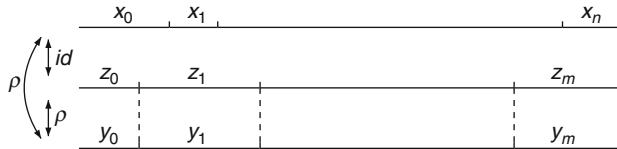

$$L(\gamma) = \left\{ w \in \Sigma^* \mid \begin{bmatrix} w \\ w' \end{bmatrix}_\rho \in LM(\gamma) \text{ for some } w' \in \Sigma^* \right\}$$

A language L is called a *sticker language* if there exists a sticker system γ such that $L(\gamma) = L$.

A sticker system $\gamma = (\Sigma, \rho, A, P)$ is said to be *simple* (respectively *regular*) if for each pair $(y, z) \in P$, $y, z \in S(\Sigma)$ (respectively $y = \lambda$). A simple regular system extends either the upper or lower strand, one at a time (hence the attribute “simple”), and only to the right (hence the attribute “regular”). Thus, a simple regular sticker system can be rewritten as 5-tuple $(\Sigma, \rho, A,$

Fig. 17

The idea of the proof of [Theorem 14](#). For any sticker system γ over a relation ρ , one can construct a sticker system γ' over the identity relation, such that $L(\gamma) = L(\gamma')$. The newly constructed sticker system γ' , based on id , simulates the process of γ to generate $(x, y) \in WK_{\rho}^{+}(\Sigma)$ where $x = x_0 x_1 \dots x_n$ and $y = y_0 y_1 \dots y_m$, by generating $(x, z) \in WK_{id}^{+}(\Sigma)$, where $z = z_0 z_1 \dots z_m$.

D_w and D_ℓ), where D_u and D_ℓ are finite subsets of $\binom{\Sigma^*}{\lambda}$ and $\binom{\lambda}{\Sigma^*}$, respectively. The family of languages generated by simple regular sticker systems is denoted by $SRL(n)$, where n means “no-restriction.” This variant is the most precise and realistic model of the annealing/ligation-based hybridization occurring in Adleman’s experiment. In fact, since being proposed in Kari et al. (1998), this type of sticker system has been intensively investigated.

A normal form for sticker systems with respect to the relation ρ was introduced in Hoogeboom and van Vugt (2000) for simple regular variants, and in Kuske and Weigel (2004) for general sticker systems. It says that the identity relation id suffices to generate any sticker language.

Theorem 14 (Hoogeboom and van Vugt 2000; Kuske and Weigel 2004) *For a sticker system γ over a relation ρ , one can construct a sticker system γ' over the identity relation id such that $L(\gamma) = L(\gamma')$.*

Proof The ideas proposed in Hoogeboom and van Vugt (2000) and Kuske and Weigel (2004) are essentially the same; they work for arbitrary bidirectional sticker systems. Here we present their proofs applied to *regular* (unidirectional) sticker systems to suggest the fact that the identity relation suffices also for Watson–Crick automata introduced later.

Let $\gamma = (\Sigma, \rho, A, P_r)$ be a regular sticker system. We construct a regular sticker system $\gamma' = (\Sigma, id, A', P'_r)$, [Fig. 17](#), where

$$\begin{aligned} A' &= \left\{ \begin{pmatrix} x_0 \\ z_0 \end{pmatrix} \mid \begin{pmatrix} x_0 \\ y_0 \end{pmatrix} \in A \text{ for some } y_0 \text{ such that } \begin{bmatrix} z_0 \\ y_0 \end{bmatrix}_\rho \right\} \\ P'_r &= \left\{ \begin{pmatrix} x_i \\ z_i \end{pmatrix} \mid \begin{pmatrix} x_i \\ y_i \end{pmatrix} \in P_r \text{ for some } y_i \text{ such that } \begin{bmatrix} z_i \\ y_i \end{bmatrix}_\rho \right\} \end{aligned}$$

Assume that $x \in L(\gamma)$, that is, there is a word y such that $(x, y) \in WK_{\rho}^{+}(\Sigma)$, $x = x_0 x_1 \dots x_n$ and $y = y_0 y_1 \dots y_m$, where $(x_0, y_0) \in A$, and $(x_j, y_j) \in P'_r$ ($1 \leq j \leq m$). Due to the symmetric property of ρ , x can also be written as the catenation of words z_0 and $z_1, \dots, z_m \in \Sigma^*$ such that $(z_k, y_k) \in WK_{\rho}(\Sigma)$ ($0 \leq k \leq m$). According to the definition of A' , $(x_0, z_0) \in A'$, and $(x_j, z_j) \in P'_r$ ($1 \leq j \leq m$). As a result, $\begin{bmatrix} x_0 x_1 \dots x_n \\ z_0 z_1 \dots z_m \end{bmatrix}_{id} = \begin{bmatrix} x \\ x \end{bmatrix}_{id} \in LM(\gamma')$, and hence $x \in L(\gamma')$. The proof that $L(\gamma') \subseteq L(\gamma)$ is similar.

As mentioned in the previous proof, this theorem proved to be valid for general sticker systems in Kuske and Weigel (2004). Moreover, in the paper, the authors show that an analogous result holds even for Watson–Crick automata, that is, the identity relation suffices for WK-automata. From a historical viewpoint of the theory of computation, the normal forms for grammars and acceptors have proved to be useful tools. Analogously, Theorem 14 will be useful for several proofs in the rest of this section.

The simple regular sticker system is one of the most “natural” computational models for annealing/ligation-based hybridization. Kari et al. (1998) initiated an investigation into the generative capacity of general sticker systems, including the simple regular variant, and the investigation continued in Freund et al. (1998) and Păun and Rozenberg (1998). The conclusion was that some classes of sticker systems can even characterize the recursively enumerable languages. On the contrary, the simple regular variant turned out to be quite weak.

Theorem 15 (Kari et al. 1998; Păun et al. 1998) $\text{SRSL}(n) \subsetneq \text{REG} = \text{Cod}(\text{SRSL}(n))$.

Thus, this “natural variant” of sticker systems has no more generative power than finite automata, even with the aid of encoding.

In Kari et al. (1998), the notion of *fair computation* was proposed. Let γ be a simple regular sticker system. A complete computation in γ is said to be *fair* if through the computation, the number of extensions occurring on the upper strand is equal to the number of extensions occurring on the lower strand. A language L is called a *fair sticker language* if there exists a simple regular sticker system γ such that L is the set of all words that are generated by fair computations in γ . The family of fair sticker languages is denoted by $\text{SRSL}(f)$.

It is known that $\text{REG} \subsetneq \text{Cod}(\text{SRSL}(f))$ and also that we cannot obtain characterizations of RE starting from languages in $\text{SRSL}(f)$ and using an arbitrary generalized sequential machine (*gsm*) mapping, including a coding (see Păun et al. 1998)). Hence the question of whether $\text{SRSL}(f)$ is included in CF (or even in LIN) arose. The answer to this question was obtained in Hoogeboom and van Vugt (2000). First, their example can be introduced to show that $\text{SRSL}(f) \not\subseteq \text{LIN}$.

Example 4 Let $\gamma = (\{a, b, c, d\}, \rho, A, D_u, D_\ell)$ be a simple regular sticker system, where $\rho = \{(a, a), (b, b), (b, c), (d, d)\}$, $A = \left\{ \begin{bmatrix} d \\ d \end{bmatrix} \right\}$, $D_u = \left\{ \begin{pmatrix} aa \\ \lambda \end{pmatrix}, \begin{pmatrix} b \\ \lambda \end{pmatrix} \right\}$, and $D_\ell = \left\{ \begin{pmatrix} \lambda \\ a \end{pmatrix}, \begin{pmatrix} \lambda \\ bc \end{pmatrix} \right\}$. This is a technical modification of Example 2 from Hoogeboom and van Vugt (2000) in order to make an axiom well started. Then $LM_n(\gamma) = \begin{bmatrix} d \\ d \end{bmatrix} \left\{ \begin{bmatrix} aa \\ aa \end{bmatrix}, \begin{bmatrix} bb \\ bc \end{bmatrix} \right\}^*$, and hence $L_n(\gamma) = d\{aa, bb\}^*$, $L_f(\gamma) = \{x \in L_n(\gamma) \mid \#_a(x) = \#_b(x)\}$. The pumping lemma for linear languages can be used to prove that $L_f(\gamma)$ is not linear.

Theorem 16 (Hoogeboom and van Vugt 2000) $\text{SRSL}(f) \subsetneq \text{Cod}(\text{SRSL}(f)) \subsetneq \text{CF}$.

Kari et al. (1998) imposed an additional constraint on fair computations called *coherence*, the use of which leads to a representation of RE. In the rest of this section, two new approaches are introduced to the problem of how to obtain characterizations of RE by using sticker systems augmented with more practical assumptions. Regarding the generative capacity and further topics about sticker systems, the reader is referred to the thorough summary in chapter 4 of Păun et al. (1998).

6.1.1 Sticker Systems with Complex Structures

Sakakibara and Kobayashi (2001) proposed a novel use of stickers, that involved the formation of *DNA hairpins*. In [Sect. 5](#), a hairpin was modeled as a linear word $w_1a_1\dots a_nw_2b_{n+1}\dots b_1w_3$, where $(a_i, b_i) \in \rho$, $1 \leq i \leq n$. Here we represent the same hairpin vectorially as $\begin{pmatrix} \langle w_2 \rangle \\ w_1 | w_3 \end{pmatrix} \in \begin{pmatrix} \Sigma^* \\ \Sigma^* \end{pmatrix}$ as shown in [Fig. 18](#). This hairpin-shaped molecule may stick to other molecules by its two sticky ends w_1 and w_3 or by its loop part w_2 . The sets of this type and inverted type of hairpins are denoted by $T_u(\Sigma)$ and $T_\ell(\Sigma)$, respectively, that is,

$$T_u(\Sigma) = \left\{ \begin{pmatrix} \langle w_2 \rangle \\ w_1 | w_3 \end{pmatrix} \mid w_1, w_2, w_3 \in \Sigma^* \right\}, \quad T_\ell(\Sigma) = \left\{ \begin{pmatrix} w_1 | w_3 \\ \langle w_2 \rangle \end{pmatrix} \mid w_1, w_2, w_3 \in \Sigma^* \right\},$$

The operation of “sticking a hairpin $x = \begin{pmatrix} \langle w_2 \rangle \\ w_1 | w_3 \end{pmatrix}$ onto a single-stranded molecule y ” is defined whenever $y = y_1y_2y_3$, and y_2 is complementary to w_1w_3 as follows:

$$\mu(y, x) = \begin{pmatrix} \lambda & \langle w_2 \rangle \\ \begin{pmatrix} \lambda \\ y_1 \end{pmatrix} & \begin{bmatrix} t_1 | v_1 \\ z_1 \end{bmatrix} & \begin{bmatrix} t_2 | v_2 \\ z_2 \end{bmatrix} & \cdots & \begin{bmatrix} t_n | v_n \\ z_n \end{bmatrix} & \begin{pmatrix} \lambda \\ z_{n+1}z_{n+2} \end{pmatrix} \end{pmatrix}.$$

Moreover, this operation $\mu(y, x)$ is extended to the general case; for a molecule,

$$z = \begin{pmatrix} \lambda & \langle u_1 \rangle & \langle u_2 \rangle & \cdots & \langle u_n \rangle & \lambda \\ \begin{pmatrix} \lambda \\ z_0 \end{pmatrix} & \begin{bmatrix} t_1 | v_1 \\ z_1 \end{bmatrix} & \begin{bmatrix} t_2 | v_2 \\ z_2 \end{bmatrix} & \cdots & \begin{bmatrix} t_n | v_n \\ z_n \end{bmatrix} & \begin{pmatrix} \lambda \\ z_{n+1}z_{n+2} \end{pmatrix} \end{pmatrix}$$

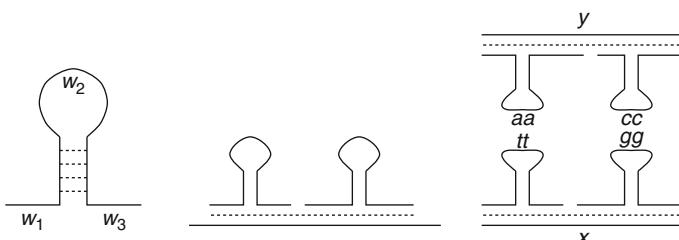

such that w_1w_3 is complementary to z_{n+1} , $\mu(z, x)$ is defined as

$$\mu(z, x) = \begin{pmatrix} \lambda & \langle u_1 \rangle & \langle u_2 \rangle & \cdots & \langle u_n \rangle & \langle w_2 \rangle & \lambda \\ \begin{pmatrix} \lambda \\ z_0 \end{pmatrix} & \begin{bmatrix} t_1 | v_1 \\ z_1 \end{bmatrix} & \begin{bmatrix} t_2 | v_2 \\ z_2 \end{bmatrix} & \cdots & \begin{bmatrix} t_n | v_n \\ z_n \end{bmatrix} & \begin{bmatrix} w_1 | w_3 \\ z_{n+1} \end{bmatrix} & \begin{pmatrix} \lambda \\ z_{n+2} \end{pmatrix} \end{pmatrix}.$$

Thus, this sticking operation forms “multiple hairpins” structures as illustrated in [Fig. 18](#) (Middle). The set of molecules with this type of structures and the set of molecules with inverted structures are denoted by $TW_u(\Sigma)$ and $TW_\ell(\Sigma)$, respectively, that is,

Fig. 18

(Left) A hairpin that the word $w_1a_1\dots a_nw_2b_{n+1}\dots b_1w_3$ may form if $(a_i, b_i) \in \rho$, $1 \leq i \leq n$; the sticky ends w_1, w_3 or the hairpin loop w_2 can bind to other molecules; (Middle) two hairpins stick to the lower strand via their sticky ends, leaving sticky ends at both ends of the lower strand; (Right) two “complete” molecules can bind together via their hairpin loops, if they are matched as shown.

$$\text{TW}_u(\Sigma) = \left(\begin{array}{c} \lambda \\ \lambda \\ \Sigma^* \end{array} \right) \left(\begin{bmatrix} \langle \Sigma^* \rangle \\ \Sigma^* \\ \Sigma^* \end{bmatrix} \right)^* \left(\begin{array}{c} \lambda \\ \lambda \\ \Sigma^* \end{array} \right), \quad \text{TW}_\ell(\Sigma) = \left(\begin{array}{c} \Sigma^* \\ \lambda \\ \lambda \end{array} \right) \left(\begin{bmatrix} \Sigma^* \\ \Sigma^* \\ \langle \Sigma^* \rangle \end{bmatrix} \right)^* \left(\begin{array}{c} \Sigma^* \\ \lambda \\ \lambda \end{array} \right).$$

Similarly, the hybridization operation $\mu(z, x)$ is defined for $z \in \text{TW}_\ell(\Sigma)$ and $x \in T_\ell(\Sigma)$. Note that $\begin{pmatrix} \lambda \\ \lambda \\ x \end{pmatrix} \in \text{TW}_\ell(\Sigma)$ or $\begin{pmatrix} x \\ \lambda \\ \lambda \end{pmatrix} \in \text{TW}_u(\Sigma)$ can be regarded as a word $x \in \Sigma^*$. Hence we will give also a word as a first argument of μ in the following. Now we can define another type of “complete” molecules, namely elements in the set $\text{TWK}(\Sigma) = \text{TWK}_u(\Sigma) \cup \text{TWK}_\ell(\Sigma)$, where

$$\text{TWK}_u(\Sigma) = \left(\begin{bmatrix} \langle \Sigma^* \rangle \\ \Sigma^* \\ \Sigma^* \end{bmatrix} \right)^*, \quad \text{TWK}_\ell(\Sigma) = \left(\begin{bmatrix} \Sigma^* \\ \Sigma^* \\ \langle \Sigma^* \rangle \end{bmatrix} \right)^*.$$

Second, we consider another sticking operation for the loop (w_2 of x) of a hairpin, which is illustrated in  Fig. 18 (Right). Consider two complete molecules $x \in \text{TWK}_u(\Sigma)$ and $y \in \text{TWK}_\ell(\Sigma)$ defined as

$$x = \left(\begin{bmatrix} \langle s_1 \rangle \\ r_1 | t_1 \\ x_1 \end{bmatrix} \quad \begin{bmatrix} \langle s_2 \rangle \\ r_2 | t_2 \\ x_2 \end{bmatrix} \quad \cdots \quad \begin{bmatrix} \langle s_n \rangle \\ r_n | t_n \\ x_n \end{bmatrix} \right), \quad y = \left(\begin{bmatrix} \gamma_1 \\ u_1 | w_1 \\ \langle v_1 \rangle \end{bmatrix} \quad \begin{bmatrix} \gamma_2 \\ u_2 | w_2 \\ \langle v_2 \rangle \end{bmatrix} \quad \cdots \quad \begin{bmatrix} \gamma_n \\ u_n | w_n \\ \langle v_n \rangle \end{bmatrix} \right).$$

When s_i is complementary to v_i ($1 \leq i \leq n$), $\phi(x, y)$ is defined as

$$\phi(x, y) = \left(\begin{bmatrix} \gamma_1 \\ u_1 | w_1 \\ \langle v_1 \rangle \\ \langle s_1 \rangle \\ r_1 | t_1 \\ x_1 \end{bmatrix} \quad \begin{bmatrix} \gamma_2 \\ u_2 | w_2 \\ \langle v_2 \rangle \\ \langle s_2 \rangle \\ r_2 | t_2 \\ x_2 \end{bmatrix} \quad \cdots \quad \begin{bmatrix} \gamma_n \\ u_n | w_n \\ \langle v_n \rangle \\ \langle s_n \rangle \\ r_n | t_n \\ x_n \end{bmatrix} \right).$$

Thus, for two complete molecules $x \in \text{TWK}_u(\Sigma)$ and $y \in \text{TWK}_\ell(\Sigma)$, $\phi(x, y)$ is well defined to be an element of the set

$$\text{DTWK}(\Sigma) = \left(\begin{bmatrix} \Sigma^* \\ \Sigma^* \\ \langle \Sigma^* \rangle \\ \langle \Sigma^* \rangle \\ \Sigma^* \\ \Sigma^* \end{bmatrix} \right)^*.$$

A *sticker system with complex structures* is a 4-tuple $\gamma = (\Sigma, \rho, D_u, D_\ell)$, where D_u and D_ℓ are finite subsets of $T_u(\Sigma)$ and $T_\ell(\Sigma)$, respectively. For molecules $x, y \in \text{TW}_u(\Sigma)$, we write $x \Rightarrow_u y$ if $y = \mu(x, v)$ for some $v \in D_u$. Analogously, for $x', y' \in \text{TW}_\ell(\Sigma)$, we write $x' \Rightarrow_\ell y'$ if $y' = \mu(x', v')$ for some $v' \in D_\ell$. The reflexive and transitive closures of these operations are denoted by \Rightarrow_u^* and \Rightarrow_ℓ^* .

A sequence $x_1 \Rightarrow_\alpha x_2 \Rightarrow_\alpha \cdots \Rightarrow_\alpha x_k$, with $x_i \in \Sigma^*$ and $\alpha \in \{u, \ell\}$, is called a computation in γ . (In this context, x_1 , the start of the computation, can be regarded as either a word in Σ^* or an element of $\text{TW}_\alpha(\Sigma)$.) A computation $x_1 \Rightarrow_\alpha^* x_k$ is said to be *complete* when $x_k \in \text{TWK}_\alpha(\Sigma)$.

Suppose that one has two complete computations $x \Rightarrow_u^* y$ and $x \Rightarrow_\ell^* z$ for a word $x \in \Sigma^*$. When $\phi(y, z)$ becomes a complete matching, that is, $\phi(y, z) \in \text{DTWK}(\Sigma)$, this computation process is said to be *successful*. The following language is associated with γ :

$$\begin{aligned} L(\gamma) = \{x \in (\Sigma \setminus \{\#\})^* \mid & x \# \Rightarrow_u^* y, y \in \text{TWK}_u(\Sigma) \\ & x \# \Rightarrow_\ell^* z, z \in \text{TWK}_\ell(\Sigma), \text{ and } \phi(y, z) \in \text{DTWK}(\Sigma)\}. \end{aligned}$$

Thus, one can consider this system as a language-accepting device. The family of languages accepted by sticker systems with complex structures is denoted by SLDT.

Now it can be shown that the use of hairpins enables one to characterize RE based on the following lemma.

Lemma 1 (Kari et al. 1998) *For each recursively enumerable language $L \subseteq \Sigma^*$, there exist two λ -free morphisms $h_1, h_2 : \Sigma_2^* \rightarrow \Sigma_1^*$, a regular language $R \subseteq \Sigma_1^*$, and a projection $\text{pr}_\Sigma : \Sigma_1^* \rightarrow \Sigma^*$ such that $L = \text{pr}_\Sigma(h_1(\text{EQ}(h_1, h_2)) \cap R)$.*

Theorem 17 (Sakakibara and Kobayashi 2001) *Every recursively enumerable language is the weak coding of a language in the family SLDT.*

Proof Let $L \in \text{RE}$. Due to **Lemma 1**, L can be obtained from $h_1(\text{EQ}(h_1, h_2)) \cap R$ by a projection, where $h_1, h_2 : \Sigma_2^* \rightarrow \Sigma_1^*$ are λ -free morphisms, and $R \in \text{REG}$. Hence it suffices to construct a sticker system with complex structures γ that accepts an *encoding* of $h_1(\text{EQ}(h_1, h_2)) \cap R$. Consider a complete deterministic finite automaton $M = (Q, \Sigma_1, \delta, q_0, F)$ for R , where $Q = \{q_0, q_1, \dots, q_m\}$. Any word $w = b_1 b_2 \dots b_k$ ($b_i \in \Sigma_1$) is encoded uniquely as $q_{l_0} b_1 q_{l_1} q_{l_1} b_2 q_{l_2} \dots q_{l_{k-1}} b_k q_{l_k} q_{l_k}$, where $q_{l_0} = q_0$, $q_{l_1}, \dots, q_{l_k} \in Q$ such that $\delta(q_{l_{j-1}}, b_j) = q_{l_j}$ for $1 \leq j \leq k$. So $w \in R$ iff $q_{l_k} \in F$.

Let $\Sigma_2 = \{a_1, \dots, a_n\}$, and for each a_i let $h_1(a_i) = c_1 c_2 \dots c_{k_i}$ ($c_j \in \Sigma_1$). Note that for an arbitrary state in Q , there is a unique transition on M by $h_1(a_i)$ because M is a complete deterministic automaton. Thus, a set of encodings of all such transitions is defined for each $a_i \in \Sigma_2$ as follows:

$$T_1(h_1(a_i)) = \bigcup_{q_{l_0} \in Q} \{q_{l_0} b_1 q_{l_1} \dots q_{l_{k_i-1}} b_{k_i} q_{l_{k_i}} \mid \delta(q_{l_{j-1}}, b_j) = q_{l_j}, 1 \leq j \leq k_i\}$$

Following the same idea, $T_2(h_2(a_i))$ is defined for each $a_i \in \Sigma_2$. Now γ is constructed as $(\Sigma_1 \cup \Sigma_2 \cup Q \cup \{\#\}, \text{id}, D_u \cup D_\ell)$, where

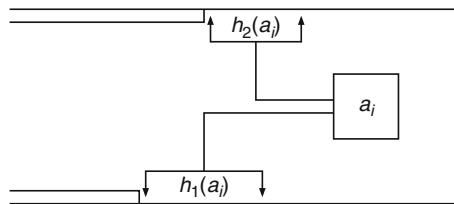

$$\begin{aligned} D_\ell &= \left\{ \left(\begin{array}{c} t_2 \\ \langle a_i \rangle \end{array} \right) \middle| t_2 \in T_2(h_2(a_i)) \right\} \cup \left\{ \left(\begin{array}{c} q_f \# \\ \langle \# \rangle \end{array} \right) \middle| q_f \in F \right\} \\ D_u &= \left\{ \left(\begin{array}{c} \langle a_i \rangle \\ t_1 \end{array} \right) \middle| t_1 \in T_1(h_1(a_i)) \right\} \cup \left\{ \left(\begin{array}{c} \langle \# \rangle \\ q_f \# \end{array} \right) \middle| q_f \in F \right\} \end{aligned}$$

Figure 19 illustrates the idea of how γ recognizes the language $h_1(\text{EQ}(h_1, h_2))$ (the encoding mentioned above for R is omitted for clarity).

By this construction, $L(\gamma)$ is the set of encodings of words $u \in R$ for which there exists a word $w \in \Sigma_2^*$ with $h_1(w) = h_2(w) = u$. Projection being a weak coding, there exists a weak coding h such that $h(L(\gamma)) = L$.

Fig. 19

A brief sketch of the proof for **Theorem 17**. Two hairpins, one with sticky end $h_1(a_i)$ and the other with sticky end $h_2(a_i)$, binding together via their matching loops, can be abstracted as a finite control (square) labeled by a_i , with two heads (bifurcated arrows). The control checks for each i , $1 \leq i \leq n$, if the single-stranded part of the upper strand begins with $h_2(a_i)$, and the lower strand begins with $h_1(a_i)$; if so, then the corresponding hairpins are stuck. This process is repeated until either this system cannot proceed in this way anymore or it generates a complete matching of two complete molecules. In fact this system is essentially equivalent to Watson-Crick automata, which will be introduced in **Sect. 6.2**.

6.1.2 Observable Sticker Systems

Another idea to strengthen a computational system is to let someone observe and report how the system works step by step. This composite system, inspired by the common practice of observing the progress of a biology or chemistry experiment, has been introduced in Cavaliere and Leupold (2004) to “observe” membrane systems. There, a finite automaton observed the change of configurations of a “computationally weak” membrane system (with context-free power). Surprisingly, this composite system proved to be universal. Following this idea, many computations were “observed”: splicing systems, derivations of grammars and string-rewriting systems, and also sticker systems. For the details of these observations as well as the formal definition of computation by observation in general, the readers are referred to Cavaliere and Leupold (2004), Cavaliere (2008), and references thereof.

The idea of observing sticker systems was introduced in Alhazov and Cavaliere (2005). Informally, an *observable sticker system* is composed of a “computationally weak” sticker system and an external observer. Observing the computation of a sticker system, starting from an axiom, the observer notes – at each computational step – the current configuration, and processes it according to its own rules, producing an output. The catenation of all the outputs thus produced by the observer during a complete computation, constitutes a word in the language of the observable sticker system. The collection of all words thus obtained is the language generated by this observable sticker system.

Formally speaking, configurations of a sticker system, which are elements of Σ_d^* , are observed so that an observer is implemented as a finite automaton that works on elements of Σ_d^* . This automaton is defined as a 6-tuple $O = (Q, \Sigma_d, \Delta, q_0, \delta, \sigma)$, where a finite set of states Q , an input alphabet Σ_d , the initial state $q_0 \in Q$, and a complete transition function $\delta : \Sigma_d \times Q \rightarrow Q$ are defined as usual for conventional finite automata: whereas Δ is an output alphabet and σ is a labeling function $Q \rightarrow \Delta \cup \{\perp, \lambda\}$, \perp being a special symbol.

An *observable (simple regular) sticker system* is a pair $\phi = (\gamma, O)$ for a simple regular sticker system γ and an observer O . For a computation $c : x_0 \Rightarrow_{\gamma} x_1 \Rightarrow_{\gamma} \dots \Rightarrow_{\gamma} x_k$ ($x_i \in R_p(\Sigma)$), $O(c)$ is defined as $O(x_0)O(x_1)\dots O(x_k)$. The language $L(\phi)$ generated by ϕ is defined as $L(\phi) = \{O(c) \mid c \text{ is a complete computation by } \gamma\}$.

Theorem 18 (Alhazov and Cavaliere 2005) *There exists an observable simple regular sticker system which generates a non-context-free language.*

This theorem shows how stronger very restricted sticker systems can get with the aid of the observer (cf. [Theorem 15](#)). A natural question that follows is of how to get universality within the framework of observable sticker systems. The next theorem proves that observers with the capability to discard any “bad” evolution endow simple regular sticker systems with universality.

The symbol $\perp \notin \Delta$ makes it possible for an observer O to distinguish bad evolutions by a sticker system γ from good ones in a way that the observation of bad evolutions leads to the output of \perp . For the observable sticker system $\phi = (\gamma, O)$, one can weed out any word that contains \perp from $L(\phi)$ by taking $\widehat{L}(\phi) = L(\phi) \cap \Delta^*$.

Theorem 19 (Alhazov and Cavaliere 2005) *For each $L \in \text{RE}$, there exists an observable simple regular sticker system $\phi = (\gamma, O)$ such that $\widehat{L}(\phi) = L$.*

Due to the fact that recursive languages are closed under intersection with regular languages, [Theorem 19](#) has the following result as its corollary.

Corollary 1 (Alhazov and Cavaliere 2005) *There exists an observable simple regular sticker system $\phi = (\gamma, O)$ such that $L(\phi)$ is a non-recursive language.*

6.2 Watson–Crick Automata

While sticker systems generate complete double-stranded molecules by using the sticking operation, their accepting counterparts, the Watson–Crick automata, parse a given complete double-stranded molecule and determine whether the input is accepted or not. A Watson–Crick automaton is equipped with a finite state machine with two heads. This machine has its heads read the respective upper and lower strands of a given complete double-stranded molecule simultaneously, and changes its state accordingly. The basic idea of how Watson–Crick automata work was described in [Fig. 19](#).

In parallel to the research on sticker systems, these biologically inspired automata have been intensively investigated within the last decade. Early studies including, for example, Freund et al. (1999) and Martin-Vide et al. (1998) investigate variants of WK-automata, relationships among them with respect to generative capacity, and universal Watson–Crick automata, topics summarized in chapter 5 of Păun et al. (1998). A more recent survey Czeizler and Czeizler (2006c) includes results on complexity measures (Păun and Păun 1999) and Watson–Crick automata systems (Czeizler and Czeizler 2006a,b). Other studies on WK-automata comprise Watson–Crick ω -automata (Petre 2003), the role of the complementarity relation (Kuske and Weigel 2004) (see [Theorem 1](#)), local testability and regular reversibility (Sempere 2007, 2008), 5' → 3' sensing Watson–Crick finite automata (Nagy 2008), and deterministic Watson–Crick automata (Czeizler et al. 2008a).

In this section, we present recent results in this field, such as studies of deterministic WK-automata, and the role of the complementarity relation. In particular, deterministic WK-automata are essential for the design of efficient molecular parsers.

A (*nondeterministic*) Watson–Crick (*finite*) automaton over a symmetric relation $\rho \subseteq \Sigma \times \Sigma$ is a 6-tuple $M = (\Sigma, \rho, Q, q_0, F, \delta)$, where Σ , Q , q_0 , and F are defined in the same manner as for finite automata. The *transition function* δ is a mapping $\delta : Q \times \Sigma^* \times \Sigma^* \rightarrow 2^Q$ such that $\delta\left(q, \begin{pmatrix} w_1 \\ w_2 \end{pmatrix}\right) \neq \emptyset$ only for *finitely many* pairs $(q, w_1, w_2) \in Q \times \Sigma^* \times \Sigma^*$. We can replace the transition function by rewriting rules, by denoting $q\left(\begin{matrix} w_1 \\ w_2 \end{matrix}\right) \rightarrow q'$ instead of $q' \in \delta\left(q, \begin{pmatrix} w_1 \\ w_2 \end{pmatrix}\right)$. Transitions in M are defined as follows. For $q, q' \in Q$ and $\begin{pmatrix} x_1 \\ x_2 \end{pmatrix}, \begin{pmatrix} w_1 \\ w_2 \end{pmatrix}, \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} \in \begin{pmatrix} \Sigma^* \\ \Sigma^* \end{pmatrix}$ such that $\begin{bmatrix} x_1 w_1 y_1 \\ x_2 w_2 y_2 \end{bmatrix} \in \text{WK}_\rho(\Sigma)$, we write $\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} q\left(\begin{matrix} w_1 \\ w_2 \end{matrix}\right) \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} \Rightarrow \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \left(\begin{matrix} w_1 \\ w_2 \end{matrix}\right) q'\left(\begin{matrix} y_1 \\ y_2 \end{matrix}\right)$ iff $q' \in \delta\left(q, \begin{pmatrix} w_1 \\ w_2 \end{pmatrix}\right)$. If \Rightarrow^* is the reflexive and transitive closure of \Rightarrow , then the language accepted by M is

$$L(M) = \left\{ w_1 \in \Sigma^* \mid q_0 \left[\begin{matrix} w_1 \\ w_2 \end{matrix} \right] \Rightarrow^* \left[\begin{matrix} w_1 \\ w_2 \end{matrix} \right] q_f \text{ for some } q_f \in F \text{ and } w_2 \in \Sigma^* \text{ such that } \left[\begin{matrix} w_1 \\ w_2 \end{matrix} \right] \in \text{WK}_\rho(\Sigma) \right\}.$$

Other languages are also considered in Freund et al. (1999) and Păun et al. (1998) such as control words associated to computations — but they are not introduced here. By convention, as suggested also in Păun and Păun (1999), in this section we consider two languages differing only by the empty word λ as identical.

A WK-automaton $M = (\Sigma, \rho, Q, q_0, F, \delta)$ is said to be *stateless* if $Q = F = \{s_0\}$; *all-final* if $Q = F$; *simple* if for any rewriting rule $q\left(\begin{matrix} w_1 \\ w_2 \end{matrix}\right) \rightarrow q'$, either w_1 or w_2 is λ ; *1-limited* if for any transition $q\left(\begin{matrix} w_1 \\ w_2 \end{matrix}\right) \rightarrow q'$, we have $|w_1 w_2| = 1$. By AWK, NWK, FWK, SWK, and 1WK, we denote the families of languages accepted by WK-automata that are arbitrary (A), stateless (N, no-state), all-final (F), simple (S), and 1-limited (1). When two restrictions are imposed at the same time, both of the corresponding symbols are used to identify the family.

As customary in automata theory, normal forms for WK-automata are available. For example, we can convert any WK-automaton into a 1-limited one without changing the language accepted, or the symmetric relation over which the original WK-automaton is defined (Martin-Vide et al. 1998). Another normal form, standardizing the symmetric relation, is as follows:

Theorem 20 (Kuske and Weigel 2004) *For any WK-automaton M , we can construct a WK-automaton M_{id} over the identity relation id with $L(M) = L(M_{id})$.*

A 1-limited WK-automaton over the identity relation is equivalent to a *two-head finite automaton*. Therefore the next theorem follows, where TH denotes the family of languages accepted by two-head finite automata.

Theorem 21 (Păun et al. 1998) $1\text{WK} = \text{SWK} = 1\text{SWK} = \text{AWK} = \text{TH}$.

Czeizler et al. (2008a) proposed three criteria of determinism. A WK-automaton M is said to be *weakly deterministic* if at any point of computation by M , there is at most one possibility to continue the computation; and *deterministic* if for any pair of transition rules $q\left(\begin{smallmatrix} u \\ v \end{smallmatrix}\right) \rightarrow q'$ and $q\left(\begin{smallmatrix} u' \\ v' \end{smallmatrix}\right) \rightarrow q''$, we have $u \sim_p u'$ or $v \sim_p v'$. Clearly, a deterministic WK-automaton is weakly deterministic. Moreover, a deterministic WK-automaton over a symmetric relation ρ is said to be *strongly deterministic* if ρ is the identity. The families of languages accepted by *weakly deterministic*, *deterministic*, and *strongly deterministic* WK-automata are denoted by wdAWK , dAWK , and sdAWK , respectively. The symbol “A” can be replaced with N, F, S, 1, or their combination as in the nondeterministic case.

Proposition 1 (Czeizler et al. 2008a) $\text{sdAWK} \subseteq \text{dAWK} \subseteq \text{wdAWK} \subseteq \text{AWK}$.

The generative power of finite automata or Turing machines remains unchanged by bringing in determinism, while the determinism strictly weakens pushdown automata (Hopcroft and Ullman 1979). Thus, a natural question is whether the relation in (2) Proposition 1 includes some strict inclusion or all of the families are the same.

Czeizler et al. (2008a) proved that $\text{dAWK} = \text{d1WK}$ using a similar proof technique for $\text{AWK} = \text{1WK}$. As mentioned above, the technique keeps the symmetric relation unchanged. As such, $\text{sdAWK} = \text{sd1WK}$ follows immediately. Following the same reasoning to prove $\text{AWK} = \text{TH}$ (2) Theorem 21), we can see that sdAWK is equivalent to the family dTH of languages accepted by *deterministic two-head finite automata*. It is known that there exists a language in $\text{TH} \setminus \text{dTH}$, for example, $L' = \{w \in \Sigma^* \mid w \neq w^R\}$. This means that nondeterministic WK-automata are strictly more powerful than strongly deterministic ones. In fact, the following stronger result holds.

Theorem 22 (Czeizler et al. 2008a) $\text{sdAWK} \subsetneq \text{dAWK}$.

Proof It suffices to prove that $L' \in \text{dAWK}$. We prove the statement only for the case when Σ is binary, but the statement holds for arbitrary finite alphabets.

Let $M = (\Sigma \cup \{c, d_a, d_b\}, \rho, Q, q_0, F, \delta)$ be a WK-automaton, where $\rho = \{(a, a), (a, d_a), (b, b), (b, d_b), (a, c), (b, c)\}$, $Q = \{q_0, q_f, q_a, q_b\}$, $F = \{q_f\}$, and δ consists of the following rules:

$$\begin{aligned} q_0\left(\begin{smallmatrix} \lambda \\ x \end{smallmatrix}\right) &\rightarrow q_0, \quad q_0\left(\begin{smallmatrix} \lambda \\ d_x \end{smallmatrix}\right) \rightarrow q_x, \text{ with } x \in \{a, b\} \\ q_x\left(\begin{smallmatrix} y \\ z \end{smallmatrix}\right) &\rightarrow q_x, \text{ with } x, y, z \in \{a, b\} \\ q_x\left(\begin{smallmatrix} zy \\ c \end{smallmatrix}\right) &\rightarrow q_f, \text{ with } x, y, z \in \{a, b\}, \quad x \neq y \\ q_f\left(\begin{smallmatrix} x \\ \lambda \end{smallmatrix}\right) &\rightarrow q_f, \text{ with } x \in \{a, b\} \end{aligned}$$

It is clear that M is deterministic. Let $w = w_1 w_2 \dots w_n$ with $w_i \in \Sigma$. If $w \neq w^R$, then there exists a position k in the first half of w such that $w_k \neq w_{n-k+1}$. The characters d_a, d_b are used as

a marker of this position. When M runs on the input $\binom{w_1 \cdots w_{k-1} w_k w_{k+1} \cdots w_{n-1} w_n}{w_1 \cdots w_{k-1} d_{w_k} w_{k+1} \cdots w_{n-1} c}$, it accepts w . On the other hand, M does not accept any palindrome regardless of what complement one chooses; thus $L(M) = \{w \in \{a, b\}^+ \mid w \neq w^R\}$.

This contrasts with the nondeterministic case where the complementarity relation does not play any active role (❸ [Theorem 20](#)). Though it is natural now to ask if dAWK \subseteq wdAWK is strict or not, this question remains open. Note that there exists a weakly deterministic WK-automaton that is not deterministic.

❸ [Proposition 1](#) and ❸ [Theorem 22](#) conclude that strong determinism strictly weakens WK-automata. However, deterministic WK-automata are still more powerful than finite automata. Since the construction of a strongly deterministic WK-automaton that simulates a given deterministic finite automaton is straightforward, in the following a stronger result is included.

Theorem 23 $\text{REG} \subseteq \text{sdF1WK}$.

Proof In order to simulate a deterministic finite automaton $A = (Q, \Sigma, q_0, F, \delta)$ with $Q = \{q_0, q_1, \dots, q_n\}$, we construct a strongly deterministic all-final 1-limited WK-automaton $M = (\Sigma, id, Q', q_{0,0}, Q', \delta')$, where $Q' = \{q_{i,j}, \overline{q_{i,j}} \mid 0 \leq i, j \leq n\}$, and for $a \in \Sigma, 0 \leq i, j \leq n$,

$$\begin{aligned}\delta'\left(q_{i,j}, \binom{a}{\lambda}\right) &= \begin{cases} q_{k,j} & \text{if } \delta(q_i, a) = q_k \text{ and } q_k \notin F \\ \overline{q_{k,j}} & \text{if } \delta(q_i, a) = q_k \text{ and } q_k \in F \end{cases} \\ \delta'\left(\overline{q_{i,j}}, \binom{\lambda}{a}\right) &= \begin{cases} \overline{q_{i,k}} & \text{if } \delta(q_j, a) = q_k \text{ and } q_k \notin F \\ q_{i,k} & \text{if } \delta(q_j, a) = q_k \text{ and } q_k \in F \end{cases}\end{aligned}$$

The recognition of a sequence $\left[\begin{smallmatrix} w \\ w \end{smallmatrix} \right]$ consists of two identical simulations of recognition process of w on A over the upper and lower strands. Current states of the automaton A working on upper and lower strands are recorded as first and second subscripts of states in Q' . The overline of states indicates that M is now in the simulation over the lower strand. One switches these two phases every time the simulated automaton reaches some final state of A . We can see easily that $L(M) = L(A) \cup \{\lambda\}$.

From ❸ [Theorem 23](#), it is clear that WK-automata are more powerful than finite automata. Additional results on the generative capacity of WK-automata can be found in, for example, Păun et al. (1998). Moreover, it was shown in Czeizler et al. (2008a) and Păun and Păun (1999) that WK-automata recognize some regular languages in a less space-consuming manner. Usage of space is measured by the *state complexity* (for more details, see Păun and Păun (1999) and Yu (2002)). It is well-known that the state complexity of some families of finite languages is unbounded when one considers the finite automata recognizing them. In other words, for any $k \geq 1$, there is a finite language that cannot be recognized by any finite automaton with at most $k - 1$ states. On the contrary, any finite language can be recognized by a WK-automaton with two states (Czeizler et al. 2008a).

Determinism is one of the most essential properties for the design of an efficient parser. Due to the time-space trade-off, the stronger the determinism is, the more space-consuming WK-automata get. For example, it was shown in Czeizler et al. (2008a) that in order to

recognize a finite language $L_k = \{a, aa, \dots, a^{k-1}\}$, the strongly deterministic WK-automaton needs at least k states, while for any k , two states are enough once the strong determinism is changed to determinism. Little is known about the state complexity with respect to the (strongly, weakly) deterministic WK-automata.

As a final result on this topic, the following undecidability property about determinism of WK-automata is mentioned.

Theorem 24 (Czeizler et al. 2008a) *It is undecidable whether a given WK-automaton is weakly deterministic.*

7 DNA Complementarity and Combinatorics on Words

⌚ Sections 5 and ⌚ 6 described new concepts and results in formal language theory and automata theory that attest to the influence that the notion of DNA-based information and its main aspect, the Watson–Crick complementarity, has had on formal language theory, coding theory, and automata theory. This section is devoted to describing some of the ideas, notions, and results that DNA-based information has brought to another area of theoretical computer science, namely combinatorics on words. Indeed, the “equivalence” from the informational point of view between a DNA single strand and its Watson–Crick complement led to several interesting generalizations of fundamental notions such as bordered word, palindrome, periodicity, conjugacy, and commutativity. Moreover, these generalizations led to natural extensions of two of the most fundamental results in combinatorics on words: the Fine and Wilf theorem and the Lyndon–Schützenberger equation. This section presents some of these concepts and results in combinatorics of words motivated by the Watson–Crick complementarity property of DNA-based information.

In the following, θ will denote an antimorphic involution. For further details on combinatorics on words, the reader is referred to Choffrut and Karhumäki (1997).

As mentioned in ⌚ Sect. 2, recognition sites of enzymes are often palindromic in a biological sense. Conventionally speaking, a palindrome is a word that reads the same way from the left and from the right, such as “racecar” in English. In contrast, in molecular biology terms, a palindromic DNA sequence is one that is equal to its WK complementary sequence. For example, TGGATCCA is palindromic in this sense. The biological palindromic motif is herein modeled as θ -palindrome (or, more generally, *pseudopalindrome*) defined as follows: A word w is a θ -palindrome if $w = \theta(w)$. θ -palindromes were investigated intensively from a theoretical computer science perspective, see for example, in de Luca and Luca (2006) and Kari and Mahalingam (2010).

The properties of θ -sticky-freeness and θ -overhang-freeness motivate the generalization of the notions of *border*, *commutativity*, and *conjugacy* of words into θ -*border*, θ -*commutativity*, and θ -*conjugacy* of words. A word $w \in \Sigma^+$ is *bordered* if there exists a word $v \in \Sigma^+$ satisfying $w = vx = yv$ for some $x, y \in \Sigma^+$. Kari and Mahalingam (2007) proposed an extended notion called the θ -borderedness of words as w is θ -bordered if $w = vx = y\theta(v)$ for some $v, x, y \in \Sigma^+$. Note that θ -sticky-free languages do not contain any θ -bordered word. The *pseudoknot-bordered-word* proposed in Kari and Seki (2009) is a further extension of the notion of θ -bordered word. A word $w \in \Sigma^+$ is *pseudoknot-bordered* if $w = uvx = y\theta(u)\theta(v)$. A pseudoknot-bordered word models the crossing dependency occurring in DNA and RNA

pseudoknots. A word $v \in \Sigma^+$ is said to be a *conjugate* of another word $u \in \Sigma^+$ if $v = yx$ and $u = xy$ for some $x, y \in \Sigma^*$, that is, $ux = xv$ holds. This notion was extended in Kari and Mahalingam (2008) as follows: a word $u \in \Sigma^+$ is a θ -*conjugate* of a word $v \in \Sigma^+$ if $ux = \theta(x)v$ for some $x \in \Sigma^+$. In this case, either $v = \theta(u)$ or $u = \theta(x)z$, $v = zx$ for some $z \in \Sigma^+$; hence a language that contains both u and v cannot be strictly θ -sticky-free.

In contrast with the above two notions, the θ -*commutativity of words* introduced in Kari and Mahalingam (2008) has a purely theoretical significance, being a mathematical tool for obtaining results involving WK complementarity. Two words $u, v \in \Sigma^+$ are said to *commute* if $uv = vu$ holds. For two words u, v , we say that u θ -commutes with v if $uv = \theta(v)u$. This equation is a special case of conjugacy equations. Thus, by applying a known result in combinatorics on words, one can deduce the following results.

Theorem 25 (Kari and Mahalingam 2008) *For an antimorphic involution θ , and two words $u, v \in \Sigma^+$, if $uv = \theta(v)u$ holds, then $u = r(tr)^i$, $v = (tr)^j$ for some $i \geq 0$, $j \geq 0$, and θ -palindromes $r, t \in \Sigma^*$ such that rt is primitive.*

This theorem relates the three important notions: θ -commutativity of words, θ -palindrome, and primitivity.

Another interesting perspective is the informational equivalence between the two strands of a DNA double helix. Indeed, the two constituent single strands of a DNA double strand are “equivalent” with respect to the information they encode, and thus we can say that w and $\theta(w)$ are equivalent in this sense. Practical applications of this idea include an extended Lempel–Ziv algorithm for DNA molecules proposed in Grumbach and Tahi (1993).

A word $w \in \Sigma^+$ is called *primitive* if it cannot be written as a power of another word; that is, $w = u^n$ implies $n = 1$ and $w = u$. For a word $w \in \Sigma^+$, the shortest $u \in \Sigma^+$ such that $w = u^n$ for some $n \geq 1$ is called the *primitive root* of the word w and is denoted by $\rho(w)$. It is well known that for each word $w \in \Sigma^*$, there exists a unique primitive word $t \in \Sigma^+$ such that $\rho(w) = t$, that is, $w = t^n$ for some $n \geq 1$, see for example, Choffrut and Karhumäki (1997). In Czeizler et al. (2008b), the primitivity was extended to θ -primitivity for an antimorphic involution θ . A word $u \in \Sigma^+$ is said to be θ -*primitive* if there does not exist any word $t \in \Sigma^+$ such that $u \in \{t, \theta(t)\}^{\geq 2}$. For a word $w \in \Sigma^+$, we define the θ -*primitive root* of w , denoted by $\rho_\theta(w)$, as the shortest word $t \in \Sigma^+$ such that $w \in t\{t, \theta(t)\}^*$. Note that if w is θ -primitive, then $\rho_\theta(w) = w$. Note also that θ -primitivity can be defined also for θ being a morphic involution. However, as it is meant as a model of WK complementarity, we will continue to assume that θ is antimorphic. For counterparts of the following results when θ is a morphic involution see Czeizler et al. (2008b).

We start by looking at some basic properties of θ -primitive words.

Proposition 2 (Czeizler et al. 2008b) *If a word $w \in \Sigma^+$ is θ -primitive, then it is also primitive. Moreover, the converse is not always true.*

Proof By definition, it is clear that θ -primitive words are primitive. Remark that if there exists $a \in \Sigma$ satisfying $a \neq \theta(a)$, then the word $a\theta(a)$ is not θ -primitive, but is primitive.

If a word $w \in \Sigma^+$ is in $\{t, \theta(t)\}^+$ for some word $t \in \Sigma^+$ and t in turn is in $\{s, \theta(s)\}^+$ for some word $s \in \Sigma^+$, then we have that $w \in \{s, \theta(s)\}^+$. Thus, we have the following result.

Proposition 3 (Czeizler et al. 2008b) *The θ -primitive root of a word is θ -primitive, and hence primitive.*

It is a well-known fact that any conjugate of a primitive word is primitive. This fact is heavily employed in obtaining fundamental results including the Fine and Wilf theorem and solutions to the Lyndon–Schützenberger equation. In contrast, a conjugate of a θ -primitive word need not be θ -primitive. For instance, for the DNA involution τ defined in [Sect. 5](#), the word $w = GCTA$ is τ -primitive, while its conjugate $w' = AGCT = AG\tau(AG)$ is not.

Proposition 4 (Czeizler et al. 2008b) *The class of θ -primitive words is not closed under circular permutations.*

An essential property of primitive words is that a primitive word cannot be equal to its conjugate. In other words, for a primitive word u , the equation $uu = xuy$ implies that either x or y is empty. Thus, u^i and u^j , with $i, j \geq 1$, cannot overlap non-trivially on a sequence longer than $|u|$. This is not the case when considering overlap between $\alpha(v, \theta(v)), \beta(v, \theta(v)) \in \{v, \theta(v)\}^+$ for some θ -primitive word $v \in \Sigma^+$. For instance, for the DNA involution τ and a τ -primitive word $v = CCGGAT$, $v^2 = CCGG \cdot \tau(v) \cdot AT$ holds. Nevertheless, an analogous result for θ -primitive words was obtained.

Theorem 26 (Kari et al. 2010) *Let $v \in \Sigma^+$ be a θ -primitive word. Neither $v\theta(v)$ nor $\theta(v)v$ can be a proper infix of a word in $\{v, \theta(v)\}^3$.*

Furthermore, Czeizler et al. completely characterized all such nontrivial overlaps with the set of all solutions of the corresponding equation (Czeizler et al. 2009).

Theorem 27 (Czeizler et al. 2009) *Let $v \in \Sigma^+$ be a θ -primitive word. The only possible proper overlaps of the form $\alpha(v, \theta(v)) \cdot x = y \cdot \beta(v, \theta(v))$ with $\alpha(v, \theta(v)), \beta(v, \theta(v)) \in \{v, \theta(v)\}^+$, $x, y \in \Sigma^+$ and $|x|, |y| < |v|$ are given in [Table 1](#) (modulo a substitution of v by $\theta(v)$) together with the characterization of their sets of solutions.*

Table 1

Characterization of possible proper overlaps of the form $\alpha(v, \theta(v)) \cdot x = y \cdot \beta(v, \theta(v))$. For the last three equations, $n \geq 0, m \geq 1, r, t \in \Sigma^+$ such that $r = \theta(r), t = \theta(t)$, and rt is primitive. Note that the fourth and fifth equations are the same up to the antimorphic involution θ

Equation	Solution
$v^i x = y\theta(v)^j, i \geq 1$	$v = yp, x = \theta(y), p = \theta(p)$, and whenever $i \geq 2, y = \theta(y)$
$vx = yv$	$v = (pq)^{j+1}p, x = qp, y = pq$ for some $p, q \in \Sigma^+, j \geq 0$
$v\theta(v)x = yv\theta(v),$	$v = (pq)^{j+1}p, x = \theta(pq), y = pq$, with $j \geq 0, qp = \theta(qp)$
$v^{i+1}x = y\theta(v)^j v, i \geq 1$	$v = r(tr)^{n+m}r(tr)^n, x = (tr)^m r(tr)^n, y = r(tr)^{n+m}$
$v\theta(v)^i x = yv^{i+1}, i \geq 1$	$v = (rt)^n r(rt)^{m+n}r, y = (rt)^n r(rt)^m, x = (rt)^{m+n}r$
$v\theta(v)^i x = yv^j\theta(v), i \geq 2$	$v = (rt)^n r(rt)^{m+n}r, y = (rt)^n r(rt)^m, x = (tr)^m r(tr)^n$

We now shift one's attention to extensions of two essential results in combinatorics on words. The following theorem is known as the *Fine and Wilf theorem* (Fine and Wilf 1965), in its form for words (Choffrut and Karhumäki 1997; Lothaire 1983). It illustrates a fundamental periodicity property of words. Its concise proof is available, in, for example, Choffrut and Karhumäki (1997). As usual, $\gcd(n, m)$ denotes the *greatest common divisor* of n and m .

Theorem 28 *Let $u, v \in \Sigma^*$, $n = |u|$, and $m = |v|$. If a power of u and a power of v have a common prefix of length at least $n + m - \gcd(n, m)$, then $\rho(u) = \rho(v)$. Moreover, the bound $n + m - \gcd(n, m)$ is optimal.*

A natural question is whether one can obtain an extension of this result when, instead of taking powers of two words u and v , one looks at a word in $u\{u, \theta(u)\}^*$ and a word in $v\{v, \theta(v)\}^*$. The answer is yes. Note that without loss of generality, one can suppose that the two words start with u and v because θ is an involution. Czeizler, Kari, and Seki provided extensions of Theorem 28 in two forms (Theorems 29 and 30) (Czeizler et al. 2008b). As illustrated in the following example, the bound given by Theorem 28 is not sufficient anymore.

Example 5 (Czeizler et al. 2008b) Let $\theta : \{a, b\}^* \rightarrow \{a, b\}^*$ be the mirror image mapping defined as follows: $\theta(a) = a$, $\theta(b) = b$, and $\theta(w_1 \dots w_n) = w_n \dots w_1$, where $w_i \in \{a, b\}$ for all $1 \leq i \leq n$. Obviously, θ is an antimorphic involution on $\{a, b\}^*$. Let $u = (ab)^k b$ and $v = ab$. Then, u^2 and $v^k \theta(v)^{k+1}$ have a common prefix of length $2|u| - 1 > |u| + |v| - \gcd(|u|, |v|)$. Nevertheless, u and v do not have the same θ -primitive root, that is $\rho_\theta(u) \neq \rho_\theta(v)$.

In the following, $\text{lcm}(n, m)$ denotes the *least common multiple* of n and m .

Theorem 29 (Czeizler et al. 2008b) *Let $u, v \in \Sigma^+$, and $\alpha(u, \theta(u)) \in u\{u, \theta(u)\}^*$, $\beta(v, \theta(v)) \in v\{v, \theta(v)\}^*$ be two words sharing a common prefix of length at least $\text{lcm}(|u|, |v|)$. Then, there exists a word $t \in \Sigma^+$ such that $u, v \in t\{t, \theta(t)\}^*$, i.e., $\rho_\theta(u) = \rho_\theta(v)$. In particular, if $\alpha(u, \theta(u)) = \beta(v, \theta(v))$, then $\rho_\theta(u) = \rho_\theta(v)$.*

This theorem provides us with an alternative definition of the θ -primitive root of a word.

Corollary 2 (Czeizler et al. 2008b) *For any word $w \in \Sigma^+$ there exists a unique θ -primitive word $t \in \Sigma^+$ such that $w \in t\{t, \theta(t)\}^*$, i.e., $\rho_\theta(w) = t$.*

Corollary 3 (Czeizler et al. 2008b) *Let $u, v \in \Sigma^+$ be two words such that $\rho(u) = \rho(v) = t$. Then, $\rho_\theta(u) = \rho_\theta(v) = \rho_\theta(t)$.*

Next, another bound is provided for this extended Fine and Wilf theorem, which is in many cases much shorter than the bound given in Theorem 29. As noted before, due to Proposition 4, it is intuitive that one cannot use the concise proof technique based on the fact that a conjugate of a primitive word is primitive. The proof given in Czeizler et al. (2008b) involves rather technical case analyses.

Theorem 30 (Czeizler et al. 2008b) Given two words $u, v \in \Sigma^+$ with $|u| > |v|$, if there exist two words $\alpha(u, \theta(u)) \in u\{u, \theta(u)\}^*$ and $\beta(v, \theta(v)) \in v\{v, \theta(v)\}^*$ having a common prefix of length at least $2|u| + |v| - \gcd(|u|, |v|)$, then $\rho_\theta(u) = \rho_\theta(v)$.

This section is concluded with an extension of another fundamental result related to the periodicity on words, namely the solution to the *Lyndon–Schützenberger equation*. The equation is of the form $u^\ell = v^n w^m$ for some $\ell, n, m \geq 2$ and $u, v, w \in \Sigma^+$. Lyndon and Schützenberger proved that this equation implies $\rho(u) = \rho(v) = \rho(w)$ (Lyndon and Schützenberger 1962). A concise proof when u, v, w belong to a free semigroup can be found in, for example, Harju and Nowotka (2004).

Incorporating the idea of θ -periodicity, the Lyndon–Schützenberger equation has been extended in Czeizler et al. (2009) in the following manner. Let $u, v, w \in \Sigma^+$, θ be an antimorphic involution over Σ , and ℓ, n, m be integers ≥ 2 . Let $\alpha(u, \theta(u)) \in \{u, \theta(u)\}^\ell$, $\beta(v, \theta(v)) \in \{v, \theta(v)\}^n$, and $\gamma(w, \theta(w)) \in \{w, \theta(w)\}^m$. The *extended Lyndon–Schützenberger equation* is

$$\alpha(u, \theta(u)) = \beta(v, \theta(v))\gamma(w, \theta(w))$$

In Czeizler et al. (2009), the authors investigated the problem of finding conditions on ℓ, n, m such that if the equation holds, then $u, v, w \in \{t, \theta(t)\}^+$ for some $t \in \Sigma^+$. If such t exists, we say that (ℓ, n, m) imposes θ -periodicity on u, v, w . The original condition $\ell, n, m \geq 2$ is not enough for this extension as shown below.

Example 6 (Czeizler et al. 2009) Let $\Sigma = \{a, b\}$ and θ be the mirror image. Take now $u = a^k b^2 a^{2k}$, $v = \theta(u)^l a^{2k} b^2 = (a^{2k} b^2 a^k)^l a^{2k} b^2$, and $w = a^2$, for some $k, l \geq 1$. Then, although $\theta(u)^{l+1} u^{l+1} = v^2 w^k$, there is no word $t \in \Sigma^+$ with $u, v, w \in \{t, \theta(t)\}^+$.

Example 7 (Czeizler et al. 2009) Consider again $\Sigma = \{a, b\}$ and the mirror image θ , and take $u = b^2(aba)^k$, $v = u^l b = (b^2(aba)^k)^l b$, and $w = aba$ for some $k, l \geq 1$. Then, although $u^{2l+1} = v\theta(v)w^k$, there is no word $t \in \Sigma^+$ with $u, v, w \in \{t, \theta(t)\}^+$.

Example 8 Let $\Sigma = \{a, b\}$ and θ be the mirror image. Let $v = a^{2m} b^{2j}$ and $w = aa$ for some $m \geq 1$ and $j \geq 1$. Then $v^n w^m = (a^{2m} b^{2j})^n a^{2m}$. This is θ -palindrome of even length and hence it can be written as $u\theta(u)$ for some $u \in \Sigma^+$. Clearly $\rho_\theta(w) = a$ and $\rho_\theta(v) \neq a$ because v contains b . Hence $(2, n, m)$ is not enough to impose the θ -periodicity.

Thus, once either n or m is 2, it is not always the case that there exists a word $t \in \Sigma^+$ such that $u, v, w \in \{t, \theta(t)\}^+$. On the other hand, it was proved that (ℓ, n, m) imposes θ -periodicity on u, v, w if $\ell \geq 5$, $n, m \geq 3$.

Theorem 31 (Czeizler et al. 2009) For words $u, v, w \in \Sigma^+$ and $\ell, n, m \geq 2$, let $\alpha(u, \theta(u)) \in \{u, \theta(u)\}^\ell$, $\beta(v, \theta(v)) \in \{v, \theta(v)\}^n$, and $\gamma(w, \theta(w)) \in \{w, \theta(w)\}^m$. If $\alpha(u, \theta(u)) = \beta(v, \theta(v))\gamma(w, \theta(w))$ holds and $\ell \geq 5$, $n, m \geq 3$, then $u, v, w \in \{t, \theta(t)\}^+$ for some $t \in \Sigma^+$.

This theorem requires rather complex case analyses, too, and hence the proof is omitted here. However, if ℓ, n, m are “big” enough, one can easily see that there is much room to employ the extended Fine and Wilf theorem.

Table 2**Summary of the extended Lyndon–Schützenberger equation results**

<i>l</i>	<i>n</i>	<i>m</i>	θ -Periodicity	Proved by
≥ 5	≥ 3	≥ 3	Yes	Theorem 31
4	≥ 3	≥ 3	?	
3	≥ 3	≥ 3	?	
≥ 3	2	≥ 2	No	Examples 6 and 7
≥ 3	≥ 2	2	No	
2	≥ 2	≥ 2	No	Example 8

This section is concluded with [Table 2](#), which summarizes the results obtained so far on the extended Lyndon–Schützenberger equation.

8 Conclusions

In this chapter we described how information can be encoded on DNA strands and how bio-operations can be used to perform computational tasks. In addition, we presented examples of the influence that fundamental properties of DNA-encoded information, especially the Watson–Crick complementarity, have had on various areas of theoretical computer science such as formal language theory, coding theory, automata theory, and combinatorics on words.

A few final remarks are in order regarding DNA-encoded data and the bio-operations that are used to act on it. The descriptions of DNA structure and DNA bio-operations point to the fact that DNA-encoded information is very different from electronically encoded information, and bio-operations also differ from electronic computer operations. A fundamental difference arises, for example, from the fact that in electronic computing data interaction is fully controlled, while in a test-tube DNA-computer, free-floating data-encoding DNA single strands can interact because of Watson–Crick complementarity. Another difference is that, in DNA computing, a bio-operation usually consumes both operands. This implies that, if one of the operands is either involved in an illegal binding or has been consumed by a previous bio-operation, it is unavailable for the desired computation. Yet another difference is that, while in electronic computing a bit is a single individual element, in DNA experiments, each submicroscopic DNA molecule is usually present in millions of identical copies. The bio-operations operate in a massively parallel fashion on all identical strands and this process is governed by the laws of chemistry and thermodynamics, with the output obeying statistical laws.

Differences like the ones mentioned above point to the fact that a fresh approach is needed when employing as well as when theoretically investigating bioinformation and biocomputation, and they offer a wealth of problems to explore at this rich intersection between molecular biology and computer science.

Examples of such fascinating research areas and topics include models and wet implementations of molecular computing machineries, membrane computing, DNA computing by splicing and insertion–deletion operations, bacterial computing and communication, DNA memory, DNA computing by self-assembly, and computational aspects of gene assembly in ciliates, as described in, for example, the chapter [Computational Nature of Gene Assembly in Ciliates](#) of this handbook.

Abstract

This chapter presents both the theoretical results of molecular computing models mainly from the viewpoint of computing theory and the biochemical implementations of those models in wet lab experiments. Selected topics include a variety of molecular computing models with computabilities ranging from finite automata to Turing machines, and the associated issues of molecular implementation, as well as some applications to logical controls for circuits and medicines.

1 Introduction

Molecular computing machineries (molecular machineries, in short), the primary theme of this chapter, are novel computing devices inspired by the biochemical nature of biomolecules. In the early days it was understood that molecular machineries would replace silicon-based hardware with biological hardware through the development of molecular-based computers. However, it is now recognized that molecular machineries should not substitute for existing computers but complement them.

One may be surprised at how early the term “molecular computers” appeared in the literature. In fact, one can go back to an article of *Biofizika* in 1973 where an idea of cell molecular computers is discussed (Vaintsvaig and Liberman 1973). Since 1974, M. Conrad, one of the pioneering researchers in this area, has been conducting consistent research on information-processing capabilities using macromolecules (such as proteins) (Conrad 1985), and he edited a special issue entitled *Molecular Computing Paradigms* in Conrad (1992). These initial efforts in the short history of molecular computing have been succeeded by Head’s pioneering work on splicing systems and languages in Head (1987) whose theoretical analysis on splicing phenomena is highly appreciated, in that it was the first achievement of mathematical analysis using biochemical operations of DNA recombination. It is also worth mentioning that, prior to Head’s work, one can find some amount of study dealing with DNA/RNA molecules in the framework of formal language theory, such as Eberling and Jimenez-Montano (1980), Jimenez-Montano (1984), and Brendel and Busse (1984). Then, all of these initial works were eventually evoked by Adleman’s groundbreaking attempt in 1994 (Adleman 1994), which decisively directed this new research area of *molecular computing*.

This chapter presents both the theoretical results of molecular computing models mainly from the viewpoint of computing theory and the biochemical implementations of those models in wet lab experiments. Selection of topics included here might reflect the authors’ taste and it is intended to give concise and suggestive expositions for each chosen topic.

The chapter is organized as follows. This section ends by providing the rudiments of the theory of formal languages and computation. [Section 2](#) presents a variety of molecular computing models that are classified into two categories: the first is for molecular computing models with *Turing computability* and the second is for the molecular models of *finite automata*. Among the various ideas proposed for realizing Turing computability within the framework of molecular computing theory, four typical approaches to achieving universal computability were selected. These are based on formal grammars, equality sets, Post systems, and logical formulae. It is hoped that succinct expositions of those models may help the reader to gain some new insight into the theory of molecular computing models.

Most of the molecular computing models developed so far involve both the use of structural molecules with various complexity and sophisticated control of them.

⦿ **Section 3** is devoted to those *computing models with structured molecules* in which hairpin structures, tree structures, and more involved structures are focused on, among others.

In ⦿ **Sect. 4** attention is turned to the wet implementation issues of the molecular computing models and their applications as well. The lineup of the chosen topics is as follows:

- Enzyme-based implementation of *DNA finite automata* and its application to drug delivery
- Molecular design and implementation of *logic gates and circuits* using DNAzymes and *DNA tiles*
- Abstract models called *reaction graphs* for representing various reaction dynamics of DNA assembly pathways
- DNA implementation of finite automata with *whiplash machines*
- Hairpin-based implementation of *SAT engines* for solving the 3-SAT problem

The results mentioned above are just some successful examples in the area of molecular computing machineries that have been realized through devoted efforts and collaboration between biochemists and computer scientists. It is hoped that they will be able to provide a good springboard for advanced beginners in this area and for senior researchers in other areas.

1.1 Basic Notions and Notations

The basic notions and notations required to understand this chapter are summarized below. Then standard notions and notations are assumed from the theory of formal languages (see, e.g., Hopcroft et al. 2001, Rozenberg and Salomaa 1997, and Salomaa 1985).

For a set X , $|X|$ denotes the cardinality of X . The power set of X (i.e., the set of all subsets of X) is denoted by $\mathcal{P}(X)$.

An *alphabet* is a nonempty finite set of symbols. For an alphabet V , V^* denotes the set of all strings (of finite length) over V , where the empty string is denoted by ϵ (or λ). By V^+ one denotes the set $V^* - \{\epsilon\}$. A *language* over V is a subset of V^* . For a string $x = a_1a_2\dots a_n$ over V , the *mirror image* of $x \in V^*$, denoted by $mi(x)$ (or by x^R), is defined by $a_n \dots a_2a_1$.

A collection of languages over an alphabet V is called a *family of languages* (*language family*) or a *class of languages* (*language class*) over V .

A *phrase-structure grammar* (or *Chomsky grammar*) is a quadruple $G = (N, T, S, P)$, where N and T are disjoint alphabets of nonterminals and terminals, respectively, $S (\in N)$ is the initial symbol, and P is a finite subset of $(N \cup T)^* N (N \cup T)^* \times (N \cup T)^*$. An element (u, v) of P , called a rule, is denoted by $u \rightarrow v$.

For strings $x, y \in (N \cup T)^*$, let

$$x \Rightarrow_G y \stackrel{\text{def}}{\iff} \exists x_1, x_2 \in (N \cup T)^* \text{ and } u \rightarrow v \in P \text{ such that } x = x_1ux_2, y = x_1vx_2.$$

A language generated by G is defined as $L(G) = \{x \in T^* | S \Rightarrow_G^* x\}$

A phrase-structure grammar $G = (N, T, S, P)$ is

1. *Context-sensitive* if for $u \rightarrow v \in P$ there exist $u_1, u_2 \in (N \cup T)^*$, $A \in N$, $x \in (N \cup T)^+$ such that $u = u_1Au_2$, $v = u_1xu_2$
2. *Context-free* if for $u \rightarrow v \in P$, $u \in N$
3. *(Context-free) linear* if for $u \rightarrow v \in P$, $u \in N$, and $v \in T^* NT^* \cup T^*$
4. *Regular* if for $u \rightarrow v \in P$, $u \in N$, and $v \in T \cup TN \cup \{\epsilon\}$

RE, *CS*, *CF*, *LIN*, and *REG* denote the families of languages generated by phrase-structure grammars, context-sensitive grammars, context-free grammars, (context-free) linear grammars, and regular grammars, respectively. *RE* comes from the alternative name of *recursively enumerable* language. The following inclusions (called the *Chomsky hierarchy*) are proved.

$$REG \subset LIN \subset CF \subset CS \subset RE$$

A (nondeterministic) *Turing machine* (TM) is a construct $M = (Q, V, T, p_0, F, \delta)$, where Q, V are finite sets of states and a tape alphabet, respectively. V contains a special symbol B (a blank symbol), $T(\subseteq V - \{B\})$ is an input alphabet, $p_0 (\in Q)$ is the initial state, $F (\subseteq Q)$ is a set of final states, and δ is a function from $Q \times V$ to $\mathcal{P}(Q \times V \times \{L, R\})$ acting as follows: for $p, p' \in Q, a, b \in V, d \in \{L, R\}$, if $(p', b, d) \in \delta(p, a)$, then M changes its state from p to p' , rewrites a as b , and moves the head to the left (if $d = L$) or the right (if $d = R$). M is called *deterministic* (denoted by DTM) if for each $(p, a) \in Q \times V, |\delta(p, a)| \leq 1$.

A configuration in M is a string of the form: xpy , where $x \in V^*$, $y \in V^*(V - \{B\}) \cup \{\epsilon\}$, $p \in Q$, and the head of M takes its position at the leftmost symbol of y . A binary relation \vdash on the set of configurations in M is defined by

$$\left\{ \begin{array}{l} xpay \vdash xbqy \iff (q, b, R) \in \delta(p, a) \\ xp \vdash xbq \iff (q, b, R) \in \delta(p, B) \\ xpay \vdash xqby \iff (q, b, L) \in \delta(p, a) \\ xcp \vdash xqcb \iff (q, b, L) \in \delta(p, B) \end{array} \right.$$

where $a, b, c \in V, x, y \in V^*, p, q \in Q$. Let \vdash^* be the reflexive, transitive closure of \vdash . A language $L(M)$ recognized by M is defined as

$$L(M) = \{w \in T^* \mid p_0 w \vdash^* xpy, \text{ for some } x, y \in V^*, p \in F\}$$

that is, the set of input strings such that, starting with the initial state, they drive their configurations in M to a final state. It is known that the family of languages recognized by Turing machines is equal to the family *RE*.

As subfamilies of *RE*, there are many to be noted. Among others, two families are of importance: **NP** and **P** are the families of languages recognized in polynomial-time, that is, in $f(n)$ steps by TMs and DTMs, respectively, where f is a polynomial function defined over the set of nonnegative integers and n is the size of the input string. It remains open whether **P** = **NP** or not, while the inclusion **P** ⊆ **NP** is clear from the definition. In particular, a subfamily of **NP** called *NP-complete* is of special interest, because NP-complete languages are representative of the hardness in computational complexity of **NP** in the sense that any language in **NP** is no harder than the NP-complete languages. Further, by **NSPACE**($f(n)$) and **DSPACE**($f(n)$), the families of languages recognized in $f(n)$ space (memory) are denoted by TMs and DTMs, respectively.

Due to Watson–Crick complementarity, not only single-stranded molecules but also completely hybridized double-stranded molecules can be regarded as strings over an alphabet {A, C, G, T}. Therefore, it is natural to employ the formal framework of the classical formal language theory, in order to study and formulate notions in molecular computing.

Given an alphabet Σ , a *morphism* h over Σ is a mapping defined by $h(a) \in \Sigma^*$ for each $a \in \Sigma$. Any h is extended to $h: \Sigma^* \rightarrow \Sigma^*$ by $h(\epsilon) = \epsilon$ and $h(xa) = h(x)h(a)$ for each $x \in \Sigma^*, a \in \Sigma$. A *weak coding* over Σ is a morphism h such that $h(a)$ is in $\Sigma \cup \{\epsilon\}$ for each $a \in \Sigma$.

An *involution* over Σ is a morphism h such that $h(h(a)) = a$ for each $a \in \Sigma$. Any involution h over Σ such that $h(a) \neq a$ for all $a \in \Sigma$ is called a *Watson–Crick morphism* over Σ .

In analogy to DNA molecules (where A and T (C and G) are complementary pairs), for $x, y \in \Sigma^*$, if $h(x) = y$ (and therefore, $h(y) = x$), then it is said that x and y are *complementary* to each other, and denoted by $\bar{x} = y$ ($\bar{y} = x$). An alphabet $\bar{\Sigma} = \{\bar{a} \mid a \in \Sigma\}$ is called the *complementary alphabet* of Σ .

2 Molecular Machine Models

Since Adleman's groundbreaking work on the DNA implementation of computing a small instance of the directed Hamiltonian path problem (Adleman 1994), numerous research papers in this new computation paradigm have been published. In fact, Adleman's model has been extensively studied by many researchers seeking to generalize his technique to solve larger classes of problems (Lipton 1995; Lipton and Baum 1996), provide abstract DNA computer models with Turing computability (Adleman 1996; Beaver 1995; Rothemund 1995; Winfree et al. 1996), and so forth.

In this section, the focus is on computing models of molecular machines with Turing computability and others, restricted primarily to finite automata.

2.1 Molecular Models with Turing Computability

2.1.1 Grammar Approach

The Turing machine or its grammatical equivalent (like phrase-structure grammar) is one of the most common computing models when one wants to prove the universal computability of a new computing device. Among others, most interesting is the normal form theorems proved by Geffert (1991), which tell us that each recursively enumerable language can be generated by a phrase-structure grammar with only five nonterminals $\{S, A, B, C, D\}$ (S is the initial nonterminal) and with all of the context-free rules being of the form $S \rightarrow v$ and two extra (non context-free) rules $AB \rightarrow \epsilon$ and $CD \rightarrow \epsilon$. Thus, the feature of this normal form is of great importance in that *most* of the computation processes can be carried out without checking any context-sensitivity requirement.

Geffert derived an interesting normal form theorem for phrase-structure grammars which can be conveniently rephrased here with some modifications.

Proposition 1 (Geffert 1991) *Each recursively enumerable language L over Σ can be generated by a phrase-structure grammar with $G = (\{S, A, C, G, T\}, \Sigma, R \cup \{TA \rightarrow \epsilon, CG \rightarrow \epsilon\}, S)$, where $R = R_1 \cup R_2 \cup R_3$ and*

$$R_1 = \{S \rightarrow z_a Sa \mid a \in \Sigma \text{ and } z_a \text{ is in } \{T, C\}^*\} \text{ (called Type-(i) rules)}$$

$$R_2 = \{S \rightarrow uSv \mid u \text{ is in } \{T, C\}^* \text{ and } v \text{ is in } \{A, G\}^*\} \text{ (called Type-(ii) rules)}$$

$$R_3 = \{S \rightarrow u\} \text{ (called Type-(iii) rule), where } u \text{ is in } \{T, C\}^*$$

The following properties of the phrase-structure grammar G in normal form in Proposition 1 are quite useful for deriving the computing model discussed later.

1. It is not until a Type-(iii) rule has been applied that two extra cancellation rules ($TA \rightarrow \epsilon$ and $CG \rightarrow \epsilon$) are available.

2. Mixed use of Type-(i) and Type-(ii) rules leads to sentential forms for which no chance to get terminal strings remains.
3. Any occurrence of $x (\in \Sigma)$ in any substring (except for a suffix) of a sentential form blocks a terminal string.
4. A successful derivation process can be divided into three phases: At the first phase (*Generation*), Type-(i) rules are used. The second phase (*Extension*) consists of using Type-(ii) rules and ends up with one application of the Type-(iii) rule. Finally, the third phase (*Test*) erases well-formed pairings (TA or CG) using two extra rules only.
5. There is only one occurrence of either TA or CG in any sentential form to which cancellation rules can be applied.
6. The *Test* phase can only be started up with the unique position where either TA exclusively or CG appears immediately after one application of the Type-(iii) rule.

Grammar-Based Computation of Self-Assembly: (GCS)

We can now present a way of DNA computation, GCS, which is based on the features of Geffert normal form grammars in [Proposition 1](#). GCS (this is referred to as YAC in the original paper (Yokomori 2000)), grammar-based computation of self-assembly, has the following set of basic components assembled:

1. For each Type-(ii) rule: $S \rightarrow uSv$, construct a component with the shape illustrated in [Fig. 1b](#), and let it be called a *Type-(ii)* component.
2. For the unique Type-(iii) rule: $S \rightarrow u$, construct a component with the shape illustrated in [Fig. 1c](#), where a connector is attached as an endmarker. This is called a *Type-(iii)* component.
3. Finally, for a given input string $w = b_1 \dots b_n (\in \Sigma^*)$ to be recognized, a component in the shape shown in [Fig. 1a](#) is prepared, where Z_w of the component in (a) is the binary coding of the input w and $\overline{Z_w}$ denotes the complementarity sequence of Z_w .

Under the presence of *ligase*, all these components with sufficiently high concentration in a single pot of a test tube are provided. (See [Fig. 1](#).)

Finally, the following operation is used:

- d-Detect: Given a test tube that may contain double-stranded strings, return “yes” if it contains (at least) one *completely hybridized* double-stranded string, and “no” otherwise.

[Figure 1](#) illustrates a computation schema for GCS, where a random pool is a multi-set of basic components with sufficiently high concentration that can produce all possible assembly necessary for recognizing an input string. Besides the operation d-Detect, GCS only requires two basic operations to execute its computation process: *annealing* and *melting*.

In summary, one has the following:

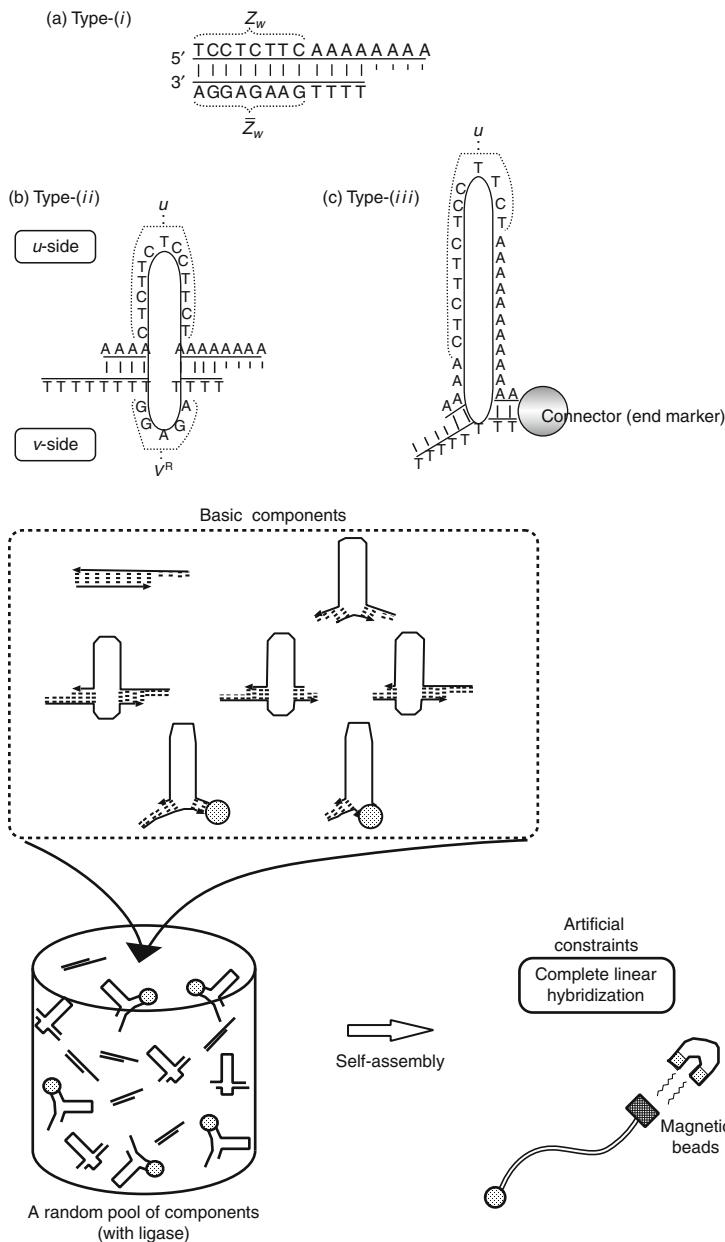

Theorem 1 (Yokomori 2000) *Any recursively enumerable language can be recognized by the GCS computation schema.*

(Note that, in contrast, GCS is based on grammatical formulation, its functional behavior is close to an acceptor rather than a generative grammar.)

The structural simplicity of computation assembly units in GCS is expected to facilitate its implementation at least in its design schema. In particular, the two groups of four DNAs (A,G:

Fig. 1

Basic components and a successful computation using the grammar-based computation process (GCS): A large quantity of molecules consisting of all basic components are put into a single test tube. Then, hybridization of those molecules produces candidate complex molecules for successful computations. By first melting the complexes and then annealing them, a desired double-stranded molecule is detected using the w -probe attached with magnetic beads when the input w is in L .

purine and C,T: pyrimidine) can be readily applied both to encoding the computational information of a language into its GCS assembly units and to checking the completeness of the computation results in the final process with its complementary property. On the other hand, as for the biomolecular feasibility of the GCS, it still remains at the conceptual level, and more molecular biological investigation is needed before the model becomes truly feasible.

2.1.2 Equality Checking Approach

In the theory of formal languages and computation, a simple computational principle called *equality checking* can often play an important role. The equality checking principle (EC principle) is simple enough for humans to understand and for machines of any kind to implement. In particular, it seems very suitable for biomolecular machines, because this EC principle only requires the task of equality checking of two memories, represented as strings of symbols, just like a completely hybridized *double-stranded DNA sequence*.

Based on the EM approach, one can present an abstract model of DNA computing, DNA-EC, which has the universal computability of Turing machines.

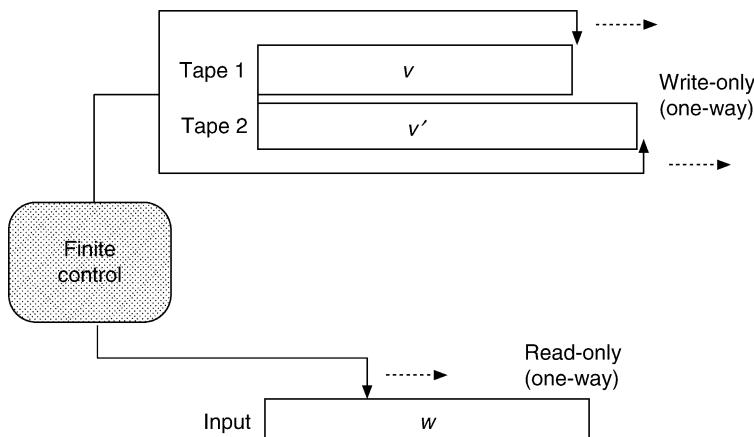

Equality Machines

An *equality machine* (Engelfriet and Rozenberg 1980) is an abstract acceptor shown in Fig. 2. Formally, an equality machine (EM) M is a structure $(Q, \Sigma, \Delta, \delta, q_0, F)$, where Q is the finite set of states, $q_0 \in Q$ is the initial state, $F \subseteq Q$ is the set of final states, Σ is the input alphabet, Δ is the output alphabet, and δ is a finite set of transition rules of the form: $(p, a) \rightarrow (q, u, i)$, where $p, q \in Q$, $a \in \Sigma \cup \{\epsilon\}$, $u \in \Delta^*$, and $i \in \{1, 2\}$.

A configuration of M is of the form $(p, w, (v_1, v_2))$, where $p \in Q$, $w \in \Sigma^*$, and $v_1, v_2 \in \Delta^*$. If $(p, a) \rightarrow (q, u, i) \in \delta$, then one writes $(p, aw, (v_1, v_2)) \vdash (q, w, (v'_1, v'_2))$, where $v'_1 = v_1u$ and $v'_2 = v_2$.

Fig. 2

Equality machine EM: the machine consists of a one-way *input tape*, a *finite control*, and two *write-only* tapes for its memory. With the initial empty memory tapes, the machine starts to read the input from the left and changes its state, then extends one of the two memory tapes by concatenating an output string, according to the transition rules specified. At the end of computation, where the input string has been fully read, the machine accepts it only if the contents of the two memory tapes are identical.

(if $i = 1$), and $v'_1 = v_1$ and $v'_2 = v_2 u$ (if $i = 2$). The reflexive and transitive closure of \vdash is denoted by \vdash^* . The language accepted by M is $L(M) = \{w \in \Sigma^* \mid (q_0, w, (\epsilon, \epsilon)) \vdash^* (q, \epsilon, (v, v)) \text{ for some } q \in F \text{ and } v \in \Delta^*\}$. An EM M is *deterministic* if δ is a mapping from $Q \times \Sigma$ into $Q \times (\Delta \times \{1,2\})^*$.

The classes of languages accepted by nondeterministic and deterministic EMs are denoted by $\mathcal{L}_N(EM)$ and $\mathcal{L}_D(EM)$, respectively.

Very interesting results from Engelfriet and Rozenberg (1980) are summed up here which motivated the results in this section.

Proposition 2 (Engelfriet and Rozenberg 1980) *The following relations hold true:*

1. $\mathcal{L}_N(EM) = RE$
2. $\mathcal{L}_D(EM) \subseteq \mathbf{DSPACE}(\log n)$ and $REG \subset \mathcal{L}_D(EM) \subset \mathbf{NSPACE}(n) = CS$
3. $\mathcal{L}_D(EM)$ is incomparable to CF but not disjoint.

DNA-EC: A Model of DNA Computing

Following the notations and definitions in Rooß and Wagner (1996), the DNA computation model called DNA-EC is described, which is based on the characterization results given in the previous section.

In the *test tube computation* discussed below, T denotes a test tube containing a set of strings over some fixed alphabet Σ , and its contents are denoted by $I(T)$. Further, it is assumed that $I(T) \subseteq \Sigma^*$ unless stated otherwise.

The DNA-EC requires the following two set *test* operations:

- EM (*Emptiness Test*): Given a test tube T , return “yes” if $I(T)$ contains a string (i.e., $I(T) \neq \emptyset$) and “no” if it contains none.
- EQ (*Equivalence Test*): Given a test tube T (where $I(T) \subseteq D^*$) that may contain double-stranded strings, return “yes” if $I(T)$ contains (at least) one complete double-stranded string, and “no” otherwise. (Note that D is the alphabet for representing double strands.)

Let T, T_1, T_2 be set variables for test tubes used in DNA-EC. ▶ [Table 1](#) shows a collection of *set* operations used in DNA-EC, where $a, b, c, d \in \Sigma$, $u, v, w \in \Sigma^*$.

Let \mathcal{O} and \mathcal{T} be collections of set operations and set test operations, respectively, introduced above. Then, $\text{DNA}(\mathcal{O}, \mathcal{T})\text{-EC}$ is the class of languages recognized by DNA-EC, which allows the use of set operations from \mathcal{O} and of set test operations from \mathcal{T} .

■ **Table 1**

Set operations (from Rooß and Wagner 1996)

Name	Syntax	$I(T)$ after the Operation
UN(union)	$T := T_1 \cup T_2$	$I(T_1) \cup I(T_2)$
LC(left cut)	$T := a \setminus T_1$	$\{u \mid au \in I(T_1)\}$
LA(left adding)	$T := a \cdot T_1$	$\{a\} \cdot I(T_1)$
EX(extraction)	$T := \text{Ex}(T_1, w)$	$I(T_1) \cap \Sigma^* \{w\} \Sigma^*$
RE(replacement)	$T := \text{Re}(T_1, u, v)$	$\{xvy \mid xuy \in I(T_1)\}$
RV(reversal)	$T := T_1^R$	$\{u^R \mid u \in I(T)\}$ (u^R is the reversal of u)

EX is essentially the same as the one often referred to as *Separation* in the literature

As for the computational power of DNA-EC, it is proved that given an EM $M = (Q, \Sigma, \Delta, \delta, q_0, F)$ and $w \in \Sigma^*$, the computation process of M with w is simulated within the DNA-EC model in a variety of ways. The idea for the simulation is simply to keep only the difference between the contents of Tapes 1 and 2 in the configuration of w in the computing schema dealing with a sequence of DNAs as a single string. The hybridization property of DNA complementarity can also be readily used for checking two memories in the case of manipulating *double-stranded strings* within the schema. The obtained results include the following:

Theorem 2 (Yokomori and Kobayashi 1999) *The following equalities hold:*

1. $\text{DNA}(\{\text{UN,LA,RV,RE}\}, \{\text{EM}\})\text{-EC} = \text{DNA}(\{\text{UN,RE}\}, \{\text{EM}\})\text{-EC} = \text{RE}$
2. $\text{DNA}(\{\text{UN,LA,LC,EX}\}, \{\text{EQ}\})\text{-EC}$

2.1.3 Post System Approach

Among a variety of computing models based on string rewriting, a classical Post system will be introduced below that has a unique position, somewhere between formal grammars and logical systems. Because of the simplicity of its components and functional behavior, a Post system can sometimes provide a clear picture of the essence of the computation.

A Lesson From Post Systems

A rewriting system called the *general regular Post system* (GRP system) is a quadruple $G = (V, \Sigma, P, A)$, where V and $\Sigma (\subseteq V)$ are alphabets, P is a finite set of rules of the form of either $uX \rightarrow wX$ or $aX \rightarrow Xb$ ($X \notin V$: variable, $u, w \in V^*, a, b \in V$), $A (\subset V^+)$ is a finite set of axioms.

Given strings $\alpha, \beta \in V^*$, define a binary relation \Rightarrow as follows:

$$\alpha \Rightarrow \beta \stackrel{\text{def}}{\iff} \begin{cases} \exists uX \rightarrow wX \in P, \delta \in V^* [\alpha = u\delta, \beta = w\delta] & \text{or} \\ \exists aX \rightarrow Xb \in P, \delta \in V^* [\alpha = a\delta, \beta = \delta b] \end{cases}$$

Let \Rightarrow^* be the reflexive and transitive closure of \Rightarrow . Then, a language generated by G is defined as

$$L(G) = \{w \in \Sigma^* \mid \exists u \in A \text{ such that } u \Rightarrow^* w\}$$

It is known that the family of languages generated by GRP systems coincides with the family of recursively enumerable languages (Salomaa 1985). The source of the universal computing capability of GRP systems comes from the use of two types of rules $\alpha X \rightarrow \beta X$ (say, type 1 rule) and $aX \rightarrow Xb$ (type 2 rule). The generative capability between these two types of rule is interesting.

Theorem 3 (Post 1943) *GRP systems with type 1 rules alone can generate only regular languages, while type 1 rules together with type 2 rules enable GRP systems to generate any recursively enumerable language.* (This fact gives the base of a technique called the “rotate-simulate method” used to prove that a computing model has universal computability.)

This result seems to be useful in analyzing the computing power of rewriting systems. As seen in the subsequent discussion, this observation leads to new types of computing models with universal computability based on splicing operations.

Multi-test Tube Models

We note that Type 1 rules of GRP systems can be generally simulated by some devices of existing rewriting models of computation. Therefore, in order to achieve Turing computability, one has to answer the question: “Is there any way to carry out a rotation rule $aX \rightarrow Xb$ within the computing system?” One possible way is to consider an extended model of test tube systems studied in Csuhaj-Varju et al. (1996) and Kobayashi and Sakakibara (1998).

An *elementary formal system* (EFS) is a triple $E = (D, \Sigma, M)$, where D is a finite set of predicate symbols, Σ is a finite alphabet, and M is a set of logic formulas. Then, F in M is an *H-form* iff it is of the form:

$$P(x_1 u_1 v_1 y_2) \leftarrow Q(x_1 u_1 u_2 x_2) R(y_1 v_1 v_2 y_2) \text{ or } P(w) \leftarrow$$

where x_1, x_2, y_1, y_2 are all distinct variables, u_1, u_2, v_1, v_2 and w are in Σ^* .

An EFS $E = (D, \Sigma, M)$ is called *H-form EFS* iff every F in M is an H-form. Further, an H-form EFS with a single predicate P , that is, an H-form EFS $E = (\{P\}, \Sigma, M)$ is called a *simple H-form EFS*.

Given a predicate P and EFS $E = (\{P\}, \Sigma, M)$, define

$$L(E, P) = \{w \in \Sigma^* | P(w) \text{ is provable from } E\}$$

It is known that a simple H-form EFS is equivalent to an H-system in its computing capability.

Theorem 4 For any H-system $S = (\Sigma, R, A)$, there effectively exists a simple H-form EFS $E = (\{P\}, \Sigma, M)$ such that $L(E, P) = L(S)$. Conversely, for any simple H-form EFS $E = (\{P\}, \Sigma, M)$, one can construct an H-system $S = (\Sigma, R, A)$ such that $L(S) = L(E, P)$.

Therefore, in order to get the computing power beyond H-systems, it is necessary to consider an H-form EFS with more than one predicate symbol, which leads to the idea of “multi-splicing models” where more than one test tube is available for splicing operations.

Given an $n > 0$, by HE_n the family of languages defined by H-form EFSs is denoted with n predicate symbols. Further, let $HE_* = \bigcup_{i \geq 1} HE_i$.

Then, the following has been proved.

Theorem 5

1. $HE(FIN, FIN) = HE_1 \subset HE_2 \subseteq HE_3 \subseteq \dots \subseteq HE_{13} = \dots = HE_* = RE$.
2. HE_2 contains non-regular languages.
3. HE_3 contains non-context-free languages.

Thus, 13 test tubes are sufficient to generate any recursively enumerable language in multi-splicing models.

The way to simulate an H-form EFS $E = (D, R, A)$ by a multi-splicing model is outlined below, where $|D| = 2$, that is, two test tubes T_1 and T_2 are available (Kobayashi and Sakakibara 1998). It suffices to show how to simulate $aX \rightarrow Xb$ using splicing operations in two test tubes. For a given string $w = ax$, make $w' = BaxE$, where B and E are new symbols of marker. Then, delete a prefix Ba from w' in T_1 and transfer xE to T_2 that contains b . Then, replace E in xE with b , resulting in xb .

It remains open to solve how many test tubes is minimally necessary to generate any recursively enumerable language. See Csuhaj-Varju et al. (1996) for related discussion.

2.1.4 Logic Approach

Horn clause logic is one of the most important logical systems in mathematical logic. Its significance was first pointed out by the logician Alfred Horn (Horn 1951). Horn clause logic is a mathematical basis of a descriptive programming language, PROLOG, and is known to have Turing computability (Tarnlund 1977). Therefore, it is natural to construct a molecular computing device based on Horn clause computation (Kobayashi et al. 1997). Kobayashi proposed to use Horn clause logic as an underlying computational framework of a molecular computing machine (Kobayashi 1999). His idea is to implement a reduction process of a subclass of a Horn program, called a *simple* Horn program, with DNA molecules.

For a predicate symbol A and a sequence X_1, \dots, X_k of constants or variables, $A(X_1, \dots, X_k)$ is called a *simple atom*. If every X_k is a constant, $A(X_1, \dots, X_k)$ is called a *simple ground atom*. A *simple Horn clause* is a formula of the form $\forall X_1, \dots, X_m (F \leftarrow F_1 \wedge \dots \wedge F_n)$, where F and F_i ($1 \leq i \leq n$) are simple atoms. For a simple Horn clause $r : F \leftarrow F_1, \dots, F_n$, F and F_i ($i = 1, \dots, n$) are called a *head* and a *body* of r , respectively. A *simple Horn program* is a finite set of simple Horn clauses.

A substitution θ is a mapping from V to $V \cup C$. An *expression* means a constant, a variable, a sequence of atoms, or a clause. For an expression E and a substitution θ , $E\theta$ stands for the result of applying θ to E , which is obtained by simultaneously replacing each occurrence of a variable X in E by the corresponding variable or constant $X\theta$.

Let H be a simple Horn program and I be a set of simple ground atoms. Then, an *immediate consequence operator*, $T_H(I)$ is defined as follows:

$$T_H(I) = \{F \mid F_1, \dots, F_k \in I \wedge A \leftarrow B_1, \dots, B_k \in H \wedge \exists \theta \text{ s.t. } (B_i\theta = F_i \wedge A\theta = F)\}$$

Let Σ be a finite alphabet. A *decision problem* is a function from Σ^* to $\{0, 1\}$. Let Γ be an alphabet (possibly infinite) for representing simple Horn programs and Γ^* be the set of all strings of *finite* length over Γ . A function π from Σ^* to Γ^* is said to be an *encoding function for problem instances* if for every $w \in \Sigma^*$, $\pi(w)$ is a finite set of simple Horn clauses and π can be computed by a deterministic Turing machine in polynomial time. Let sz be a function from Σ^* to the set of all positive integers such that for every $w \in \Sigma^*$, $sz(w) \leq |w|$ and $sz(w)$ can be computed in polynomial time with respect to $|w|$ by a deterministic Turing machine. A family $\{H_i\}_{i \geq 1}$ of simple Horn programs *computes a decision problem*, f , with *encoding function*, π , and *size function*, sz , if there exists a predicate symbol A such that for every $w \in \Sigma^*$ with $sz(w) = n$, $f(w) = 1$ holds iff $A \in T_{H_{sz(w)} \cup \pi(w)}(\emptyset)$.

It is said that a function ϕ from $\{1\}^+$ to Γ^* generates a family $\{H_i\}_{i \geq 1}$ of simple Horn programs if for every positive integer i , $\phi(1^i) = H_i$ holds. A family $\{H_i\}_{i \geq 1}$ of simple Horn programs is said to be *uniform* if it is generated by some function, which can be computed by a deterministic Turing machine in polynomial time.

Then, one can show the following theorem:

Theorem 6 *For any decision problem P in NP, there exists a uniform family of simple Horn programs which computes P in polynomial steps.*

By the above theorem, efficient DNA implementation of the operation T_H for a simple Horn program enables us to construct a DNA computer that solves problems in NP in a polynomial number of biolab steps. One idea to implement T_H is given by Kobayashi, in which

the whiplash polymerase chain reaction (PCR) technique is used to (1) check the equality of arguments in a body of a clause and (2) copy an argument from a body to a head. (For details, refer to [Sect. 4.4](#) in this chapter.)

For representing ground atoms of a given simple Horn program, it is necessary to design sequences of the following oligos:

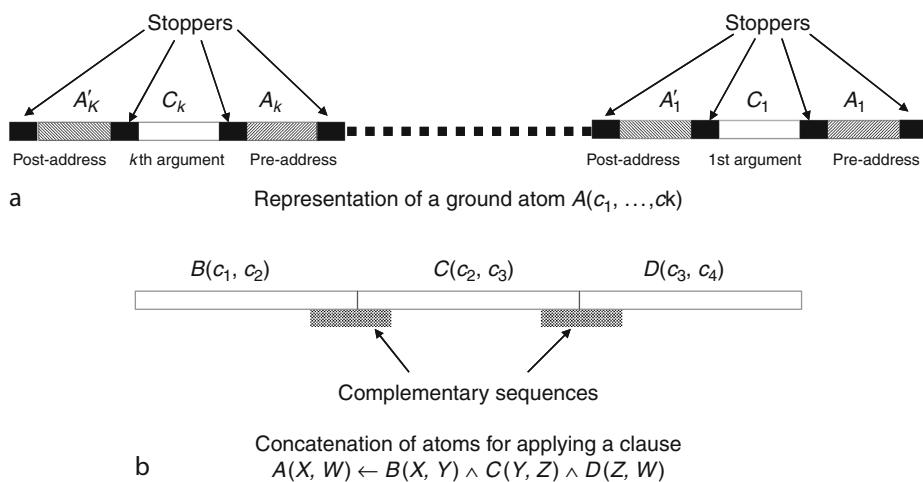

1. Oligos for representing constant symbols
2. For each predicate symbol A with k -arguments and for each i ($1 \leq i \leq k$), two different oligos A_i and A'_i , where A_i and A'_i are called a *pre-address* and a *post-address* of A at the i th position

Each ground atom $A(c_1, \dots, c_k)$ is represented as a single-stranded DNA consisting of k segments, each of which contains data c_i of each argument of A . Each segment is composed of three regions, *pre-address*, *data*, and *post-address*. The data region is an oligo representing a constant. Further, there exist stopper sequences in whiplash PCR at each of the segment ends, and at each end of the pre-address, data, and post-address regions. (See [Fig. 3a](#).)

The procedure for computing $T_H(I)$ is as follows. First, construct a set of ground instances of all possible bodies of rules in H . This is accomplished by concatenating ground atoms in DNA representation of I by using appropriate complementary sequences (see [Fig. 3b](#)). Then, check the equality constraint among arguments specified by the rule, which is implemented by using whiplash PCR with two different stopper sequences in a sophisticated manner. In this way, one can extract correct ground instances of all possible bodies of rules. Then, copy arguments from the body to the head by using whiplash PCR once again. For instance, in [Fig. 3b](#), the arguments c_1 and c_4 are copied to the head, which results in the DNA

Fig. 3

Representation of atoms and their ligation: (a) DNA representation of a ground atom $A(c_1, \dots, c_k)$. (b) Concatenation of atoms $B(c_1, c_2)$, $C(c_2, c_3)$, $D(c_3, c_4)$ for applying a clause $A(X, W) \leftarrow B(X, Y) \wedge C(Y, Z) \wedge D(Z, W)$. After checking the equivalence of corresponding arguments (the second of B and the first of C , the second of C and the first of D), one makes a new DNA sequence representing $A(c_1, c_4)$ by using the whiplash PCR technique.

representation of a ground atom $A(c_1, c_4)$. Refer to Kobayashi (1999) for details. In conclusion, from [Theorem 6](#) and the above discussion, one has:

- Claim 1**
- (1) *There effectively exists a bio-procedure based on the simple Horn clause computation model with Turing computability.*
 - (2) *For any decision problem P in NP, there effectively exists a bio-procedure of a polynomial number of steps for computing P based on the simple Horn clause computation model.*

Other approaches to the DNA implementation of Horn clause computation were also proposed by Uejima et al. (2001).

2.2 Molecular Finite State Machines

A *finite automaton* (FA) is one of the most popular concepts in theoretical computer science, and, hence, it is of great use to establish a simple implementation method for realizing an FA in the formulation of molecular computing. In particular, it is strongly encouraged to consider the problem of how simply one can construct a molecular FA using DNAs in the framework of *self-assembly computation*.

Formally, a *nondeterministic finite automaton* (NFA) is a construct $M = (Q, \Sigma, \delta, p_0, F)$, where Q is a set of states, Σ is the input alphabet, $p_0 (\in Q)$ is the initial state, $F (\subseteq Q)$ is a set of final states, and δ is defined as a function from $Q \times \Sigma$ to $\mathcal{P}(Q)$ (the power set of Q). (If δ is restricted to being a function from $Q \times \Sigma$ to Q , then M is said to be *deterministic* and is denoted by DFA.)

2.2.1 Bulge Loop Approach

The first method introduced here, proposed by Gao et al. (1999), consists of three basic phases: (1) *encoding* the transition rules of a given NFA with an input string onto DNA molecules, (2) *hybridization* and *ligation* which carry out the simulation of the state transition, and (3) *extracting* the results to decide the acceptance or rejection of the input string.

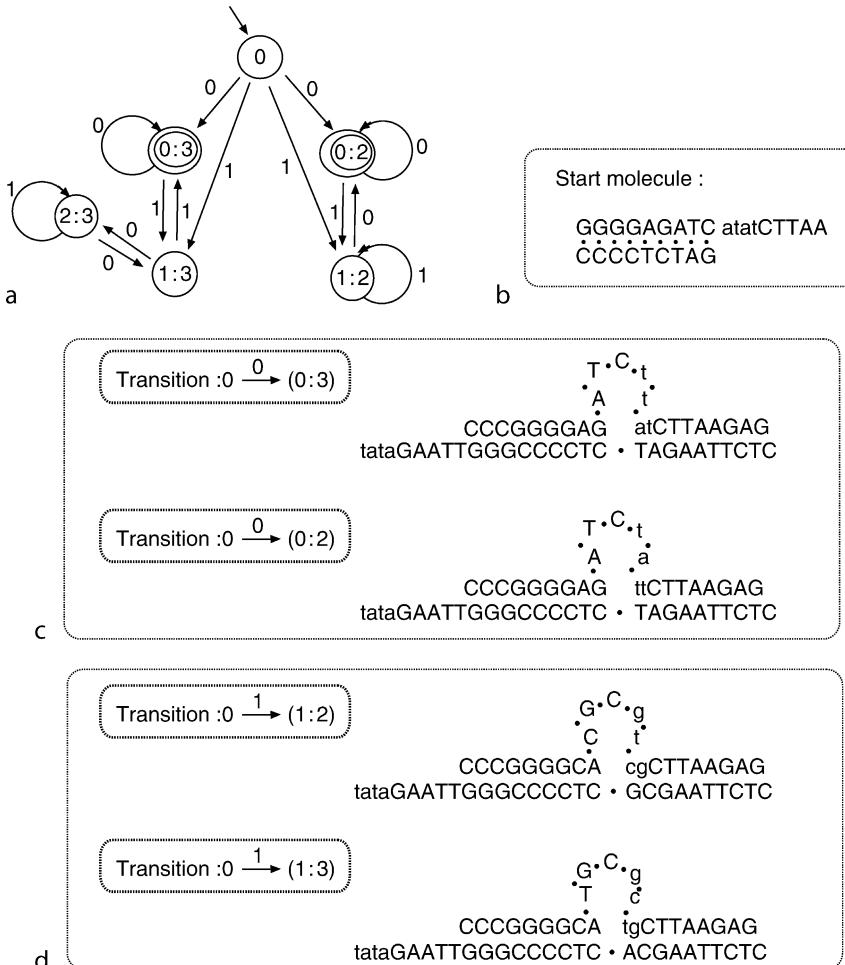

As an example, consider an NFA M with the initial state 0 and two final states (0:2) and (0:3) given as a transition graph in [Fig. 4a](#). For the phase (1), the set of six states is encoded by DNA sequences of length 4 as follows:

State 0	atat	State (0:3) ttat
State (1:3) gctg		State (2:3) ctca
State (0:2) tatt		State (1:2) gtcg

The start molecule is constructed as a double-stranded molecule with a sticky end shown in [Fig. 4b](#). Each transition rule $p \xrightarrow{a} q$ (where p, q are states, and a is in $\{0, 1\}$) is encoded as a molecule with a so-called “bulge loop” structure. For example, two transition rules: $0 \xrightarrow{0} (0:3)$ and $0 \xrightarrow{0} (0:2)$ are encoded as in [Fig. 4c](#), while two transition rules: $0 \xrightarrow{1} (1:3)$ and $0 \xrightarrow{1} (1:2)$ are encoded as in [Fig. 4d](#). All of the other transition rules have to be encoded in the same principle on structured molecules with bulge loops. (The idea behind the design principle of molecular encoding will be explained below.)

Fig. 4

NFA for divisibility by 2 or 3: Coding transition rules.

A computation in M is simulated in three steps as follows:

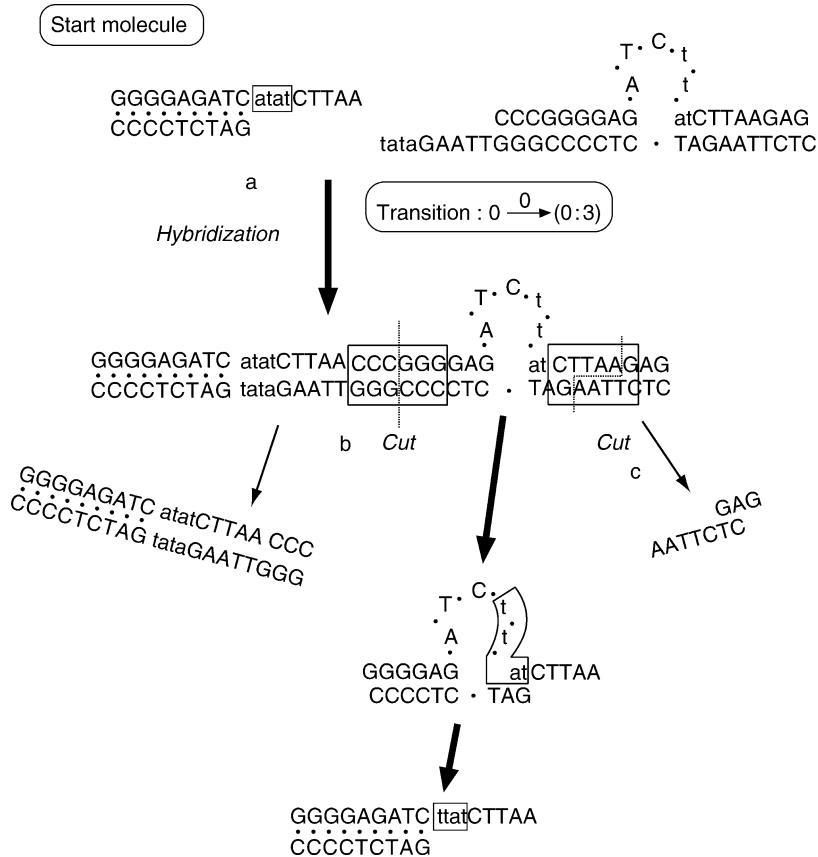

(Step 1): At the beginning of the reaction, one has the start molecule having the atatCTTAA overhang. Suppose that input 0 will be processed. Then, there are two possibilities (two molecules) that have a tata hangover, which matches atat in the hangover of the current state (of molecule). After hybridization and ligation, the remaining unreacted molecules are all washed away and collected. At this moment, the new possible states (0:3) and (0:2) from 0 with input 0 are covered by the loop part and do not show up yet. (The molecule potentially representing the state (0:3) is illustrated in Fig. 5a.)

(Step 2): Add a restriction enzyme *Sma*I which recognizes $\frac{\text{CCCCGG}}{\text{GGGCC}}$ and cut at the middle between C and G, providing two parts, one of which contains the bulge loop. (See Fig. 5b.)

(Step 3): Add a restriction enzyme *Eco*RI which recognizes $\frac{\text{CTTAAG}}{\text{GAATTTC}}$ on the portion with the bulge loop and cut it as shown in Fig. 5c, providing a molecule representing a new state (0:3), ready for the next new transition.

Fig. 5

Simulating transition with input 0 from the state 0.

The “bulge loop” structure functions to prevent the new state sequence in it from reaching the wrong blunt end reaction during ligation. The *Eco*RI recognition site is used for breaking the bulge loop to expose the next state (i.e., (0:3) or (0:2) in this example) for the subsequent reaction. That is, Steps (1)–(3) are repeated for as many input symbols as necessary. In this manner, it is seen that the nondeterministic transitions in M can be simulated by a sequence of chemical reactions with a certain chemical control.

This implementation method has several advantages: (1) The size of molecules representing “state” remains unchanged, no matter how long the computation process. (2) The reactions proceed in a cyclic way that facilitates automated implementation. (3) The manner of designing molecules representing states and transitions used in the section can be standardized in the sense that once an input alphabet and the number of states are given, a library of molecules that represent all possible transitions with inputs could be created, independent of machine specificity.

Finally, it would be interesting and instructive to compare this work with an implementation method proposed in Benenson et al. (2001) where a different type of restriction enzyme and more sophisticated encoding techniques are used; this will be described later.

2.2.2 Length-Based Approach

A new molecular implementation method based on *length-only encoding* is proposed, which leads to a very simple-molecular implementation technique to solve graph problems. Here, for example, an effective molecular implementation method for a nondeterministic finite automaton based on *one pot self-assembly* computing is demonstrated (Yokomori et al. 2002).

In the following, the focus is on ϵ -free regular languages, that is, regular languages not containing the empty string ϵ . Therefore, in any NFA M considered here, the initial state p_0 is not a final state in F of M . The following result is easily shown, but is of crucial importance to attain our objective. Given any DFA, there effectively exists an equivalent NFA M such that (1) M has the unique final state q_f , and (2) there is neither a transition into the initial state q_0 nor a transition from the final state q_f .

Thus, in what follows, one may assume that a finite automaton M is an NFA satisfying the properties (1) and (2) above.

Now, a simple molecular implementation for NFA is presented, which one may call *NFA Pot* and its computing schema is illustrated in [Fig. 6](#). NFA Pot has the following advantages:

1. In order to encode with DNAs each state transition of M , no essential design technique of encoding is required. Only the *length* of each DNA sequence involved is important.
2. Self-assembly due to hybridization of complementary DNAs is the only mechanism for carrying out the computation process.
3. An input w is accepted by M iff a completely hybridized double strand [$c(w)/\overline{c(w)}$] is detected from the pot, where $c(w)$ is a DNA sequence representing w and the “overline” version denotes its complementary sequence.

Without loss of generality, one may assume that the state set Q of M is represented as $\{0, 1, 2, \dots, m\}$ (for some $m \geq 1$) and in particular, “0” and “ m ” denote the initial and the final states, respectively.

Using an example, it is shown, how one can implement an NFA Pot for M given an NFA M .

Let one consider an NFA M (in fact, M is a DFA) in [Fig. 7](#), where an input string $w = abba$ is a string to be accepted by $M = (\{0, 1, 2, 3\}, \{a, b\}, \delta, 0, \{3\})$, where $\delta(0, a) = 1$,

Fig. 6

Finite automaton pot.

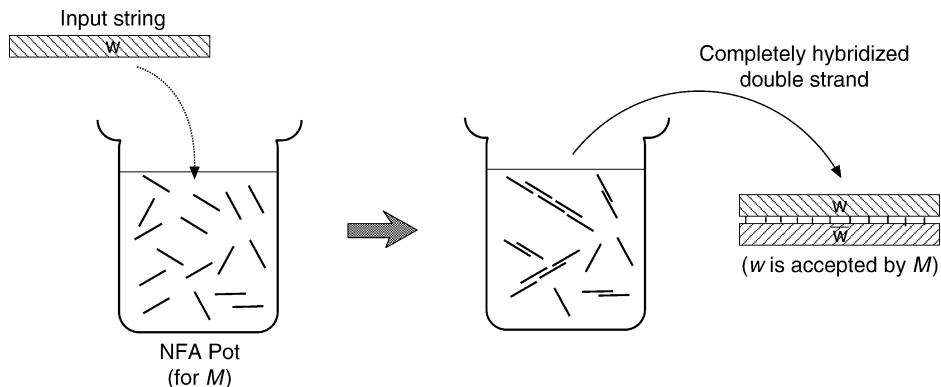

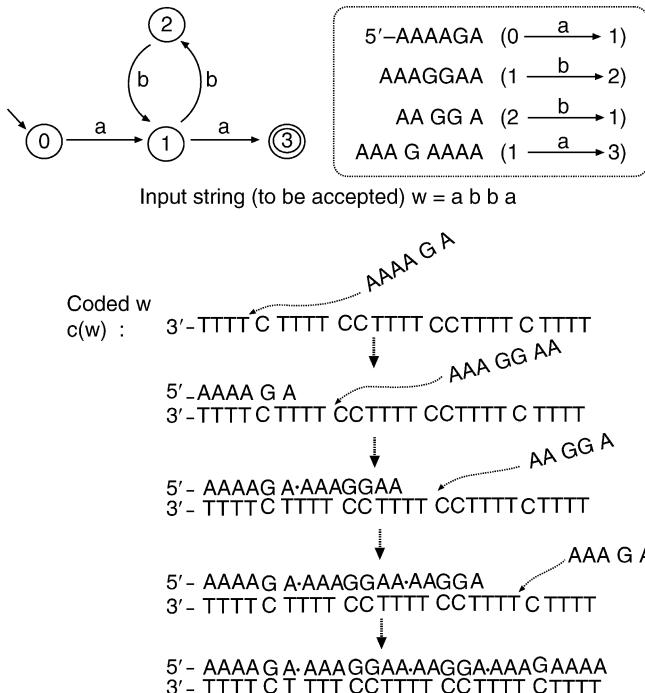

Fig. 7

FA and its DNA implementation.

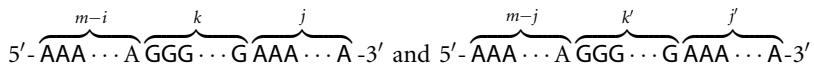

$\delta(1, b) = 2$, $\delta(2, b) = 1$, $\delta(1, a) = 3$. (Note that M satisfies properties (1) and (2) in the assumption previously mentioned and that the state 3 is the unique final state.)

In order to encode each symbol a_k from $\Sigma = \{a_1, \dots, a_n\}$, each is associated with an oligo $\text{GGG}\dots\text{G}$ of length k . Furthermore, each transition $\delta(i, a_k) = j$ is encoded as follows:

The idea is the following. Two consecutive valid transitions $\delta(i, a_k) = j$ and $\delta(j, a_{k'}) = j'$ are implemented by concatenating two corresponding encoded molecules, that is,

together make

Thus, an oligo $\overbrace{\text{AAA} \cdots \text{A}}^m$ plays the role of a “joint” between two transitions and it guarantees that the two are valid in M .

In order to get the result of the recognition task of an input w , one application of the “Detect” operation is applied to the pot, that is, the input w is accepted by M iff the operation

detects a completely hybridized double strand $[c(w)/\overline{c(w)}]$, where $c(w)$ is a DNA sequence encoding w and the “overline” version denotes its complementary sequence. Specifically, for an input string $w = a_{i_1} \dots a_{i_n}$, $c(w)$ is encoded as:

Figure 7 also illustrates the self-assembly process of computing $w = abba$ in the NFA Pot for M (although M is actually a DFA).

A method for molecular implementation is outlined to solve the directed Hamiltonian path problem (DHPP) which seems simpler than any other ever proposed. Since this implementation is also based on the “self-assembly in a one-pot computation” paradigm, one may call it *DHPP Pot*.

The DHPP Pot introduced has several advantages that are common with and similar to the implementation of NFA Pot. That is,

1. In order to encode each directed edge of a problem instance of DHPP, no essential design technique of encoding is required. Only the *length* of each DNA sequence involved is important.
2. Self-assembly due to hybridization of complementary DNAs is the only mechanism of carrying out the computation process.
3. An instance of DHPP has a solution path, p , iff a completely hybridized double strand $[c(p)/\overline{c(p)}]$ of a certain fixed length is detected from the pot, where $c(p)$ is a DNA sequence representing p and the “overline” version denotes its complementary sequence.

As seen above, the implementation methods discussed have a common distinguished feature in molecular encoding, that is, *no essential design technique is necessary* in that only the length of the DNA sequences involved in the encoding is critical. It should be remarked that this aspect of this noncoding implementation could apply to a large class of problems that are formulated in terms of graph structures. (It would be easy to list a number of problems associated with graphs.)

One can also propose a general schema for solving graph problems in the framework of the self-assembly molecular computing paradigm where the *length-only-encoding* technique may be readily applied. In fact, some of the graph-related optimization problems such as the traveling salesman problems can be handled in the schema mentioned above.

In the framework of self-assembly molecular computing, it is of great use to explore the computing capability of the self-assembly schema with “double occurrence checking (doc)” as a screening mechanism, because many of the important NP-complete problems can be formulated into this computing schema. It is shown by constructing DHPP Pot that at the sacrifice of the *nonlinear (exponential)* length increase of strands, the “doc” function can be replaced with the length-only encoding technique. It is, however, strongly encouraged to develop more practical methods for dealing with the doc function.

Finally, the biological implementations based on the method of length-only encoding (discussed here) can be found in Kuramochi and Sakakibara (2005) and in the corresponding chapter [Bacterial Computing and Molecular Communication](#).

2.3 Bibliographic Notes

Various types of abstract models for DNA computing with Turing computability have been presented. These models are classified into various principles of computation, such as a

specific grammar called “Geffert normal form” (Geffert 1991), the equality machine (or equality checking) in Engelfriet and Rozenberg (1980), Post systems (Post 1943), and logical formulations (Tarnlund 1977). In relation to the approach by equality checking discussed in [Sect. 2.1.2](#), one can find a series of intensive works on Watson–Crick automata (Freund et al. 1999b) that share the computing principle with equality machines.

Many attempts to discover grammatical DNA computation models with Turing computability have already been made (Freund et al. 1999a; Păun 1996a, b; etc.), based on the *splicing* operation (originally proposed by Head (1987) or on H-systems (refer to the chapter [DNA Computing by Splicing and by Insertion–Deletion](#) for details). In nature, there exist DNA molecules, such as bacterial DNA and plasmids, that form circular structures. This inspires a new type of splicing models of computing where “circular splicing” produces a mixture of linear and circular molecules. One can find several works on such an extended H-system, called circular splicing system, in Siromoney et al. (1992), Pixton (1995), and Yokomori et al. (1997), in which the type 2 rule of the GPS system can be simulated by using circular molecules within the framework of splicing computing.

A further extension of splicing systems is studied in which tree structural molecules are considered to be spliced (Sakakibara and Ferretti 1999). The language family generated by tree splicing systems is shown to be the family of context-free languages (refer to [Sect. 3.2](#)). Recently, CsuhaJ-Varju and Verlan proposed a new model of test tube systems with Turing computability, based on splicing, where the length-only separation of strings functions filtering in communication (CsuhaJ-Varju and Verlan 2008). More models of extended splicing systems can be found in Păun (1998), while lab experimental work on splicing systems is reported in Laun and Reddy (1997).

Kari et al. (2005) propose and investigate another type of grammatical model for DNA computation based on insertion/deletion schemes that are inspired by pioneering works on contextual grammars due to S. Marcus (1969). The reference book by Păun et al. (1998) is one of the best sources for details of many topics mentioned above (including splicing systems, Watson–Crick automata, insertion/deletion systems, and others).

Reif (1995) proposes a parallel molecular computation model called parallel associative memory (PAM), which can *theoretically* and efficiently simulate a nondeterministic Turing machine and a parallel random access machine (PRAM), where a PA-Match operation, similar to the joint operation in relational database, is employed in an effective manner. Due to the complexity of the molecular biological transformation procedure used to realize a PAM program, it seems more study is needed to fill in the technological gaps between the two computation procedures at different levels.

Roß and Wagner (1996) propose a formal framework called “DNA-Pascal” to study the computational powers of various abstract models for DNA computing and derive several interesting relationships between proposed models and known computational complexity classes within a polynomial time DNA computation. A recently published book (Ignatov et al. 2008) on DNA computing models contains broader topics in the area and partly overlaps with this chapter.

3 Computing Models with Structured Molecules

The molecules used in the first experiment in DNA computing reported in Adleman (1994) were linear non-branching structures of DNA. One of the important developments in DNA

computing is based on the use of more involved molecules, which perform specific computations essentially through the process of self-assembly.

This section, introduces some of the computing models based on such structural DNA molecules.

3.1 Computing by Hairpin Structures

Molecules with *hairpin* structure(s) form a natural extension of linear non-branched molecules, because a hairpin results from a linear molecule that folds onto itself. This structural feature of molecules is recognized as a convenient and useful tool for many applications in DNA computing based on self-assembly.

This naturally brings about the following question: what sort of problems can be computed by a schema using hairpin structures? Investigating this question leads one to consider sets of string molecules which contain complementary sequences of potential hairpin formations, that is, the set of strings containing a pair of complementary subsequences.

In Păun et al. (2001) several types of such “hairpin languages” are considered and their language theoretic complexity (using the Chomsky hierarchy) is investigated.

When forming a hairpin molecule, it is necessary that the annealed sequence is “long enough” in order to ensure the stability of the construct, so it is always imposed that this sequence is, at least, of length, k , for a given k .

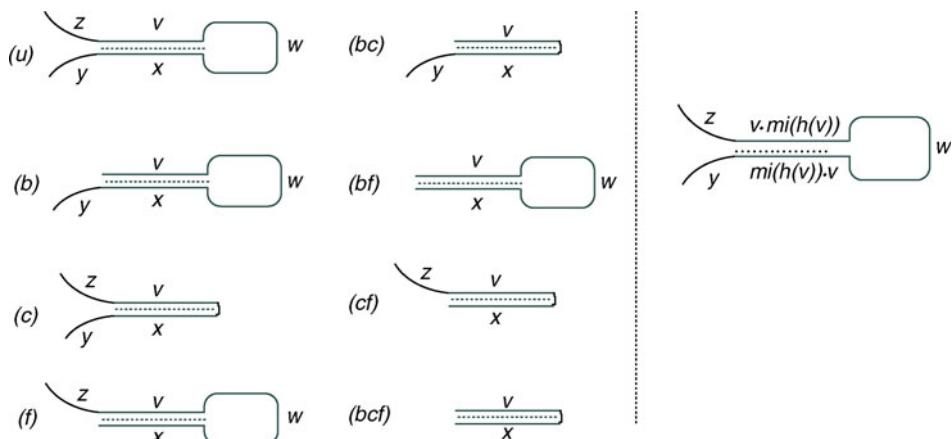

Let, then, k be a positive integer. The *unrestricted hairpin language* (of degree k) is defined by

$$uH_k = \{zvwxy \mid z, v, w, x, y \in V^*, x = mi(h(v)), \text{ and } |x| \geq k\}$$

By imposing restrictions on the location where the annealing may occur, one gets various sublanguages of uH_k (Fig. 8 illustrates the hairpin constructions corresponding to these languages):

Fig. 8

(Left) Hairpin constructions corresponding to eight languages ; (right) a hairpin formation to be removed in solving the directed Hamiltonian path problem (DHPP).

$$\begin{aligned}
 bH_k &= \{vwxy \mid v, w, x, y \in V^*, \text{ cond}(x, v; k)\}, & bfH_k &= \{vwx \mid v, w, x \in V^*, \text{ cond}(x, v; k)\}, \\
 cH_k &= \{zvxy \mid z, v, x, y \in V^*, \text{ cond}(x, v; k)\}, & cfH_k &= \{zvx \mid z, v, x \in V^*, \text{ cond}(x, v; k)\}, \\
 fH_k &= \{zvwx \mid z, v, w, x \in V^*, \text{ cond}(x, v; k)\}, & bcfH_k &= \{vx \mid v, x \in V^*, \text{ cond}(x, v; k)\}, \\
 bcH_k &= \{vxy \mid v, x, y \in V^*, \text{ cond}(x, v; k)\}, & \text{where } \text{cond}(x, v; k) \text{ means "}x = mi(h(v)) \wedge |x| \geq k\text{"}
 \end{aligned}$$

The computation schemata mentioned above is in fact embodied in the literature, for example, one subtracts a language uH_k , for some k , from a (regular) language in [Sect. 4.5](#), while one intersects a given (linear) language with bcH_1 in GCS in [Sect. 2.2.2](#). Therefore, let one consider languages of the form αH_k and $V^* - \alpha H_k$, for $\alpha \in \{u, b, c, f, bc, bf, cf, bcf\}$. As for the languages of the form αH_k , the following are obtained.

Theorem 7

- (1) All languages αH_k , for $\alpha \in \{u, b, f, c, bf\}$ and $k \geq 1$, are regular.
- (2) The languages $bcH_k, cfH_k, bcfH_k$, $k \geq 1$, are linear, but not regular

In order to see that those in (2) are not regular, one has only to consider the alphabet $V = \{a, b\}$, with a, b complementary to each other, and to intersect these languages with the regular language a^+b^+ , which leads to obtaining the following three languages: $\{a^n b^m \mid m \geq n \geq k\}$, $\{a^n b^m \mid n \geq m \geq k\}$, and $\{a^n b^n \mid n \geq k\}$ (in this order), and none of these languages is regular.

The next consequence is of interest from the viewpoint of DNA computing by hairpin removal.

Theorem 8 Let \mathcal{F} be a family of languages which is closed under intersection with regular languages. If $L \in \mathcal{F}$, then $L - \alpha H_k \in \mathcal{F}$, for all $\alpha \in \{u, b, c, f, bf\}$ and all $k \geq 1$.

3.1.1 Complements of Hairpin Languages

In turn, one can consider languages bcH_k, cfH_k and $bcfH_k$. By (2) of [Theorem 7](#), one knows already that the complements of bcH_k, cfH_k and $bcfH_k$ are not necessarily regular. However, the languages $bcfH_k, k \geq 1$, are not “very non-regular” in the sense that for each $k \geq 1$, one has $V^* - bcfH_k$ as a linear language.

For more details, the next results are obtained:

Theorem 9

- (1) If L is a regular language, then $L - bcfH_k$, $k \geq 1$, is a linear language which does not have to be regular.
- (2) If L is a context-free language, then $L - bcfH_k$, $k \geq 1$, is a context-sensitive language which does not have to be context-free.

On the other hand, for languages bcH_k and cfH_k the situation is more involved.

Theorem 10

- (1) The languages $V^* - bcH_k$, $V^* - cfH_k$, and $k \geq 1$ are not context-free.
- (2) If L is a regular language, then the languages $L - bcH_k$ and $L - cfH_k$, $k \geq 1$ are context-sensitive, but not necessarily context-free.

It would be interesting to investigate the place of the languages $L - bcH_k$ and $L - cfH_k$ with respect to families of languages intermediate between the context-free and the context-sensitive families (such as matrix or other regulated rewriting families (Dassow and Păun 1989)).

As an example of the hairpin computation schema discussed here, one can find a solution for the directed Hamiltonian path problem as well.

3.1.2 A New Hairpin-Based Operation: Hairpin Completion

Another interesting aspect of the computability involved in hairpin structures is brought about when a biological phenomenon known as *lengthening DNA by polymerases* is introduced into the DNA computation process. More specifically, consider the following hypothetical biological situation: one is given one single-stranded DNA molecule, z , such that either a prefix or a suffix of z is Watson–Crick complementary to a subword of z . Then the prefix or suffix of z and the corresponding subword of z get annealed by complementary base pairing and then z is lengthened by DNA polymerases up to a complete hairpin structure. The mathematical expression of this hypothetical situation leads to a new formal operation in DNA computing theory; starting from a single word, one can generate a set of words by this formal operation called *hairpin completion*. One can also consider the inverse operation of hairpin completion, namely hairpin reduction. That is, the *hairpin reduction* of a word x consists of all words y such that x can be obtained from y by hairpin completion. These operations are schematically illustrated in Fig. 9.

However, attention is focussed *only* on hairpin completion here.

Recall that for any $\alpha \in V^*$, $\overline{\alpha^R}$ denotes the complement of the mirror image of α . For any $w \in V^+$ and $k \geq 1$, the k -*hairpin completion* of w , denoted by $(w \rightarrow_k)$, is defined as follows.

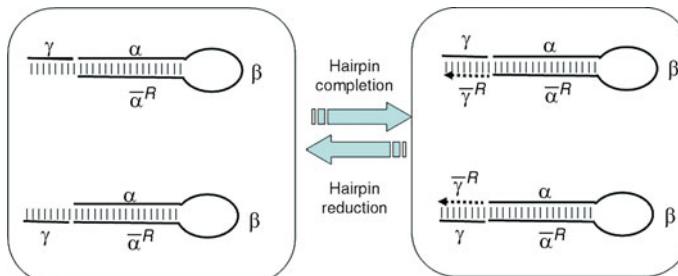

$$\begin{aligned}(w \rightarrow_k) &= \{\overline{\gamma^R}w \mid w = \alpha\beta\overline{\alpha^R}\gamma, |\alpha| = k, \alpha, \beta, \gamma \in V^+\} \\ (w \rightarrow_k) &= \{w\overline{\gamma^R} \mid w = \gamma\alpha\beta\overline{\alpha^R}, |\alpha| = k, \alpha, \beta, \gamma \in V^+\} \\ (w \rightarrow_k) &= (w \rightarrow_k) \cup (w \rightarrow_k)\end{aligned}$$

Then, the hairpin completion is naturally extended to languages by

$$(L \rightarrow_k) = \bigcup_{w \in L} (w \rightarrow_k)$$

Fig. 9

Hairpin completion and hairpin reduction: For each $k \geq 1$, hairpin completion (hairpin reduction) requires the condition of $|\alpha| = k$.

Note that all these phenomena here are considered in an idealized way. For instance, polymerase is allowed to extend in either end (3' or 5') despite that, due to the greater stability of 3' when attaching new nucleotides, DNA polymerase can act continuously only in the 5' → 3' direction. However, polymerase can also act in the opposite direction, but in short "spurts" (Okazaki fragments). Moreover, in order to have a "stable" hairpin structure, the subword α should be sufficiently long.

For a class of languages \mathcal{F} and an integer $k \geq 1$ one denotes by

$$\text{WCOD}(\mathcal{F} \rightarrow_k) = \{h(L \rightarrow_k) \mid L \in \mathcal{F} \text{ and } h \text{ is a weak coding}\}$$

the weak-coding image of the class of the hairpin completion of languages in \mathcal{F} .

The following characterizations concerning the class of linear context-free languages are interesting:

Theorem 11 (Cheptea et al. 2006) (i) For any integer $k \geq 1$, $\text{LIN} = \text{WCOD}(\text{REG} \rightarrow_k)$ holds. (Manea et al. 2009a) (ii) For any integer $k \geq 1$, $\text{WCOD}(\text{LIN} \rightarrow_k)$ is a family of mildly context-sensitive languages.

It should be remarked that this is the characterization result of a class of mildly context-sensitive languages (Joshi and Schabes 1997) that is based on a bio-inspired operation (hairpin completion) and weak codings starting from a simple class of linear languages in the Chomsky hierarchy. It remains open whether a similar result holds for the class of languages by hairpin reduction.

In contrast to its simplicity, hairpin computation as the underlying schema for DNA computing seems to be quite promising.

3.2 Computing by Tree Splicing

In their study on splicing systems, Sakakibara and Ferretti extended the notion of splicing on linear strings, proposed by Tom Head, to splicing on tree-like structures which resemble some natural molecular structures such as RNA structures at the secondary structure level (Sakakibara and Ferretti 1999).

Consider a finite alphabet V and trees over V . By V^T one denotes the set of all trees over V . A *splicing rule on tree structures over V* is given by a pair of tree substructures as in Fig. 10, where u_i 's ($i = 1, \dots, 4$) are subtrees over V , λ s are null trees, and $\#$ is a special symbol not

Fig. 10

Splicing rule on tree structures.

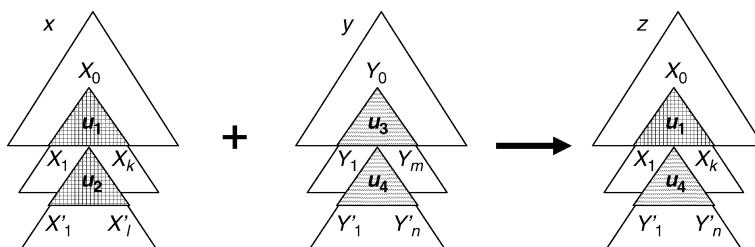

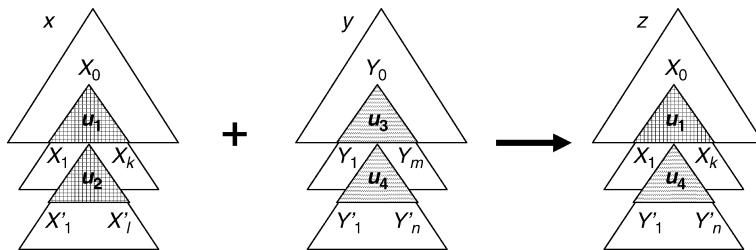

Fig. 11

Splicing on tree structures: Let x, y be trees which contain $u_1(\lambda, \dots, u_2(\lambda, \dots, \lambda), \dots, \lambda)$ and $u_3(\lambda, \dots, u_4(\lambda, \dots, \lambda), \dots, \lambda)$ as a part of the tree, respectively. Then, one can apply the rule in [Fig. 10](#) to x and y to generate a new tree z , which is obtained by replacing the subtree of x under u_2 with that of y under u_4 .

contained in the alphabet V indicating a single node in a tree. The symbol $\$$ is a separator located between the two tree substructures.

A splicing rule r takes two trees $x, y \in V^T$ as inputs and generates a tree $z \in V^T$, written $(x, y) \vdash_r z$. [Figure 11](#) illustrates an application of a splicing rule of [Fig. 10](#).

A *splicing scheme on tree structures* is a pair $\gamma = (V, R)$, where V is an alphabet and R is a set of splicing rules on tree structures over V . A pair $\mathcal{S} = (\gamma, L)$ for a splicing scheme γ and a tree language $L \subseteq V^T$ is called a *splicing scheme on tree structures* (or HT system). For an HT system $\mathcal{S} = (\gamma, L)$, the tree language generated by \mathcal{S} is defined as follows:

$$\gamma(L) = \{z \in V^T \mid (x, y) \vdash_r z \text{ for some } x, y \in L, r \in R\}$$

Iterated splicing is also defined as follows:

$$\begin{cases} \gamma^0(L) = L, \\ \gamma^{i+1}(L) = \gamma^i(L) \cup \gamma(\gamma^i(L)), \text{ and} \\ \gamma^*(L) = \bigcup_{i \geq 0} \gamma^i(L). \end{cases}$$

For a class of tree languages F_1 and a class of sets of splicing rules F_2 , the set of all tree languages $\gamma^*(L)$ is denoted by $HT(F_1 F_2)$, such that $\gamma = (V, R)$, $L \in F_1$, and $R \in F_2$.

Let FIN_T be the class of finite tree languages, and FIN_R be the class of finite sets of splicing rules. Then, $HT(FIN_T FIN_R)$ has a close relation to the class of context-free languages in the following sense.

Theorem 12 For any context-free grammar G , the set of derivation trees of G is in the class $HT(FIN_T, FIN_R)$.

3.3 Computing by PA Matching

Reif (1999) introduced an operation, called *parallel associative matching* (PA Matching), in order to provide a theoretical basis for parallel molecular computing. The operation PA Matching, denoted by \bowtie , is defined as follows.

Let Σ be a DNA alphabet $\Sigma = \{\sigma_0, \sigma_1, \dots, \sigma_{n-1}, \bar{\sigma}_0, \bar{\sigma}_1, \dots, \bar{\sigma}_{n-1}\}$ of $2n$ distinct symbols where for each i , the symbols $\sigma_i, \bar{\sigma}_i$ are called (Watson–Crick) *complements*. Note that the DNA alphabet is extended theoretically to have symbols more than four. Consider another finite alphabet A and an encoding function E from A^+ to Σ^+ . Thus, for a string $\alpha \in A^s$ of length s for some positive integer s , $E(\alpha)$ is an encoded DNA sequence of α . For a pair $\alpha, \beta \in A^s$, let $E(\alpha, \beta)$ denote an encoding of the ordered paired strings (α, β) . (For details of how to encode a pair of strings, refer to Reif (1999).)

For each $\alpha, \beta, \beta', \gamma \in A^s$, the *PA-Match* operation \bowtie is defined to be $E(\alpha, \beta) \bowtie E(\beta', \gamma) = E(\alpha, \gamma)$ when $\beta = \beta'$, and the operation \bowtie yields no value if $\beta \neq \beta'$.

Reif introduced a formal parallel computation model, called the PAM model, in which the following five operations are allowed to be executed in one step:

1. Merge: Given test tubes T_1, T_2 , produce the union $T_1 \cup T_2$.
2. Copy: Given a test tube T_1 , produce a test tube T_2 containing the same contents of T_1 .
3. Detect: Given a test tube T , say “yes” if T is not empty and say “no” otherwise.
4. Separation: Given a test tube T and a string $\alpha \in \Sigma^+$ produce a test tube T_1 consisting of all strings of T , which contain α as a substring, and also a test tube T_2 consisting of all strings of T , which do not contain α .
5. PA-Match: Given test tubes T_1, T_2 , apply the operation \bowtie to yield the test tube $T_1 \bowtie T_2$.

Reif showed a surprising simulation result of a nondeterministic Turing machine based on PAM model.

Theorem 13 *Nondeterministic Turing machine computation with space bound s and time bound $2^{O(s)}$ can be simulated by the PAM model using $O(s \log s)$ PAM operations that are not PA-Match and $O(s)$ PA-Match operations, where strings of length $O(s)$ over the alphabet size $O(s)$ (corresponding to DNA of length $O(s \log s)$ base-pairs) are used in the simulation.*

Motivated by Reif’s work, Kobayashi et al. studied the formal properties of the PA-Match operation, where the operation \bowtie was extended in order to deal with string pairs of different length (Kobayashi et al. 2001).

Informally speaking, the operation consists of cutting two strings in two segments such that the prefix of one of them matches the suffix of another, removing these two matching pieces, and pasting the remaining parts. Formally, given an alphabet V , a subset X of V^+ , and two strings $u, v \in V^+$, one defines

$$PAm_X(u, v) = \{wz \mid u = wx, v = xz, \text{ for } x \in X, \text{ and } w, z \in V^*\}$$

The operation is naturally extended to languages over V by

$$PAm_X(L_1, L_2) = \bigcup_{u \in L_1, v \in L_2} PAm_X(u, v)$$

When $L_1 = L_2 = L$, $PAm_X(L)$ is written instead of $PAm_X(L_1, L_2)$. Since one shall only deal either with finite sets X or with $X = V^+$, one uses the notation *fPAm* for finite PA-matching and the notation *PAm* for arbitrary PA-matching PAm_{V^+} .

Theorem 14

- (1) *The families REG and RE are closed under PAm.*
- (2) *The families LIN, CF, and CS are not closed under PAm.*

They further investigate the iterated version of the PA-match operation which is defined as follows. For a language $L \subseteq V^*$ and a finite set $X \subseteq V^+$, one defines:

$$\begin{cases} PAm_X^0(L) = L, \\ PAm_X^{k+1}(L) = PAm_X^k(L) \cup PAm_X(PAm_X^k(L)), \quad k \geq 0, \\ PAm_X^*(L) = \bigcup_{k \geq 0} PAm_X^k(L). \end{cases}$$

When X is finite, the iterated PA-matching operation is denoted by $fPAm^*$; in the case $X = V^*$, the corresponding operation is denoted by PAm^* . Then, one has:

Theorem 15

- (1) *The families REG and RE are closed under both $fPAm^*$ and PAm^* .*
- (2) *The family LIN is not closed under $fPAm^*$ and PAm^* .*
- (3) *The family CF is closed under $fPAm^*$ but it is not closed under PAm^* .*
- (4) *The family CS is closed neither under $fPAm^*$ nor under PAm^* .*

As shown above, if one extends the operation \bowtie to deal with string pairs of different length, then the computational power of the PA-Matching operation is rather weak, because one cannot escape from regularity when one starts from regular languages. In this sense, the length condition of \bowtie is important in Reif's results.

3.4 Bibliographic Notes

Needless to say, it is of great importance in molecular computing theory to investigate the computational properties of structural molecules. In fact, there is a variety of structural complexity of computing molecules which range from 1-D linear to 3-D structures such as a duplex with hairpin molecules (Eng 1997), molecular graphs (Jonoska et al. 1998), quite sophisticated structures like double crossover molecules (Winfree et al. 1996) and DNA tiles (LaBean et al. 2000; Lagoudakis and LaBean 2000). Among others, Jonoska et al. used the 3-D graph structure of molecules to solve two NP-complete problems (SAT and 3-vertex-colorability problems). Further, Winfree et al. investigated the computational capability of various types of linear tile assembly models (Winfree et al. 2000).

Kari et al. studied hairpin sets and characterized the complexity and decidability properties of those sets (Kari et al. 2005b). They also extended their study to *scattered* hairpin structures in which the stem allows any number of unbounded regions (Kari et al. 2005a). Furthermore, the notion of DNA trajectory is proposed to describe the bonding between two separate DNA strands, and is used to study *bond-free* properties of DNA code design (Kari et al. 2005c), while the notion is also adopted to model the scattered hairpin structures (Doramatzki 2006).

On the other hand, hairpin molecules find many applications in DNA computing. For example, the use of hairpin formation of single-stranded DNA molecules in solving 3-SAT problems is demonstrated in Sakamoto et al. (2000) (for details, refer to [Sect. 4.5](#)). Also, as previously seen in [Sect. 2.2.2](#), a molecular computing schema GCS uses the power of hairpin formation in finalizing its computation process (Yokomori 2000), and so forth. These two computation models share a common feature, which follows a general computational schema called “generation and test” strategy and is described as follows: (i) first, prepare the initial random pool of all possible structured molecules, (ii) then extract only

target molecules with (or without) hairpin formation from the pool. In fact, this paradigm is formalized and intensively studied under the formal language theoretic terms of “computing by carving” in Păun (1999).

4 Molecular Implementations and Applications

In this section, several wet lab experimental works of molecular computing machineries based on structured DNA molecules are introduced. Those molecular devices involve a variety of ideas in controlling molecular behaviors, such as utilizing specific restriction enzymes, deoxyribozymes, sophisticatedly designed DNA tiles, and so forth.

4.1 DNA Finite Automata

4.1.1 Enzyme-Based DNA Automata

An interesting wet lab experimental work has been reported from Israel’s group led by Shapiro, where an autonomous computing machine that comprises DNAs with DNA manipulating enzymes and behaves as a finite automaton was designed and implemented (Benenson et al. 2001). The hardware of the automaton consists of a restriction nuclease and ligase, while the software and input are encoded by double-stranded DNAs.

Encoding DFA onto DNA

Using an example DFA M given in Fig. 12a, it will be demonstrated how to encode state transition rules of M onto DNA molecules.

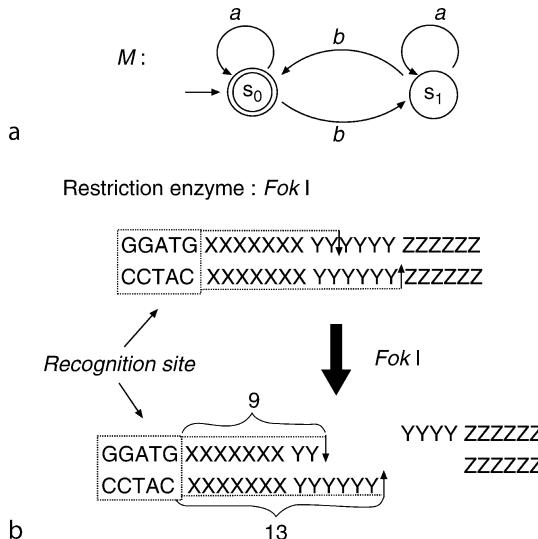

Before going into the details, however, it is important to observe how a restriction enzyme *FokI* works on double-stranded molecules to recognize the site and to cut them into two portions, which is illustrated in Fig. 12b. A restriction enzyme *FokI* has its recognition site GGATG and cuts out a double-stranded DNA molecule as shown in Fig. 12b. That is, splicing by *FokI* takes place nine DNAs to the right of the recognition site on the upper strand and 13 DNAs to the right of the recognition site on the lower strand.

A transition molecule detects the current state and symbol and determines the next state. It consists of (1) a pair (state, symbol) detector, (2) a *FokI* recognition site, and (3) a spacer; all these three together determine the location of the *FokI* cleavage site inside the next symbol encoding, which in turn defines the next state: For example, 3-base-pair spacers maintain the current state, and 5-base-pair spacers transfer s_0 to s_1 , etc. Also, a special molecule for detecting the “acceptance” of an input is prepared as shown in Fig. 13c. (Note that the details of the actual design of molecules for implementing the automaton M is not given here; rather only the principle of encoding the molecules and computation will be outlined.)

Taking this fact into account, encoding *transition molecules* for the transition rules of DFA is designed as follows. First, there are two points to be mentioned in designing transition molecules: One is that neither a state nor symbol alone is encoded but a pair (state, symbol) is taken into consideration to be encoded, and the other is that a sticky end of 6-base length encoding (state, symbol) is sophisticatedly designed such that the length 4 prefix of the sticky end represents (s_1, x) , while the length 4 suffix of the same sticky end represents (s_0, x) , where x

Fig. 12

(a) DFA M with states s_0, s_1 and input symbols a, b . The initial state is s_0 , which is the unique final state as well. M accepts the set of strings containing an even number of b 's. (b) How a restriction enzyme *Fok I* works on molecules.

is in $\{a, b, t\}$, and t is the special symbol, not in the input alphabet, for the endmarker (see [Fig. 13a](#)). Reflecting this design philosophy, the structures of the transition molecules are created as shown in [Fig. 13b](#), where molecules for two transition rules: $s_0 \xrightarrow{a} s_0$ and $s_0 \xrightarrow{b} s_1$ are selectively described. The transition molecule $m_{s_0,a}$ for $s_0 \xrightarrow{a} s_0$ consists of the recognition site of *Fok I*, the center base-pairs of length 3 and the sticky end CCGA, because its complementary sequence GGCT is designed to represent the pair (s_0, a) as seen from the table. A transition $s_0 \xrightarrow{b} s_1$ is encoded by a similar principle onto the transition molecule $m_{s_0,b}$ shown in [Fig. 13b](#), where a noteworthy difference from $m_{s_0,a}$ is that it has the center base-pairs of length 5. In this principle of designing transition molecules, a transition molecule has the center base-pairs of length 5 iff the transition changes its state (from s_0 to s_1 or vice versa). Thus the distinct length of the center base-pairs plays a crucial role.

Computing Process

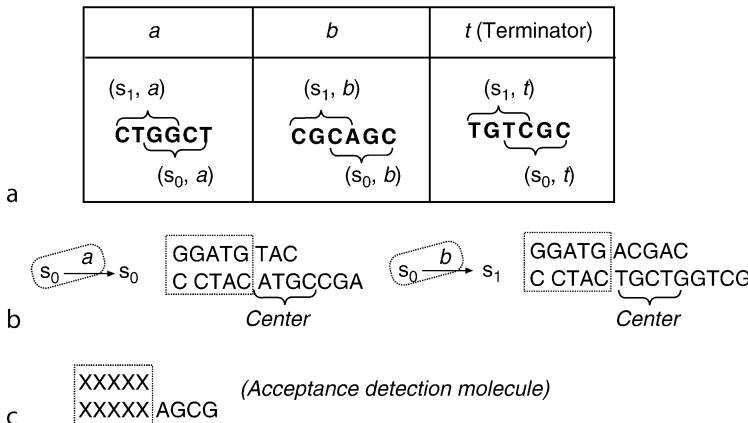

The molecular automaton processes the input as shown in [Fig. 14](#), where input w is assumed to be of the form $ab\dots(t)$, where t is the endmarker. First, the input w is encoded into the form of the molecule shown in [Fig. 14a](#), where seven X base-pairs represent a “spacer” consisting of arbitrary bases.

The input molecule is cleaved by *Fok I*, exposing a 4-base sticky end that encodes the pair of the initial state and the first input symbol, that is, (s_0, a) in the running example. The computation process is performed in a cyclic manner: In each cycle, the sticky end of an applicable transition molecule ligates to the sticky end of the (remaining) input molecule (obtained immediately after cleaved by the last transition), detecting the current state and the input symbol ([Fig. 14b](#)). (Note that it is assumed at the beginning of computation that all

Fig. 13

States and symbols encoding.

Coding a pair (state, symbol)

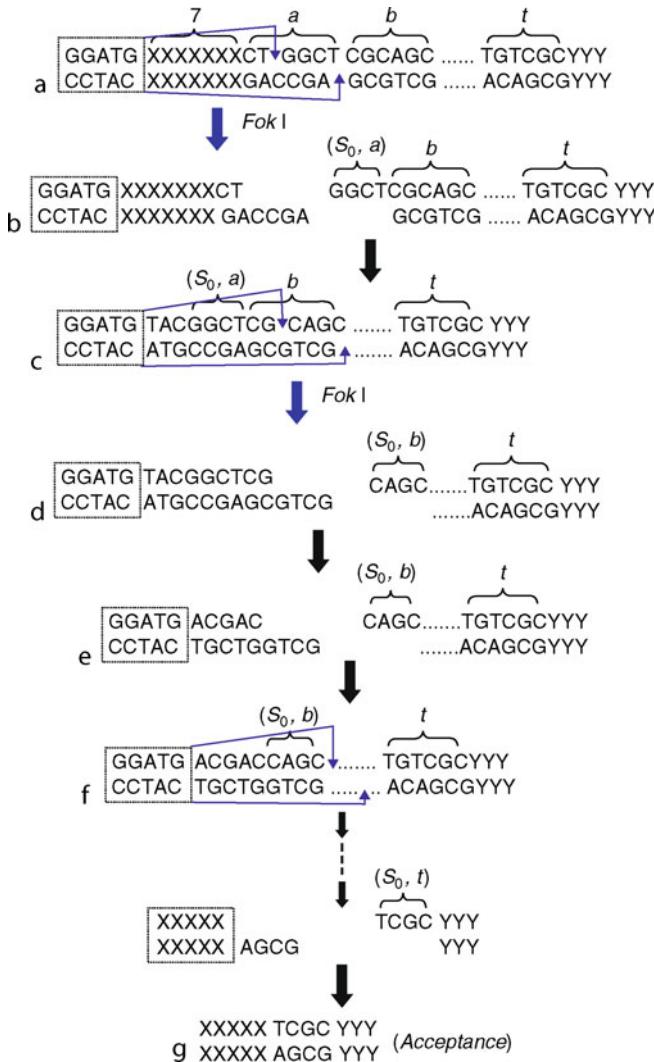

of the possible transition molecules are contained in a solution pot together with the initial molecule and the acceptance detect molecules.)

At this moment, since the transition molecule for (s_0, a) , shown in [Fig. 13b](#), can get access to the remaining input molecule on the right-hand side in [Fig. 14b](#), it produces the hybridized molecule shown in [Fig. 14c](#). Therefore, the resulting molecule is again cleaved by *FokI*, exposing a new 4-base sticky end ([Fig. 14d](#)). The design of the transition molecule ensures that the 6-base-pair long encodings of the input symbols *a* and *b* are cleaved by *FokI* at only two different “frames” as seen above, the prefix frame of 4-base-pair length for s_1 , and the suffix frame of 4-base-pair length for s_0 . Thus, the next restriction site and the next state are exactly determined by the current state and the length of the center base-pairs in an applicable transition molecule. In the example, since the sticky end of the remaining input molecule can match that of the transition molecule $m_{s_0, b}$ for (s_0, b) ([Fig. 14e](#)) and the molecule $m_{s_0, b}$ exists in the solution pot, so that these two can hybridize to form the double-stranded molecule shown in [Fig. 14f](#).

The computation process proceeds until no transition molecule matches the exposed sticky end of the rest of the input molecule, or until the special terminator symbol is cleaved, forming an output molecule having the sticky end encoding the final state (see [Fig. 14g](#)). The latter means that the input string *w* is accepted by the automaton *M*.

In summary, the implemented automaton consists of a restriction nuclease and ligase for its hardware, and the software and input are encoded by double-stranded DNA, and programming amounts to choosing the appropriate software molecules. Upon mixing solutions containing these components, the automaton processes the input molecule by a cascade cycle of restriction, hybridization, and ligation, producing a detectable output molecule that encodes the final state of the automaton.

In the implementation, a total amount of 10^{12} automata sharing the same software (“transition molecules”) run independently and parallel on inputs in $120 \mu\ell$ solution at room temperature at a combined rate of 10^9 transitions per second with a transition fidelity greater than 99.8%, consuming less than 10^{10} W. (For detailed reports of the experimental results, refer to Benenson et al. (2001).)

Fig. 14Computing process of input $w=ab(t)$.

4.1.2 Application to Drug Delivery

As an application of the molecular finite automata, Benenson et al. (2004) proposed an idea to use their molecular automata for carrying out a diagnosis *in vivo*, and demonstrated an *in vitro* experiment, which shows the feasibility of logical control of gene expression for drug delivery. An excellent review article on the work by Benenson et al. is given by Condon (2004).

In order to carry out a medical diagnosis, it is necessary to achieve *in vivo* checking of a medical statement such as “if a certain series of diagnostic conditions are true, then the drug

is administered.” Such an *if–then* mechanism is critically essential in computing models and in diagnostic process as well. It is assumed that each condition is described in the form: “a certain type of gene expression is regulated by either high or low level of concentrations of particular mRNA (called *indicator molecule*) for the gene.”

❷ [Figure 15](#) outlines the idea used in the diagnostic molecular automaton (*DMA*) experiments by Benenson et al. Suppose that a certain disease involves four conditions of gene expression to be checked before administering a drug for the disease, and each gene-*i* (for $i = 1, \dots, 4$) as its label is encoded into a structured molecule (called the *computation molecule*) with a hairpin in which the drug is enclosed (❷ [Fig. 15a](#)). Note that a diagnostic rule is of the form: if the conditions for gene-1 through gene-4 are all true, then the drug is released. The *DMA* (based on the automaton described in the previous section) can carry out the checking of each diagnostic condition in one transition step, and is constructed in such a way that it has two states “Yes” and “No” and three transitions: Yes → Yes if indicator molecules are present, Yes → No if indicator molecules are absent, and No → No in any other situation. Note that once the transition Yes → No occurs, the state of *DMA* remains unchanged, that is, it keeps staying in No no matter what the situation of the indicator molecule is. Therefore, starting with the initial state Yes, the *DMA* behaves as follows: after each transition, the state is either Yes indicating that the corresponding conditions tested *so far* are all true, or No otherwise (i.e., at least one of the conditions tested is false). Thus, if the *DMA* can successfully make four transitions, then the drug is released.

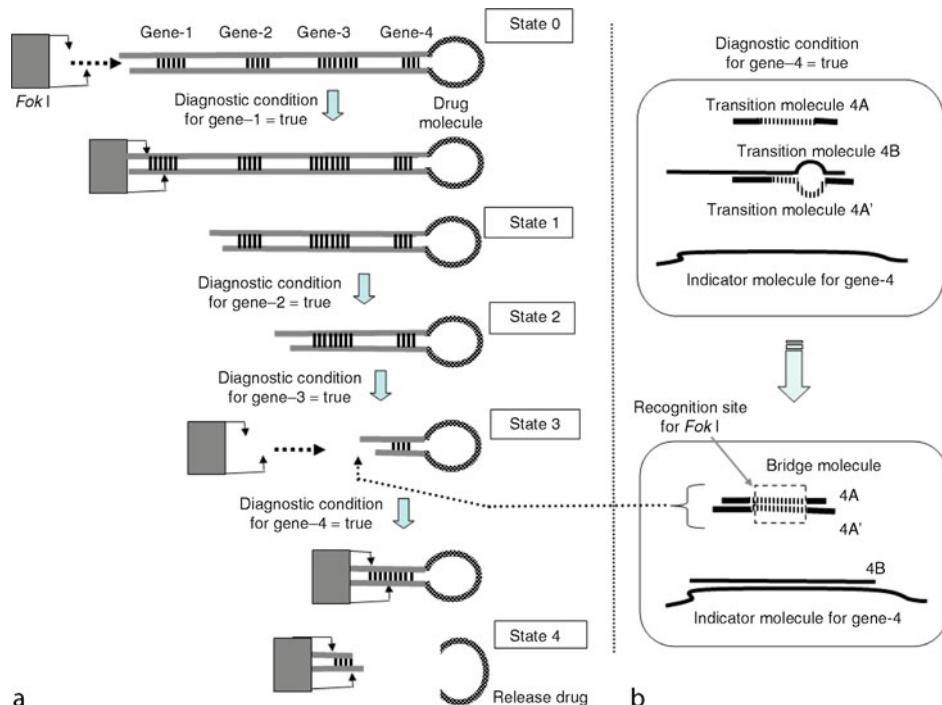

In ❷ [Fig. 15](#), at the initial state (State 0), a hairpin structural molecule (computation molecule) is designed so that the diagnostic condition is the conjunction of four logical statements on gene expression, each of which is true for gene-*i* if the level of a particular indicator molecule for gene-*i* is either high or low (depending upon the requirement on each gene expression), for each $i = 1, \dots, 4$. In order to make a transition from State $(i-1)$ to State i , the *DMA* requires a specific molecule, say a *bridge molecule*, which is supposed to be created from a team of molecules designed for each gene-*i* ($i = 1, \dots, 4$) under a certain condition.

Suppose, for example, the *DMA* is in State 3 and is going to effect a transition to State 4, which must diagnose a high level of indicator molecule for gene-4. The team of molecules to do the task comprises *transition molecules* 4A, 4B, and 4A', where 4B and 4A' initially form a binding structure, 4A and 4A' contain a sequence of oligonucleotides and its complementary one, respectively, and annealing the two can provide a bridge molecule containing the recognition site for the restriction enzyme *FokI* (❷ [Fig. 15b](#)). In addition to the team molecules, when an indicator molecule for gene-4 is present in the solution, the scenario for the *DMA* to complete a successful transition to State 4 goes as follows. Transition molecule 4B is designed so that it prefers to pair with the indicator molecule for gene-4 rather than transition molecule 4A' (current partner), because 4B shares a longer complementary region with indicator molecule 4 than 4A'. Therefore, after leaving transition molecule 4A', transition molecule 4B settles in to pair with the indicator molecule for gene-4. On the other hand, transition molecules 4A and 4A' get together forming a structure due to their mutual affinity. As a result, this structured molecule can participate as a bridge molecule in the successful transition to gene-4 which is carried out by *FokI*.

It should be noted that the *DMA* is stochastic in overall behavior, because the transition is strictly dependent upon the level of concentration of indicator molecules in each diagnostic condition, and there remain some problems to be solved before the demonstrated mechanism will work *in vivo* as well. However, without question, this is the first achievement to prove the great potential of developing medical diagnostic molecular devices for antisense therapies.

Fig. 15

DNA automaton for logical control of drug delivery: (a) At the initial state (State 0), a hairpin molecule (computation molecule) is designed so that a hairpin may maintain the drug molecule that is guarded by four specific sequences gene- i ($i = 1, \dots, 4$) each of which corresponds to one of four conjunctive logical statements in a diagnostic rule for the disease. Each State ($i - 1$) is associated with a team of molecules (given in b of this figure for $i = 4$), and in the presence of the indicator molecule for gene- i , the team can produce a specific molecule (bridge molecule) which is necessary for cleaving the guarded gene- i , resulting in a successful transition to State i . (b) A team of molecules needed for a transition from State 3 to State 4 comprises transition molecules 4A, 4B, and 4A'. In the presence of the indicator molecule for gene-4, members in the team can be relocated into the new formation in which a bridge molecule (involving the recognition site of FokI) is created to contribute to a transition to State 4.

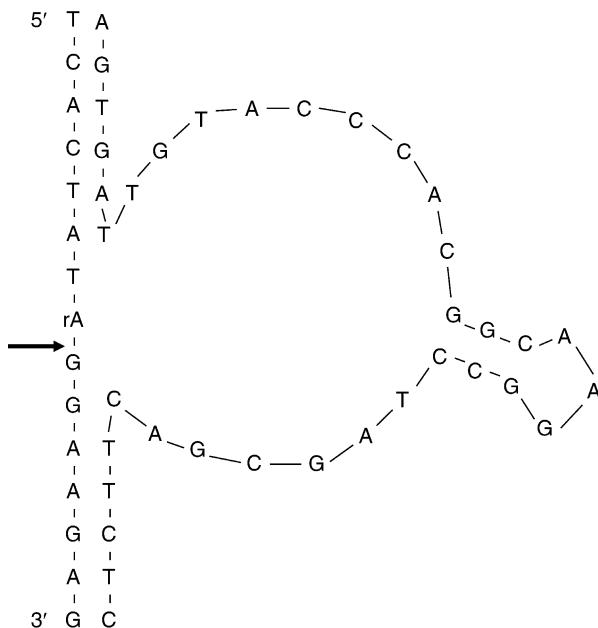

4.2 Molecular Gates and Circuits

4.2.1 DNAzymes

Stojanovic et al. established the use of DNAzymes to implement logic gates by DNA (Stojanovic et al. 2002). Just as a ribozyme refers to an enzyme made of RNA, a DNAzyme (deoxyribozyme) is a DNA molecule that has some catalytic function. **Figure 16** shows the DNAzyme named E6. The strand forming a loop structure is the DNAzyme that partially hybridizes with the target strand and cleaves it at the site shown by the arrow. The base denoted as rA is a single ribonucleotide (RNA nucleotide) inserted in the target strand. The enzyme cuts the phosphodiester bond at this site.

Fig. 16

DNAzyme named E6. The strand containing a ribonucleotide denoted as rA is cleaved at the site shown by the arrow.

After the target strand is cleaved, the partially double-stranded structure becomes unstable and the two pieces that arise from the target strand come apart. They can be regarded as outputs of the logic gate. If a fluorescent group and a quencher group are attached at the terminals of the target strand, an increase of fluorescence is observed when the strand is cleaved.

They introduced various modifications into the DNAzyme in order to control its catalytic function. Existence or non-existence of some strands affects the structure of such a modification and turns the catalytic function on or off. They can be regarded as inputs to the logic gate implemented by the modified DNAzyme.

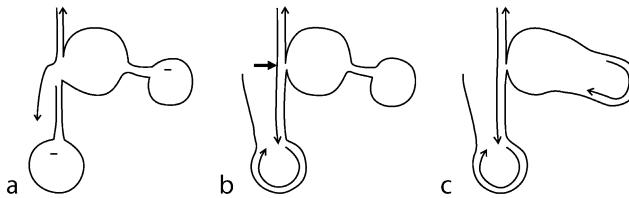

Figure 17a shows a schematic figure of the logic gate $A \wedge \neg B$. The modified enzyme implementing this gate has two more loops in addition to the loop of the original DNAzyme. It has the catalytic function if the loop denoted by $\overline{I_A}$ is opened while the loop denoted by $\overline{I_B}$ is intact. If the strand I_A which is complementary to the loop $\overline{I_A}$ is present, the loop is opened and the DNAzyme gains its catalytic function (Figure 17b). On the other hand, if the strand I_B is present, the loop $\overline{I_B}$ is opened and the catalytic function is lost because the structure of the original loop is changed (Figure 17c). Simply mixing this gate and the similar gate $B \wedge \neg A$ together results in the disjunction $(A \wedge \neg B) \vee (B \wedge \neg A)$, which is the XOR function of A and B .

Using logic gates implemented DNAzymes, Stojanovic and Stefanovic programmed a strategy to play the game of tic-tac-toe for demonstrating the expressiveness of DNAzyme-based logic circuits (Stojanovic and Stefanovic 2003).

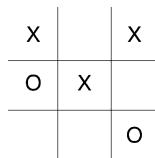

A move of a human player is represented by one of nine single strands of DNA, each corresponding to one of the nine positions on the board of tic-tac-toe. A logic circuit made of

Fig. 17

The schematic figure of the gate $A \wedge \neg B$. The DNAzyme is functional only if A is present and B is not.

**Fig. 18**

A move in tic-tac-toe. The next move of the DNA side is at the upper right position.

DNAzymes are placed at each position. For each move of the human player, the corresponding single strand is given to all the circuits. The programmed strategy shows the next move by making the circuit at the position of the move return output 1. More concretely, fluorescence emitted by the cleaved strand is increased at the position of the next move.

In [Fig. 18](#), two strands corresponding to the two moves of the human player (denoted by O) are put to all the nine positions. Then the circuit at the upper right position is triggered and gives output 1, or fluorescence at the position is increased.

In this work by Stojanovic and Stefanovic, all logic circuits at the nine positions are disjunctive normal forms and implemented by simply mixing the gates of all disjuncts. Each disjunct is a conjunction consisting of at most three literals. Each conjunction with three literals is of the form $A \wedge B \wedge \neg C$. This kind of conjunction can be implemented by a modified DNAzyme shown in [Fig. 19](#), which has three additional loops.

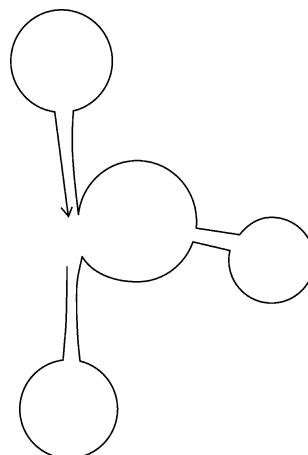

DNAzymes or ribozymes are used to implement logic circuits in many applications other than that of Stojanovic and Stefanovic as mentioned above. For example, Win and Smolke use a hammerhead ribozyme to control translation from mRNA to protein (Win and Smolke 2008).

They insert a hammerhead ribozyme with some additional structures into an untranslated region of a gene. As in the upper panel of [Fig. 20](#), the hammerhead ribozyme cleaves itself at the site shown by the arrow. The lower panel of the same figure shows additional structures attached at the loops of the ribozyme. These structures contain sensors and logic gates. Sensors are implemented by so-called aptamers, which are RNA molecules that change their structure if they bind to a certain small molecule. Logic gates are implemented by loop structures similar to those in Stojanovic's logic gates.

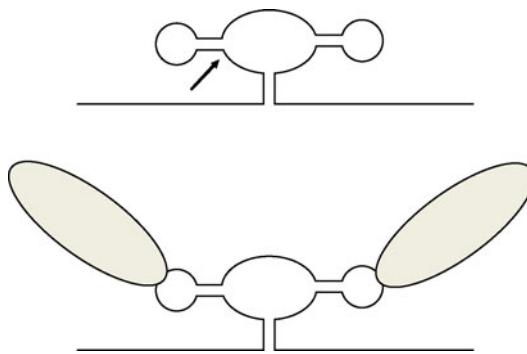

After the gene is transcribed, the hammerhead ribozyme in the mRNA transcript becomes active under some specific conditions depending on the additional structures, and cleaves the transcript itself. As a result, the rate of translation from the transcript is decreased. In this way,

Fig. 19

A schematic figure of a three-literal conjunction. A conjunction of the form $A \wedge B \wedge \neg C$ can be implemented in this way.

**Fig. 20**

A hammerhead ribozyme. The upper panel shows the original structure of the ribozyme, which cleaves itself at the site shown by the arrow. The lower panel shows the additional structures containing sensors and logic gates.

it is possible to control the expression of the gene by a combination of conditions that can be detected by the sensors.

4.2.2 Strand Displacements

As shown in the previous section, many bio-molecular machineries and logic gates have been proposed. Such molecular systems sophisticatedly utilized various restriction enzymes or DNAzymes (RNAzymes) to control their state transitions. However, enzyme-based logic

gates have a disadvantage in that it is difficult to cascade from one gate to another one because of design restrictions.

In this section, logic gates without enzymes (or enzyme-free logic gates) are introduced, which were developed by Seelig et al. (2006b). The driving force of Seelig's logic gates is a branch migration rather than enzymatic reactions. A branch migration, which is also called "strand displacement" or "oligonucleotide replacement," is the process in which a single strand hybridizes to a dangling end of duplex and then removes the resident strand from the duplex, resulting in the formation of a new duplex (see ▶ Fig. 21). The dangling end used to promote a branch migration is called a toehold, the length of which dominantly affects the kinetics of the reaction (Yurke and Mills 2003). The process of branch migration is regarded as a random walk (▶ Fig. 21a–c); the branching point moves left or right when two strands competitively hybridize to their complementary strand. If the resident strand wins the competition, the state comes back to ▶ Fig. 21a. In contrast, once the resident strand is removed from the duplex, the reaction stops because the new duplex does not have a toehold region (▶ Fig. 21d).

By using this branch migration reaction, various logic gates were successfully constructed (▶ Figs. 22 and ▶ 23). The reaction pathways of these gates are as follows:

- **AND gate** – First, by the branch migration, the input1 hybridizes to the toehold of the output complex (▶ Fig. 22b) and removes one single strand from the complex, resulting in

Fig. 21
Branch migration.

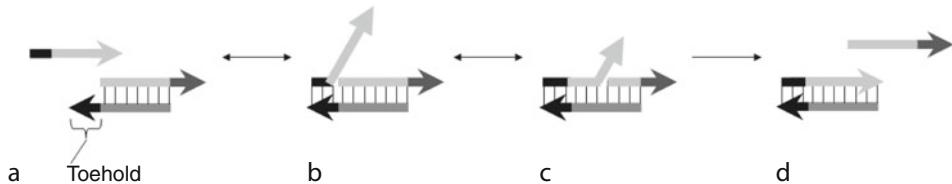

Fig. 22
AND gate.

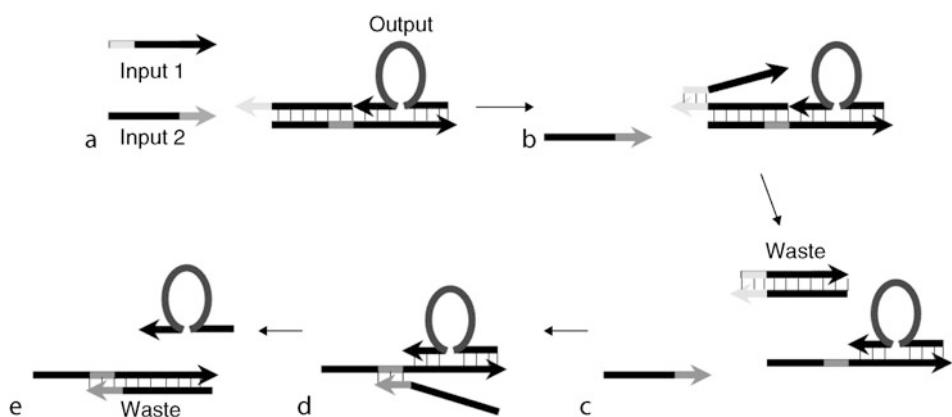

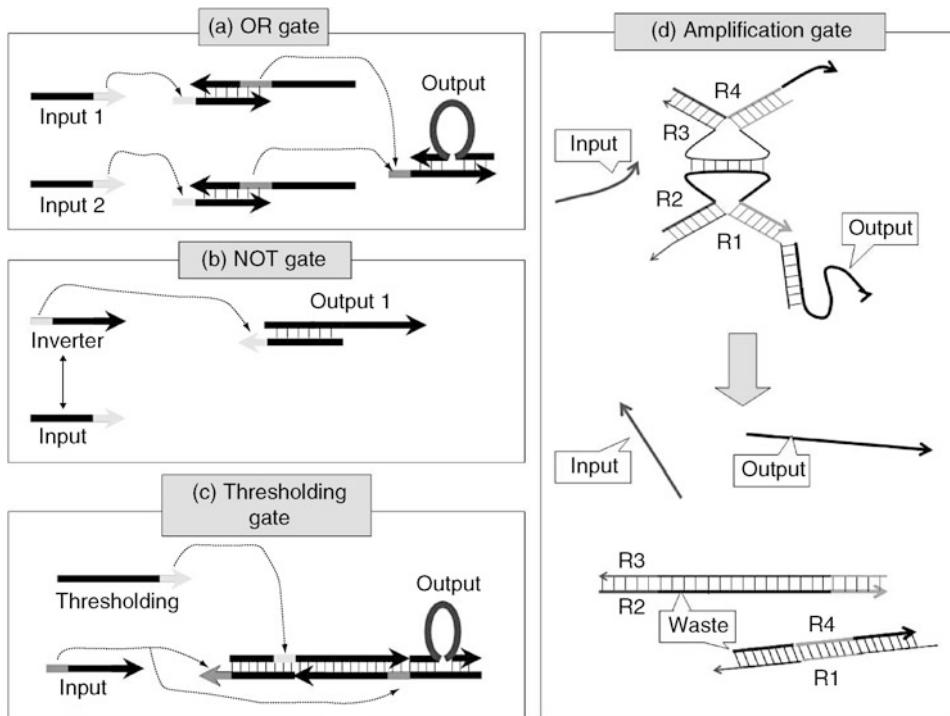

Fig. 23
Various gates.

the exposed toehold region for input2 (► Fig. 22c). Then, input2 removes the second single strand from the complex (► Fig. 22d, e), producing a single output strand. Thus, only if both input strands exist, is an output released as a single strand.

- **OR gate** – After either input1 or input2 hybridizes to the corresponding intermediate gate, either of their output strands produces the final output strand (► Fig. 23a). Therefore, the output strand is produced if either input1 or input2 exists.
- **NOT gate** – This gate consists of the output complex and the inverter strand that is complementary to the input strand (► Fig. 23b). The inverter strand hybridizes to the toehold of the complex and produces the single output strand. In contrast, if the input exists, it hybridizes to the inverter and prevents the branch migration between the inverter and output complex. Thus, this works as a NOT gate.
- **Thresholding gate** – This gate, which consists of a “thresholding” strand and output complex, can be used to remove the extra single strand that was produced unexpectedly (► Fig. 23c). The output complex has three toeholds. The first and third toeholds are complementary to the subsequence of input, while the second toehold corresponds to the thresholding strand. Thus, the output strand is released only if two inputs and one thresholding strand complete their branch migrations. Due to this stoichiometry, if input concentrations are twice as high as the thresholding strand, most gates will produce the output (see the supporting online material of Seelig et al. (2006b) for the theoretical consideration). Therefore, the threshold value can be controlled by the concentration of the thresholding strand.

- **Amplification gate** – Although the previous thresholding gate can remove the extra single strand, the concentration of the output does not exceed half of the input concentration. To restore the signal, this amplification gate is used (Fig. 23d). This gate produces input and output as a single strand after the multiple-stage branch migrations. Note that the input strand can react again with the other amplification gate. Thus, as long as amplification gates remain, input strands produce the output. Therefore, by combining the thresholding and amplification gates, one can exclude incorrect signals without deleting correct ones wrongly. For the detailed reaction pathway, please refer to Seelig et al. (2006a).

These enzyme-free logic gates have a great advantage in the cascading of gates. Because the output of each gate is a single strand, it can be easily used as the input of the other gates.

Here, readers may wonder if the above logic gates must be redesigned and reconstructed when one selects the other sequences as inputs. This problem can be solved with the following converter, which converts an input strand to another output strand (Fig. 24). By two-step branch migration, the input strand is converted into the output strand, whose sequence is not relevant to the input sequence. Thus, logic gates shown above can accept any input sequences by combining appropriate converters unless the sequences unfortunately cross-hybridize with each other.

With these logic gates shown above, one can construct the more complex logic circuits. In fact, Seelig et al. achieved the logic circuit including 11 gates and six inputs (Seelig et al. 2006b).

Based on Seelig's logic gates, Tanaka et al. developed a DNA comparator, which is a DNA machine for comparing DNA concentrations (Tanaka et al. 2009). The purpose of the DNA comparator is to determine whether the concentration of the target strand is higher than that of the reference strand. If the concentration of the target is higher, the DNA comparator outputs a single-strand, which may be an input strand to another molecular logic gate.

A DNA comparator consists of three double strands and two inputs (see Fig. 25). One of the two inputs is a target strand whose concentration one wants to compare, while the other is a reference strand whose concentration is the standard. Two of three double strands have bulge loops in the middle of the sequences and toehold structures, whose two inputs can hybridize to, at the 5'-end of the opposite sequences. The DNA comparator was designed to work as follows: First, two inputs *reference* and *target* hybridize to the toeholds of *cp_B1* and *cp_B2*, respectively. Then, *reference* and *cp_B1* form a double strand, while *target* and *cp_B2* also form a double strand by the branch migration reaction. After that, *B1* and *B2* are released as single strands and immediately form a double strand because the loop domains of *B1* and *B2* are complementary to each other. Thus, only the extra amount of *B2* can hybridize to the toehold of *cp_out*, resulting in branch migration. As a result, *output* is released as a single

Fig. 24
Converter based on branch migration.

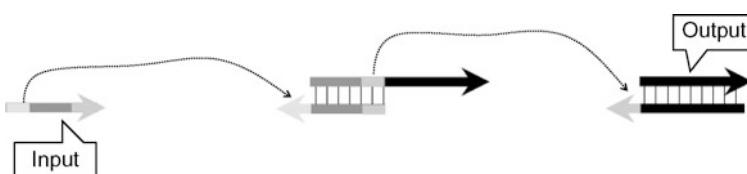

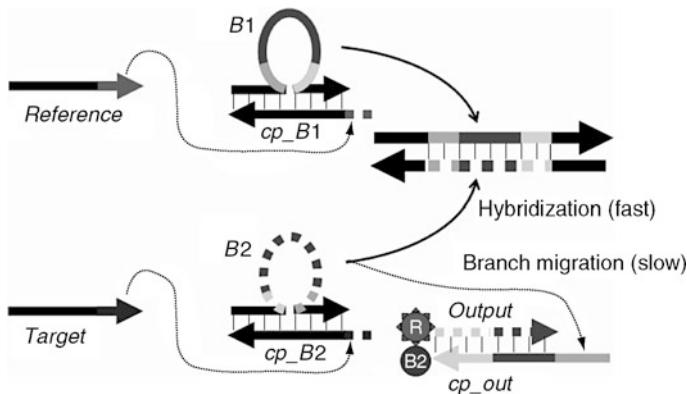

Fig. 25
DNA comparator.

strand, which can be monitored by the fluorescent intensity of a fluorophore. The key point is that the hybridization between $B1$ and $B2$ is much faster than the branch migration between $B2$ and $output \& cp_out$. Thus, if the concentration of $B2$ is lower than that of $B1$, almost all $B2$ will probably hybridize to $B1$ rather than the toehold of cp_out . Therefore, only if the concentration of $target$ is higher than that of $reference$ can $B2$ hybridize to the toehold of cp_out and remove $output$ from cp_out by branch migration.

4.2.3 DNA Tiles

Self-assembly of tiles has a powerful computational ability as shown by Wang (1961, 1962), and it even has universal computability, because it can simulate cellular automata and therefore Turing machines. More precisely, Wang showed that it is undecidable whether a given set of tiles can completely fill out the entire plane. Winfree reformulated this result in the context of DNA tiles (Winfree 1998). In this section, the focus is on the use of DNA tiles for implementing logic gates.

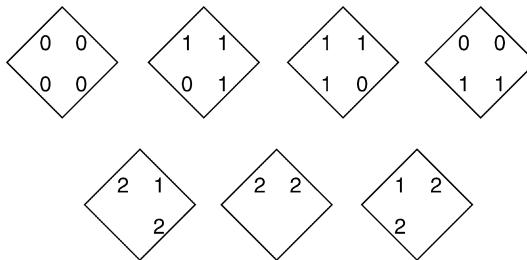

Figure 26 shows tiles for computing XOR and constructing Sierpinski's triangle. The four tiles in the top row implement the XOR function. The two edges facing down accept two inputs to XOR and the other two edges facing up give the (same) output of XOR. The three tiles in the bottom row form the boundary of Sierpinski's triangle.

In the mathematical model of tile assembly known as aTAM (abstract tile assembly model), proposed by Winfree, tiles self-assemble under the condition that only edges with the same label can bind together. Moreover, each label has its own binding strength. A tile can bind to a tile complex (aggregate) only if the sum of the strengths of the binding edges is greater than or equal to the predefined threshold called the temperature.

In this example, labels 0 and 1 have binding strength 1, while label 2 has binding strength 2. The temperature is set to 2. Therefore, as in Fig. 27, beginning with the corner tile (the middle tile in the bottom row of Fig. 26), the boundary of Sierpinski's triangle is formed. The tiles for XOR then bind to the boundary and construct Sierpinski's triangle as in Fig. 28.

Fig. 26

Tiles for Sierpinski's triangle. The upper tiles compute the XOR function. The lower tiles form the boundary of Sierpinski's triangle.

**Fig. 27**

The boundary of Sierpinski's triangle.

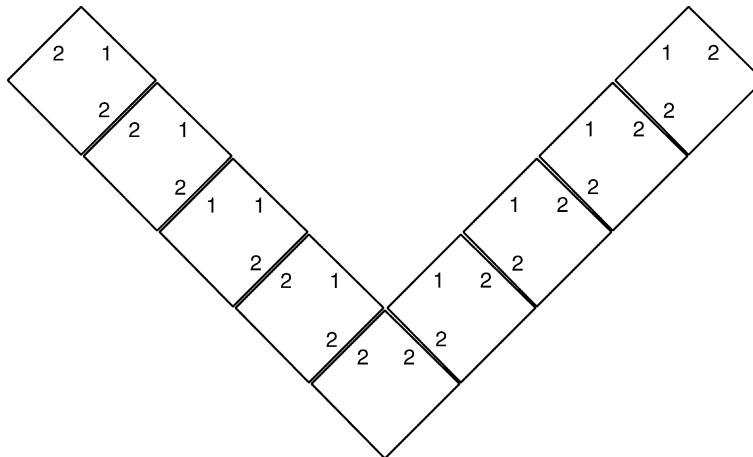

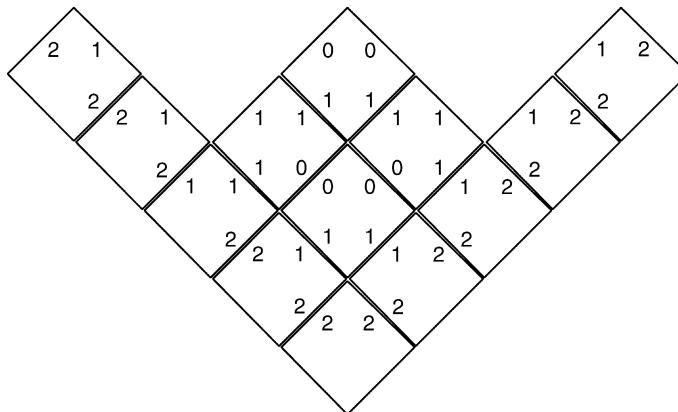

Figure 29 shows an actual implementation of tiles by DNA (Rothenmund et al. 2004). This structure, called a double crossover molecule, consists of four single strands of DNA. In other words, it consists of two double strands that exchange their single strands at two positions. This rectangular structure has four sticky ends, through which one instance of the structure can hybridize with four other instances.

Consequently, it works as a tile with four edges as mentioned above, and as in Figure 30, the self-assembly of DNA tiles forms a planar structure. Sticky ends of a DNA tile correspond to edges of an abstract tile, and different sequences of sticky ends correspond to different edge labels. Their length roughly corresponds to their binding strength.

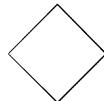

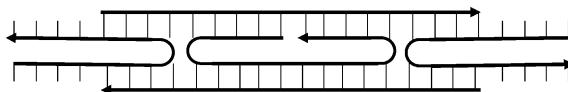

More complex computations can be performed by tiling (Mao 2000). For example, Figure 31 shows the addition of two binary numbers. The full-adder tile in the upper panel receives the corresponding bits of two numbers and the carry bit through its upper, lower, and right edges. It propagates its carry bit through its left edge. Addition of two three-bit numbers is performed as in the lower panel of the figure. The full-adder tile can be implemented by a triple crossover molecule, which has six sticky ends.

Fig. 28

Sierpinski's triangle.

**Fig. 29**

A double crossover molecule, also called a DNA tile. It consists of four single strands of DNA and forms a rectangular planar structure.

4.3 Reaction Graphs

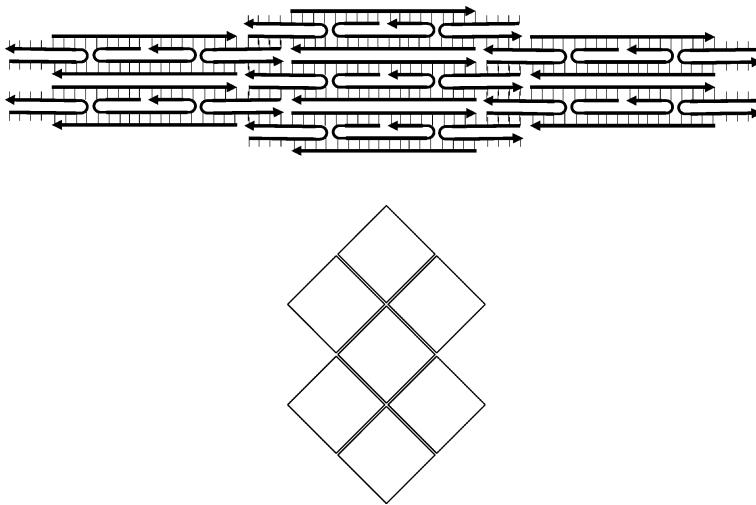

Many bio-molecular machineries and logic gates have been constructed successfully (Seelig et al. 2006a, b). As mentioned in [Sect. 4.2.2](#), DNA logic circuits without enzymes have attracted attention recently (Stojanovic et al. 2002; Stojanovic and Stefanovic 2003). However, such logic circuits are sometimes complicated because multiple sequences react with each other in various ways such as assembly, disassembly, and branch migration. Furthermore, sequences often consist of many domains, where some domains may be toeholds, and others may be loops of hairpin structures. This complexity leads to difficulties in understanding or designing the reaction dynamics of logic circuits.

To simply describe the self-assembly pathways, Peng Yin and his colleagues proposed the abstract model named “reaction graph,” which mainly focuses on circuits consisting of versatile DNA hairpin motifs (Yin et al. 2008a). With the reaction graph, the reaction dynamics can be simply described by nodes including input/output ports and arrows between nodes.

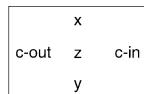

A simple example is shown in [Fig. 32](#). [Fig. 32a](#) shows the reaction dynamics. First, the sequence I hybridizes to the toehold region of hairpin A and then opens the hairpin by the branch-migration reaction ([Fig. 32a](#) (1)). Second, the complex structure $A \cdot I$ hybridizes to

Fig. 30

Self-assembly of DNA tiles. Through sticky ends, a DNA tile can hybridize with four other DNA tiles.

**Fig. 31**

Addition by tiles. The upper panel shows a full-adder tile, and the lower panel shows addition of two three-bit numbers.

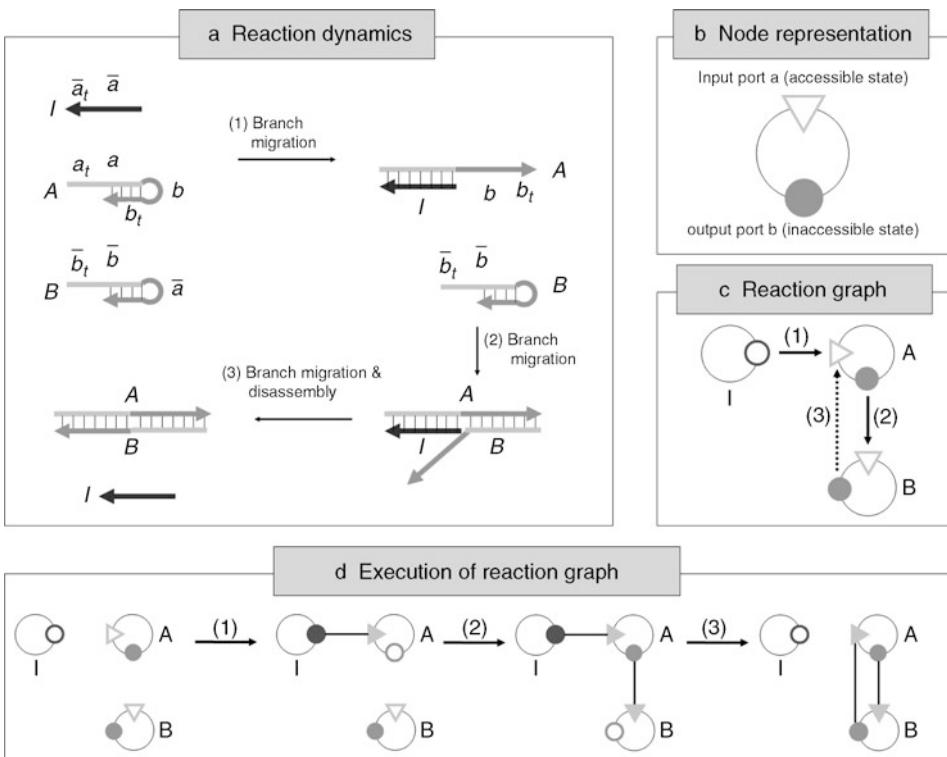

x2	x1	x0
c-out	z2	z0 0
y2	y1	y0
y2	y1	y0

the toehold region of B and then opens the hairpin (Fig. 32a (2)). Third, the sequence B removes the sequence I from A by branch migration (Fig. 32a (3)). Because the removed I is a single strand, it can hybridize to the toehold of hairpin A again. Thus, the sequence I works as a catalyst to promote the hybridization between sequences A and B . (Note that without I , sequences A and B cannot hybridize to each other, because the complementary regions are blocked by their hairpin structures.)

This reaction explained above can be represented by the reaction graph shown in Fig. 32c. Each sequence is represented by a node (see Fig. 32b). Each node has some ports (input/output ports), which correspond to domains in each sequence. Input ports correspond to the domains which can receive the upstream outputs and are represented by triangles, while output ports are the domains which can be inputs for downstream hairpins and are

Fig. 32

Simple example from Yin et al. (2008a) (slightly changed).

represented by circles. Input and output ports have two states, accessible or inaccessible. If a domain is a single-stranded region, the corresponding port is accessible (represented by open triangles/circles) because the single-stranded region can hybridize with other sequences. In contrast, if a domain is a double-stranded region, the corresponding port is inaccessible (represented by filled triangles/circles). A solid arrow from an output port to an input port represents that the output port can hybridize to the input port if both ports are accessible. Furthermore, a dashed arrow from an output port to an input port represents that the output port can hybridize to the input port and remove the hybridized sequence from the input port. For example, the solid arrow denoted by (1) in Fig. 32c represents that the sequence I can hybridize to the toehold domain of A , while the dashed arrow denoted by (3) represents that B can hybridize to A and remove I from A .

Figure 32d is the transition of the reaction graph shown in Fig. 32c. The thin lines represent the hydrogen bonds between input and output ports. As readers can check easily, the reaction graph correctly represents the reaction dynamics: When I hybridizes to A , the output port of I and the input port of A are flipped to inaccessible states and connected by a thin line (Fig. 32d (1)). Then, the output port of A is flipped to accessible state and hybridizes to the input port of B . Both ports are flipped to inaccessible states and connected by a thin line, while the output port of B removes I from A and hybridizes to the input port of A , when both ports are flipped to inaccessible and

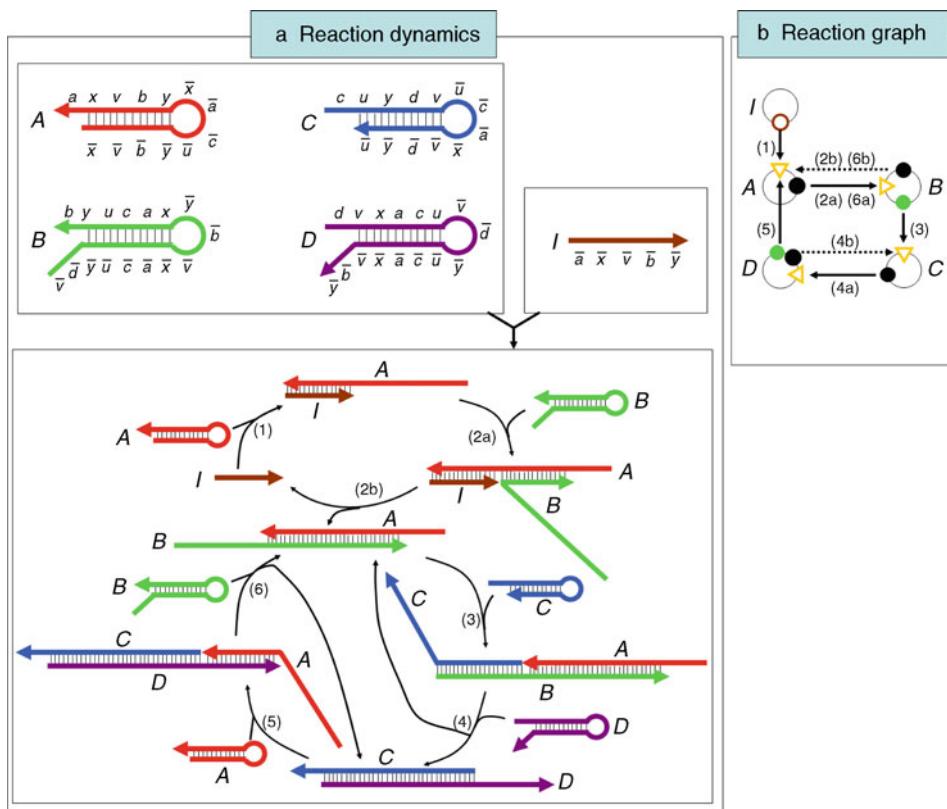

connected by a thin line. Finally, the system outputs I with the accessible output port and the $A \cdot B$ complex with inaccessible input/output ports (► Fig. 32d (3)).

► Figure 33 shows a more complicated example from Yin et al. (2008a). This example may be somewhat confusing. Complex $A \cdot B$ is produced by the hybridization between A and B promoted by I . Furthermore, $A \cdot B$ promotes the hybridization between C and D , while $C \cdot D$ does the hybridization between A and B simultaneously. Thus, the reaction dynamics are complicated and cannot be easily understood. With the reaction graph, however, the system can be simplified as shown in ► Fig. 33b:

- Sequence I hybridizes to the input port of A and opens the hairpin, resulting in the accessible output port of A (1).
- Then, the output port of A hybridizes to the input port of B (2a), when one output port of B , denoted by a black circle, is flipped to accessible, removes I from A , and hybridizes to the input port of A (2b).
- At the same time, the other output port of B , denoted by a gray circle, is flipped to accessible. This accessible output port can hybridize to the input port of C , resulting in the accessible output port of C (3).

► Fig. 33

More complicated example from Yin et al. (2008a) (slightly changed).

- The accessible output port of C hybridizes to the input port of D , when two output ports of D are flipped to accessible (4a).
- The accessible output port of D , denoted by a black circle, removes the complex $A \cdot B$ from C and hybridizes to the input port of C (4b), while the gray output port of D hybridizes to the input port of A (5).
- Then, the accessible output port of A hybridizes to the input port of B (6a), when the accessible black output port of B removes the complex $C \cdot D$ from A (6b).
- As a result, the system promotes the formation of complexes $A \cdot B$ and $C \cdot D$.

Readers can find some other examples of reaction graphs in Yin et al. (2008a), including three- or four-arm junctions, dendritic growth structures, and DNA walkers with two legs.

4.4 Whiplash Machines

4.4.1 Single-Molecule DNA State Machine

A distinctive DNA-based computing machine, called the *Whiplash machine*, has been continuously studied by a Japanese research group; it is a finite state machine implemented by encoding with a single DNA molecule. The parallel execution of multiple programs with different inputs in one reaction pot is realized by *Whiplash PCR* (WPCR), which is the recursive, self-directed polymerase extension of single-stranded DNA (ssDNA), proposed by Hagiya et al. (2000) and Sakamoto et al. (1999).

DNA Implementation of a Finite State Machine

The Whiplash machine utilizes the facts: a single-stranded DNA can form a *hairpin structure* by autonomously hybridizing the complementary sequences, and polymerase extension can generate a new DNA sequence as a reading out operation. Note that the rate of the computing process of the Whiplash machine is independent of the DNA concentration since hairpin formation is the intramolecular reaction.

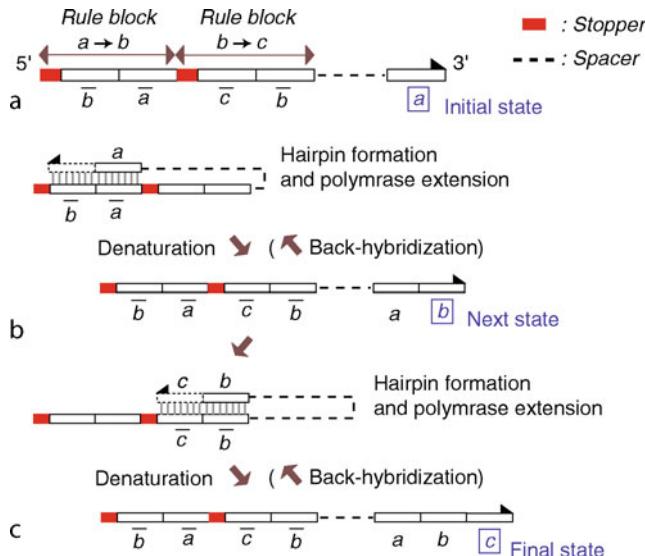

Suppose that a finite state machine M having transition rules for the three-state, two-step transitions, $a \rightarrow b \rightarrow c$. Then, the DNA implementation of M is carried out as follows.

(1) *Designing transition rules:* WPCR involves a sophisticated coding design of a ssDNA sequence (Fig. 34a). The set of transition rules are encoded in the form of catenated *rule blocks*, each encoding a state transition from state x to state y by an adjacent pair of sequences, $5' - \bar{y} \, \bar{x} - 3'$. Here, \bar{x} denotes the complementary sequence of x . A rule block also contains at its 5' side the *stopper*, which is commonly implemented by a short DNA sequence, AAA. Specifically, states a, b, c are encoded by sequences consisting of C, G, and T. The *transition rule region* contains rule blocks, $a \rightarrow b$ and $b \rightarrow c$. The 3' most sequence forms the *head*, which represents the Whiplash machine's current state.

(2) *Carrying out state transition:* By annealing, the complementary sequences a and \bar{a} come to hybridize, then a polymerase extension of the head takes place and the extension will be terminated automatically when the polymerase encounters the stopper, where the polymerization buffer is assumed to miss T (deoxythymidine triphosphate). The first transition, $a \rightarrow b$ is completed (Fig. 34b (the upper panel)). Then, by denaturation, the DNA again becomes the single-stranded form (Fig. 34b (the lower panel)). The 3' end of the ssDNA retains the current state b , renewed by reading out the complementary sequence \bar{b} in the rule block $a \rightarrow b$.

Fig. 34

Computing process of finite state machine by Whiplash PCR.

(3) *Successive transitions*: The process mentioned above can be repeated to perform further simulation of the state transition of M . After denaturation, the head representing the current state b is now ready for performing another simulation of the next transition, $b \rightarrow c$ (Fig. 34c).

Eight successive state transitions were so far achieved in the wet experiment (Komiya et al. 2006). As each DNA may be encoded with a distinct set of transition rules and a distinct initial state, parallel computation is achievable by the production of a combinatorial mixture of ssDNA. What is called the “multiple-instruction, multiple-data (MIMD)” computing paradigm is implemented by biomolecules. A solution to a 6-city instance of the directed Hamiltonian path problem using the Whiplash machine was demonstrated by Komiya et al. (2006). In addition, the WPCR model equipped with input/output interface was proposed in Komiya et al. (2001). Note that, in WPCR, a record of computation is encoded at the ssDNA’s 3’ end as a string of catenated state sequences. In Fig. 34c, this corresponds to the string, 5’-abc-3’. Implementation of evolutionary computation and its application to a novel protein evolution technique, taking advantage of the *computation record region*, were proposed (Rose et al. 2002b, 2003; Wood et al. 2002).

Back-Hybridization

Although the Whiplash machine is highly versatile in principle, it is known to suffer from an efficiency problem due to its systematic tendency towards self-inhibition, a problem called *back-hybridization*. Consider again the two-step transitions, shown in Fig. 34. The second polymerase extension requires the hybridization of the head sequence b with the sequence \bar{b} of rule block $b \rightarrow c$ (Fig. 34c). The efficiency of this process, however, is compromised by the ability of the ssDNA to form the alternative hairpin shown in Fig. 34b, which is no longer extendable and energetically more favorable than the planned, extendable hairpin. For multiple rounds of WPCR implementation, the number of distinct back-hybridized configurations

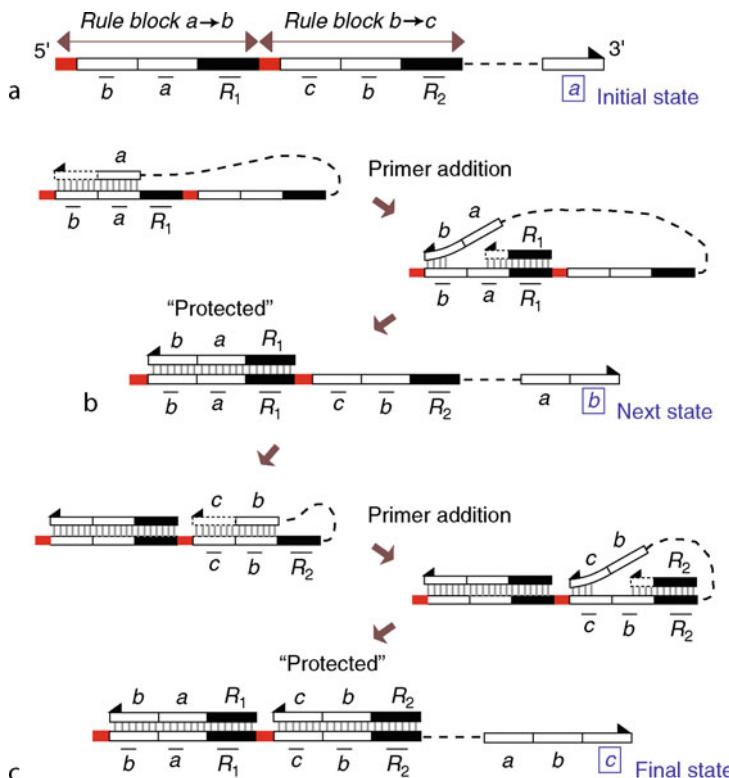

increases as the computation continues. Back-hybridization is a serious obstacle to practical application of the Whiplash machine (Rose et al. 2002a). In the next section, an optimally reengineered architecture of the Whiplash machine to overcome this efficiency problem is described.

4.4.2 Efficient and Controllable Whiplash Machine

An extended architecture of the WPCR, *displacement whiplash PCR* (DWPCR), was proposed by Rose et al. (2006). In DWPCR, the new *rule protect* operation, which is the primer-directed conversion of each implemented rule-block to double-stranded DNA, accompanied by opening the back-hybridized hairpins by strand displacement, is introduced. DWPCR implements the same series of operations applied in standard WPCR, adding only a protection step, where primer annealing, extension, and strand displacement occur at the targeted rule block, following each round of transition. A rule block contains an additional sequence at its 3' side for primer binding, represented by a black rectangle in Fig. 35.

DWPCR supports isothermal operation at physiological temperatures and is expected to attain a near-ideal efficiency by abolishing back-hybridized hairpins, and thus open the door for potential biological applications. Note that the use of rule-protect for controlling computation is being investigated (Komiya et al. 2009). Operation timing can be controlled

Fig. 35
Computing process of displacement Whiplash PCR.

by primer addition as an external signal for regulation. Furthermore, as transition rules may also be deactivated via rule-protect prior to their implementation, the transition rules to be implemented can be switched dependent on primer addition. Consequently, the extended Whiplash machine performs successive state transitions, following both a computational program encoded with an ssDNA molecule and a regulatory program implemented by a series of additions of primers, as a signal-dependent self-directed operation.

4.5 SAT Engines

The satisfiability problem (SAT, in short) is one of the well-known NP-complete problems where, given a Boolean formula, one has to decide whether or not the formula is satisfiable (i.e., there exists a truth value assignment under which the truth value of the formula is “true”).

As its name suggests, the *SAT Engine* (Sakamoto et al. 2000) has been developed for solving the SAT problem, in which the mechanism of hairpin formation is successfully employed to detect and remove many “inconsistent assignments” to a given Boolean formula.

Using an example, the idea of the SAT algorithm via DNA molecules is outlined. Consider a Boolean formula F with three variables, consisting of five clauses:

$$\begin{aligned} F &= C_1 \cdot C_2 \cdots C_5 \\ &= (a \vee b \vee c) \wedge (a \vee \neg b \vee c) \wedge (\neg a \vee b \vee c) \wedge (\neg a \vee b \vee \neg c) \wedge (\neg a \vee \neg b \vee \neg c) \end{aligned}$$

where a variable x and its negation $\neg x$ are called *literal*. A truth value assignment is a mapping, which for each variable assigns 1 or 0 (true or false). A formula F is *satisfiable* iff there exists a truth value assignment for which the value of F is true. In the running example, since there is a truth value assignment $(a, b, c) = (1, 1, 0)$ which leads to $F = 1$, F is satisfiable. If each clause C_i in F contains at most k literals, then F is called an instance of the k -SAT problem.

4.5.1 DNA SAT Algorithm

First, let one consider a string $u_F = t_1 t_2 \dots t_5$ over the alphabet $\Gamma = \{a, \neg a, b, \neg b, c, \neg c\}$, where each t_i is an arbitrary literal chosen from C_i , for each $i = 1, 2, \dots, 5$. A string u_F is called a *literal string* of F . For example, $aab \neg c \neg c$ and $acbb \neg c$ are literal strings of F . Each literal t_i chosen from C_i can be regarded as the value for which $C_i = 1$. (In the example, a literal string $aabb \neg c$ is interpreted as $(a, b, c) = (1, 1, 0)$ and it makes F consistently true, while a literal string $acbb \neg c$ is inconsistent with a variable c , that is, it contains both c and $\neg c$, failing to make F true.) A literal string of F is satisfiable if it can make F true, and it is unsatisfiable otherwise.

Now, the SAT algorithm comprises the following three steps;

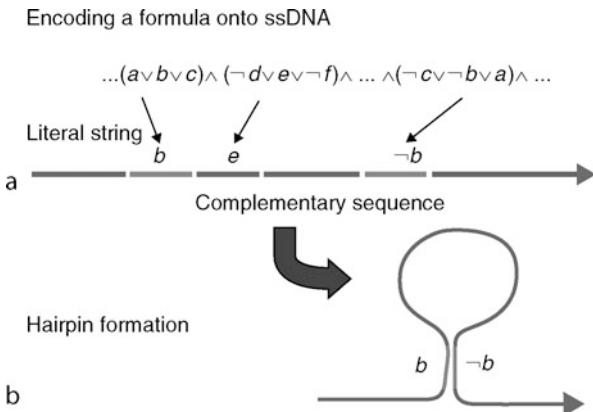

- (Step 1): For a formula F with n clauses, make the set $LS(F)$ of all literal strings of F whose length are all n . (In case of the 3-SAT problem, $LS(F)$ consists of at most 3^n literal strings.)
- (Step 2): Remove from $LS(F)$ any literal string that is unsatisfiable.
- (Step 3): After removing in Step 2, if there is any literal string remaining, then that is a satisfiable one, so that the formula F turns out to be satisfiable. Otherwise, F is not.

These can be implemented using biomolecular experimental techniques in the following manner:

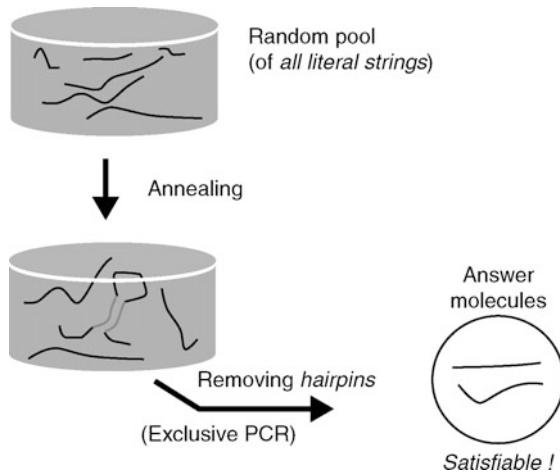

- (Step 1): By ligating each DNA molecule representing each literal, make all elements of the set $LS(F)$ in parallel.

Fig. 36

Encoding a formula onto ssDNA and hairpin formation.

**Fig. 37**

SAT algorithmic schema.

(Step 2): A variable x and its negation $\neg x$ are encoded so that these two are just complementary. Therefore, a literal string containing x and $\neg x$ is encoded into a molecule containing two subsequences which are complementary. (See [Fig. 36a](#).) Thus, an encoded molecule for an unsatisfiable literal string can form a *hairpin structure*. (See [Fig. 36b](#).)

(Step 3): Remove all DNA molecules that form hairpin structures. If there remains any molecule, then detect it and read the sequence for decoding the variable assignment. (See [Fig. 37](#))

4.5.2 Implementation and Experiments

A wet lab experiment was carried out by Sakamoto et al. (2000) where the following Boolean formula was considered

$$\begin{aligned} F = & (a \vee b \vee \neg c) \wedge (a \vee c \vee d) \wedge (a \vee \neg c \vee \neg d) \\ & \wedge (\neg a \vee \neg c \vee d) \wedge (a \vee \neg c \vee e) \wedge (a \vee d \vee \neg f) \\ & \wedge (\neg a \vee c \vee d) \wedge (a \vee c \vee \neg d) \wedge (\neg a \vee \neg c \vee \neg d) \wedge (\neg a \vee c \vee \neg d) \end{aligned}$$

The total number of literal strings of F is 3^{10} ($= 59,049$) among which only 24 literal strings are satisfiable. (In fact, these 24 literal strings are for the identical truth value assignment.)

In their experiment, each literal was conceptually encoded onto a single-stranded DNA molecule (called *literal DNA*) of length 30 as follows:

a: TTGGTTGATAGACCCAGGATCGAGTGCAT
 b: TTGGCATAAGTTGCCAGGCAGGAACCTCCAT
 c: TTGGAACGTAGTACCAGGAGTCTCCTCCAT
 d: TTGGTGATACGGACCAGGCCTTCTTACCAT
 e: TTGGTTGCCCTCCAGGTGACTAATCCAT
 f: TTGGACTGCTCATCCAGGACTGAAGACCAT,

while the negative counterpart $\neg x$ of x (x in $\Gamma = \{a, b, c, d, e, f\}$) was encoded as the complementary sequence of x .

(Step 1) was actually carried out by concatenating with ligase all literal DNAs for x and $\neg x$ ($x \in \Gamma$), where in an actual implementation, each literal DNA was designed as a dsDNA with sticky ends at either side, playing the role of a linker for concatenation. (This is because ligase used for concatenation does not act on ssDNAs but on dsDNAs.) Another purpose of a linker is to ensure that the resultant of concatenating literal DNAs contains exactly one literal from each clause. A final pot of a random pool consisting of all molecules for $LS(F)$ was created autonomously. The experimental result of (Step 1) is reported to have been successful.

In (Step 2), each dsDNA in the pot was first heated to separate into two ssDNAs, one of which was washed out. Then, the remaining ssDNAs are now ready to form *hairpin structures* if they are DNAs encoding unsatisfiable assignments. In other words, if there exist ssDNAs that do not form hairpin structures, then it means that there exists truth value assignments for a given F (i.e., the formula F is satisfiable). Note that each literal DNA contains a recognition site of a restriction enzyme *Bst*NI, and this hidden sequence will play an important role, as seen below.

In (Step 3), by using a restriction enzyme *Bst*NI, the hairpin structure formed in (Step 2) is cut out, so that all DNAs containing hairpin structures lose a chance to survive until the next procedure in which the application of PCR will multiply the remaining DNAs for sequencing them.

In practice, 6 literal strings were finally obtained which include

$$bc\neg d\neg ae\neg f\neg ac\neg a\neg a \text{ and } bc\neg d\neg ae\neg f\neg a\neg d\neg a\neg a$$

It is reported that all those literal strings were for the unique assignment:

$$(a, b, c, d, e, f) = (0, 1, 1, 0, 1, 0)$$

which provides, in fact, a correct solution to the example formula.

4.6 Bibliographic Notes

Research on computing Boolean circuits using DNA is well established and dates back to Ogihara and Ray (1999) and Amos et al. (1998). Their methods, however, require that for each logic gate an external experimental operation is applied to a test tube. On the other hand, this section focused on molecular computing machineries that can compute a series of logic gates in a self-controlled way without human intervention in the sense of autonomous molecular computers advocated by Hagiya (1999).

As DNA automata are implemented by enzymes, logic gates can also be implemented by enzymes. In particular, an autonomous molecular computer Reverse-transcription-and-TTranscription-based Autonomous Computing System (RTRACS) proposed and implemented in Nitta and Suyama (2004) and Takinoue et al. (2008) has some unique features. Modeled after the retroviral replication mechanism, RTRACS utilizes not only DNA/RNA molecules but also reverse transcriptase and other enzymatic substrates, and the computation is autonomously carried out under an isothermal environment. An *in vitro* experiment of simulating an AND gate in Takinoue et al. (2008) demonstrates a potentially high computational capability of the integrated circuits of the modularized basic units of RTRACS.

More and more efforts are being made to implement *in vivo* logic circuits as proposed by Benenson et al. in [Sect. 4.1.2](#). Smolke's RNA computer mentioned in [Sect. 4.2.1](#) is one such effort. Benenson also proposed to use small interfering RNAs (siRNAs) for implementing logic circuits (Rinaudo et al. 2007). They both use RNA to regulate gene expression. Implementing logic gates is also a main research topic in the field of synthetic biology. Logic circuits are implemented by modifying genetic circuits made of genes and regulatory proteins that regulate gene expression (Endy 2005). Artificial genetic circuits are not covered in this section, as synthetic biology is considered out of the scope of this chapter.

As is also mentioned in the bibliographic notes of [Sect. 3](#), self-assembly of DNA tiles has been one of the main topics in DNA computing research (Jonoska and McColm 2009; Winfree 1998; Winfree et al. 1996, 2000), though logic gates implemented by DNA tiling is briefly touched on in [Sect. 4.2.3](#).

The machineries based on DNAzymes and those based on strand displacements, which have been extended to reaction graphs in [Sect. 4.3](#), are being applied to implement more typical molecular machines, including walkers and transporters (Bath and Turberfield 2007).

Abstract

This chapter is devoted to two of the most developed theoretical computing models inspired by DNA biochemistry, computing by splicing (a formal operation with strings that models the recombination of DNA molecules under the influence of restriction enzymes and ligase) and by insertion–deletion. Only basic ideas and results are presented, as well as a comprehensive – although not complete – list of titles where further information can be found.

1 Introduction

DNA computing was mainly developed after the 1994 Adleman experiment of solving a small instance of the Hamiltonian path problem in a test tube, making use of standard lab operations, but from a theoretical point of view, one may say that everything started much earlier. For instance, as early as in 1987, Head introduced the so-called splicing operation (Head 1987), an operation with strings that models the recombination of DNA molecules cut by restriction enzymes and pasted together by means of ligase. This initiated a powerful research direction in computability (mainly formal language and automata theory, see Păun et al. (1998), but recently also in terms of complexity, see, e.g., Loos et al. (2008) and Loos and Ogihsara (2007)), *DNA computing by splicing*. Actually, the “prehistory” of DNA computing can be pushed further, for instance, considering the operations of inserting and of deleting strings, considered in linguistics and formal languages well before – only Galiukschov (1981) and Marcus (1969) are mentioned – and whose study was continued in the new framework of handling DNA molecules.

In what follows, both of these directions of research in theoretical DNA computing, computing by splicing and computing by insertion–deletion, will be briefly overviewed. Only basic notions are given; a few typical proofs (mainly proof ideas) and a series of results will be recalled – without attempting to be complete from this last point of view, because, on the one hand, there exists a large number of results and, on the other hand, the research in these areas is still active, so that the existing open problems are under continuous examination and there is continuous progress. In particular, only a few basic references are provided and the reader can refer to Head et al. (1997), Jonoska et al. (2004), and Păun et al. (1998, 2009) for further details and references; many PhD theses devoted to (theoretical) DNA computing can also be useful in this respect – some of them are mentioned in the bibliography of this chapter.

2 Some Prerequisites

It is assumed that the reader is familiar with elementary facts from language and automata theory, so that only a few notions and notations are recalled here. If necessary, any of the many monographs in this area may be consulted. Only Harrison (1978) and Salomaa (1973) and the handbook by Rozenberg and Salomaa (1997) are mentioned as sources of comprehensive information.

For an alphabet V , V^* is the set of all strings over V , the empty string, denoted by λ , included. The length of $x \in V^*$ is denoted by $|x|$. A mapping $h : V \rightarrow U^*$ extended to $h : V^* \rightarrow U^*$ by $h(\lambda) = \lambda$ and $h(uv) = h(u)h(v)$ for all $u, v \in V^*$ is called a *morphism*. A morphism $h : V^* \rightarrow U^*$ is called a *coding* if $h(a) \in U$ for all $a \in V$ and a *weak coding* if

$h(a) \in U \cup \{\lambda\}$. A weak coding $h: V \rightarrow U$ with $U \subseteq V$ such that $h(a) = a$ for $a \in U$, and $h(a) = \lambda$ for $a \in V - U$ is called a *projection* (on U).

A Chomsky grammar (also called type-0 grammar) is a quadruple $G = (N, T, S, P)$, where N is the nonterminal alphabet, T is the terminal alphabet, S is the axiom, and P is the set of rewriting rules. If these rules are of the following forms,

- $AB \rightarrow CD$, where $A, B, C, D \in N$ (type 1: context-sensitive rules)
- $A \rightarrow BC$, where $A, B, C \in N$ (type 2: context-free rules)
- $A \rightarrow a$, where $A \in N$ and $a \in T \cup \{\lambda\}$ (type 3: terminal rules; they may be erasing rules)

then the grammar is in the *Kuroda normal form*.

A type-0 grammar $G = (\{S, A, B, C, D\}, T, S, P)$ with P containing rules of the forms $S \rightarrow uSv$, $S \rightarrow x$, with $u, v, x \in (T \cup \{A, B, C, D\})^*$, as well as the non-context-free rules $AB \rightarrow \lambda$, $CD \rightarrow \lambda$, is said to be in the *Geffert normal form*.

The families of finite, regular, linear, context-free, context-sensitive, and recursively enumerable languages are denoted by *FIN*, *REG*, *LIN*, *CF*, *CS*, and *RE*, respectively.

A family of languages closed under union, concatenation, λ -free morphisms, inverse morphisms, intersection with regular languages, and Kleene closure is called an AFL (abstract family of languages); an AFL closed under arbitrary morphisms is called a full-AFL.

The Dyck language over an alphabet $V_n = \{a_i, b_i \mid 1 \leq i \leq n\}$ is the language generated by the context-free grammar $G_n = (\{S\}, V_n, S, P_n)$ with the following rules

$$P_n = \{S \rightarrow SS, S \rightarrow \lambda\} \cup \{S \rightarrow a_i S b_i \mid 1 \leq i \leq n\}$$

Every context-free language L can be written in the form $L = h(D_n \cap R)$, where h is a projection, D_n , $n \geq 1$, is a Dyck language, and R is a regular language. This result is known as the *Chomsky–Schützenberger characterization of context-free languages*.

A deterministic finite automaton is a construct $M = (K, V, q_0, F, \delta)$, where K is the finite set of states, V is the alphabet of the automaton, q_0 is the initial state, $F \subseteq K$ is the set of terminal states, and $\delta: K \times V \rightarrow K$ is the next-state mapping. Finite automata characterize the family, *REG*, of languages generated by Chomsky regular grammars.

3 Computing by Splicing

As mentioned in [Sect. 1](#), the splicing operation was introduced in Head ([1987](#)), as an abstraction of a biochemical operation (actually, a sequence of cut- and paste-operations) with DNA molecules. Here this abstraction process is not recalled, but we refer to the seminal paper and to Păun et al. ([1998](#)) for details. The operation proposed in Head ([1987](#)) was further generalized in Păun ([1996a](#)), formulated as a “pure” operation with strings and formal languages, and it was then mainly considered in this form in the subsequent mathematical developments. In particular, it was this version of the splicing operation that was used for defining a computing model, called an *H system* in Păun et al. ([1996](#)), with H coming from the name of the originator of this approach, Tom Head. Later, further variations were introduced, for example, in Pixton ([2000](#)) and Loos ([2006](#)). In what follows, the DNA computing is presented by splicing based on the operation as defined in Păun ([1996](#)), hence in terms of strings and languages, abstracting away such important features of the DNA molecules, always present in the background of the theoretical developments, such as the use of only four letters (representing nucleotides), the double stranded structure, the Watson–Crick

complementarity, the bidirectionality, the palindromicity of the restriction sites of many enzymes, and so on. The use of the other variants of splicing, in particular, comparisons between them, can be found in a series of papers; some of them are also included in the bibliography of this chapter.

3.1 The Splicing Operation

One can consider an arbitrary finite alphabet V . A splicing rule over V is a string $u_1\#u_2\$u_3\#u_4$, where u_1, u_2, u_3, u_4 are strings over V and $\#, \$$ are special symbols not in V . (The idea is that $(u_1, u_2), (u_3, u_4)$ represent the restriction sites of two enzymes, which cut DNA molecules in such a way that they produce sticky ends which match, hence the fragments produced by these enzymes can be recombined; the first enzyme cuts molecules – strings here – in between u_1 and u_2 , and the second enzyme cuts in between u_3 and u_4 .)

For a splicing rule $r = u_1\#u_2\$u_3\#u_4$ and four strings x, y, z, w over V , we write

$$\begin{aligned} (x, y) \models_r (z, w) &\text{ iff } x = x_1 u_1 u_2 x_2, \quad y = y_1 u_3 u_4 y_2 \\ &z = x_1 u_1 u_4 y_2, \quad w = y_1 u_3 u_2 x_2 \\ &\text{for some } x_1, x_2, y_1, y_2 \in V^* \end{aligned}$$

We say that we *splice* x, y at the sites u_1u_2, u_3u_4 , respectively, and the result consists of the strings z, w . This is called the 2-splicing, because both strings obtained by recombination are taken as the result of the operation. From a mathematical point of view, in many contexts it is sufficient/more elegant to consider only the first string, z , as the result of the splicing – and this is called the 1-splicing. The idea is that in most cases, we work with a set of splicing rules and then, together with the rule $u_1\#u_2\$u_3\#u_4$ we can also consider the symmetric rule, $u_3\#u_4\$u_1\#u_2$, and, by splicing the same strings x, y , the first rule produces the first result, z , and the second one produces the second result, w . In what follows it will be specified which of the two operations is used. Most of the results (for instance, the regularity and the universality results) are similar for the two versions of the splicing, but there are cases where a difference can be found – see, for example, Verlan and Zizza (2003).

In particular, we use \vdash to denote the 1-splicing and \models for the 2-splicing operation. When only “splicing” is referred to, it will be clear from the context which type of splicing is meant.

These operations can be extended to languages in a natural way. One can first introduce the notion of an *H scheme*, as a pair $\sigma = (V, R)$, where V is an alphabet and $R \subseteq V^* \# V^* \$ V^* \# V^*$ is a set of splicing rules. Note that in this formulation R is a language, hence we can consider its complexity with respect to various language hierarchies. For instance, if $R \in FL$, for a given family of languages, FL , then we say that the H scheme σ is of *FL type*.

Now, for a given H scheme $\sigma = (V, R)$ and a language $L \subseteq V^*$, we define

$$\sigma_1(L) = \{z \in V^* \mid (x, y) \models_r z, \text{ for some } x, y \in L, r \in R\}$$

and then, for two families FL_1, FL_2 of languages, we denote

$$S_1(FL_1, FL_2) = \{\sigma_1(L) \mid L \in FL_1 \text{ and } \sigma = (V, R) \text{ with } R \in FL_2\}$$

This is the one-step splicing operation, extended to languages and performed with respect to sets of splicing rules. The operation can be iterated, in the natural way: for an H scheme $\sigma = (V, R)$ and a language $L \subseteq V^*$ we define

$$\begin{aligned}\sigma_1^0(L) &= L \\ \sigma_1^{i+1}(L) &= \sigma_1^i(L) \cup \sigma_1(\sigma_1^i(L)), \quad i \geq 0 \\ \sigma_1^*(L) &= \bigcup_{i \geq 0} \sigma_1^i(L)\end{aligned}$$

Consequently, $\sigma_1^*(L)$ is the closure of L under the splicing with respect to σ , that is, the smallest language L' that contains L , and is closed under the splicing with respect to σ , that is to say, $\sigma_1(L') \subseteq L'$.

For two families of languages, FL_1, FL_2 , we define

$$H_1(FL_1, FL_2) = \{\sigma_1^*(L) \mid L \in FL_1 \text{ and } \sigma = (V, R) \text{ with } R \in FL_2\}$$

Of course, the same definitions can be considered for the 2-splicing and then we obtain the families $S_2(FL_1, FL_2), H_2(FL_1, FL_2)$, respectively.

3.2 The Power of the Splicing Operation

We examine now the size of families $S_1(FL_1, FL_2), H_1(FL_1, FL_2)$, for FL_1, FL_2 one of the following families: *FIN, REG, LIN, CF, CS, RE*.

For the non-iterated splicing, the following theorem synthesizes the best results known in the framework specified above; proofs and references can be found in Păun et al. (1998) and Head et al. (1997).

Theorem 1 *The relations in Table 1 hold, where at the intersection of the row marked with FL_1 with the column marked with FL_2 there appear either the family $S_1(FL_1, FL_2)$, or two families FL_3, FL_4 such that $FL_3 \subset S_1(FL_1, FL_2) \subset FL_4$. These families FL_3, FL_4 are the best possible estimations among the six families considered here.*

In the case of iterated splicing, things are more difficult, especially concerning the characterization of the families $H_1(FL, FIN)$, $FL \in \{FIN, REG\}$. Several proofs of the regularity of the languages in these families were given, some of them rather complex and some of them extended to abstract families of languages.

Table 1

The size of families $S_1(FL_1, FL_2)$

	<i>FIN</i>	<i>REG</i>	<i>LIN</i>	<i>CF</i>	<i>CS</i>	<i>RE</i>
<i>FIN</i>	<i>FIN</i>	<i>FIN</i>	<i>FIN</i>	<i>FIN</i>	<i>FIN</i>	<i>FIN</i>
<i>REG</i>	<i>REG</i>	<i>REG</i>	<i>REG, LIN</i>	<i>REG, CF</i>	<i>REG, RE</i>	<i>REG, RE</i>
<i>LIN</i>	<i>LIN, CF</i>	<i>LIN, CF</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>
<i>CF</i>	<i>CF</i>	<i>CF</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>
<i>CS</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>
<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>

Proofs of the following result, called in Păun et al. (1998) *the Regularity Preserving Lemma*, can be found in Culik II and Harju (1991), Pixton (1996) (recalled in Păun et al. (1998)), and Manca (2000):

Lemma 1 $H_1(\text{REG}, \text{FIN}) \subseteq \text{REG}$.

A stronger result has been presented in Pixton (2000); the proof is recalled in Head et al. (1997).

Lemma 2 *If FL is a full AFL, then $H_1(\text{FL}, \text{FIN}) \subseteq \text{FL}$.*

Thus, when using a finite set of rules (remember: this corresponds to a finite set of restriction enzymes), we cannot compute too much, we remain inside the computing competence of finite automata. Much more can be computed if we use a set of rules of the next level in the hierarchy of language families considered above, that is, a regular set. This result is presented, called in Păun et al. (1998) *the Basic Universality Lemma*, with a proof, mainly because the proof idea, the so-called rotate-and-simulate technique, is useful in many related contexts.

Lemma 3 *Every language $L \in \text{RE}$, $L \subseteq T^*$, can be written in the form $L = L' \cap T^*$ for some $L' \in H_1(\text{FIN}, \text{REG})$.*

Proof Consider a Chomsky type-0 grammar $G = (N, T, S, P)$, denote $U = N \cup T \cup \{B\}$, where B is a new symbol, and construct the H scheme $\sigma = (V, R)$, where

$$V = N \cup T \cup \{X, X', B, Y, Z\} \cup \{Y_\alpha \mid \alpha \in U\}$$

and R contains the following groups of rules:

- Simulate* : 1. $Xw\#uY\$Z\#vY$, for $u \rightarrow v \in P, w \in U^*$
- Rotate* : 2. $Xw\#\alpha Y\$Z\#Y_\alpha$, for $\alpha \in U, w \in U^*$
- 3. $X'\alpha\#Z\$X\#wY_\alpha$, for $\alpha \in U, w \in U^*$
- 4. $X'w\#Y_\alpha\$Z\#Y$, for $\alpha \in U, w \in U^*$
- 5. $X\#Z\$X'\#wY$, for $w \in U^*$
- Terminate* : 6. $\#ZY\$XB\#wY$, for $w \in T^*$
- 7. $\#Y\$XZ\#$

Consider also the language

$$\begin{aligned} L_0 = & \{XBSY, ZY, XZ\} \cup \{ZvY \mid u \rightarrow v \in P\} \\ & \cup \{ZY_\alpha, X'\alpha Z \mid \alpha \in U\} \end{aligned}$$

We obtain $L = \sigma_1^*(L_0) \cap T^*$.

Indeed, one can examine the work of σ , namely, the possibilities to obtain a string in T^* .

No string in L_0 is in T^* . All rules in R involve a string containing the symbol Z , but this symbol will not appear in the string produced by splicing. Therefore, at each step, we have to use a string in L_0 and, excepting the case of using the string $XBSY$ in L_0 , a string produced at a previous step.

The symbol B is a marker for the beginning of the sentential forms of G simulated by σ .

By rules in group 1 we can simulate the rules in P . Rules in groups 2–5 move symbols from the right-hand end of the current string to the left-hand end, thus making possible the simulation of rules in P at the right-hand end of the string produced by σ . However, because B is always present and marks the place where the string of G begins, it is known in each moment which is that string. Namely, if the current string in σ is of the form $\beta_1 w_1 B w_2 \beta_2$, for some β_1, β_2 markers of types X, X', Y, Y_α with $\alpha \in U$, and $w_1, w_2 \in (N \cup T)^*$, then $w_2 w_1$ is a sentential form of G .

We start from $XBSY$, hence from the axiom of G , marked to the left hand with B and bracketed by X, Y .

Let us see how the rules 2–5 work. Take a string $Xw\alpha Y$, for some $\alpha \in U, w \in U^*$. By a rule of type 2 we get

$$(Xw|\alpha Y, Z|Y_\alpha) \vdash XwY_\alpha$$

The symbol Y_α memorizes the fact that α has been erased from the right-hand end of $w\alpha$. No rule in R can be applied to XwY_α excepting the rules of type 3:

$$(X'\alpha|Z, X|wY_\alpha) \vdash X'\alpha wY_\alpha$$

Note that the same symbol α removed at the previous step is now added in the front of w . Again, we have only one way to continue, namely, by using a rule of type 4. We get

$$(X'\alpha w|Y_\alpha, Z|Y) \vdash X'\alpha wY$$

If we now use a rule of type 7, removing Y , then X' (and B) can never be removed, and hence the string cannot be turned to a terminal one. A rule of type 5 must be used:

$$(X|Z, X'|\alpha wY) \vdash X\alpha wY$$

We have started from $Xw\alpha Y$ and obtained $X\alpha wY$, a string with the same end markers. These steps can be iterated as long as we want, so any circular permutation of the string between X and Y can be produced. Moreover, what we obtain are exactly the circular permutations and nothing more (for instance, at every step, there will still be one and only one occurrence of B).

To every string XwY one can also apply a rule of type 1, providing w ends with the left-hand member of a rule in P . Any rule of P can be simulated in this way, at any place we want in the corresponding sentential form of G , by preparing the string as above, using rules in groups 2–5.

Consequently, for every sentential form w of G there is a string $XBwY$, produced by σ , and, conversely, if $Xw_1 B w_2 Y$ is produced by σ , then $w_2 w_1$ is a sentential form of G .

The only way to remove the symbols not in T from the strings produced by σ is by using rules in groups 6, 7. More precisely, the symbols XB can only be removed in the following conditions: (1) Y is present (hence the work is blocked if one uses first rule 7, removing Y : the string cannot participate in any further splicing, and it is not terminal), (2) besides one occurrence of B , the current string bracketed by X, Y consists of terminal symbols only, and (3) the symbol B is adjacent to X , in the right hand of it. After removing X and B , one can remove Y , too, and what one obtains is a string in T^* . From the previous discussion, it is clear that such a string is in $L(G)$, hence $\sigma_1^*(L_0) \cap T^* \subseteq L(G)$. Conversely, each string in $L(G)$ can be produced in this way, hence $L(G) \subseteq \sigma_1^*(L_0) \cap T^*$. We have the equality $L(G) = \sigma_1^*(L_0) \cap T^*$, which completes the proof.

Table 2The size of families $H_1(FL_1, FL_2)$

	<i>FIN</i>	<i>REG</i>	<i>LIN</i>	<i>CF</i>	<i>CS</i>	<i>RE</i>
<i>FIN</i>	<i>FIN, REG</i>	<i>FIN, RE</i>				
<i>REG</i>	<i>REG</i>	<i>REG, RE</i>				
<i>LIN</i>	<i>LIN, CF</i>	<i>LIN, RE</i>				
<i>CF</i>	<i>CF</i>	<i>CF, RE</i>				
<i>CS</i>	<i>CS, RE</i>	<i>CS, RE</i>	<i>CS, RE</i>	<i>CS, RE</i>	<i>CS, RE</i>	<i>CS, RE</i>
<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>

We also recall, without a proof, a result concerning the limitations of families $H_1(FL_1, FL_2)$.

Lemma 4 *Let FL be a family of languages closed under intersection with regular languages and restricted morphisms. For every $L \subseteq V^*$, $L \notin FL$, and $c, d \notin V$, the language $L' = (dc)^*L(dc)^* \cup c(dc)^*L(dc)^*d$ does not belong to the family $H_1(FL, RE)$.*

Based on the previous results, we get the following synthesis theorem.

Theorem 2 *The relations in [Table 2](#) hold, where at the intersection of the row marked with FL_1 with the column marked with FL_2 there appear either the family $H_1(FL_1, FL_2)$, or two families FL_3, FL_4 such that $FL_3 \subset H_1(FL_1, FL_2) \subset FL_4$. These families FL_3, FL_4 are the best possible estimations among the six families considered here.*

3.3 Extended Splicing Systems

In the sections above the power of splicing operations is considered without explicitly introducing a computing model. This can be done now, by defining the main device investigated in DNA computing by splicing, the H systems; these devices are presented directly in the extended version, with a terminal alphabet used for selecting the result of computations out of all results of splicing operations.

An *extended H system* is a quadruple $\gamma = (V, T, A, R)$, where V is an alphabet, $T \subseteq V$, $A \subseteq V^*$, and $R \subseteq V^* \# V^* \$ V^* \# V^*$, where $\#, \$$ are special symbols not in V .

We call V the alphabet of γ , T is the *terminal alphabet*, A is the set of *axioms*, and R is the set of splicing rules. Therefore, we have an *underlying H scheme*, $\sigma = (V, R)$, augmented with a given subset of V and a set of axioms. When $T = V$ we say that γ is a *non-extended H system*.

The *language generated* by γ is defined by $L(\gamma) = \sigma_1^*(A) \cap T^*$, where σ is the underlying H scheme of γ .

For two families of languages, FL_1, FL_2 , we denote by $EH_1(FL_1, FL_2)$ the family of languages $L(\gamma)$ generated by extended H systems $\gamma = (V, T, A, R)$, with $A \in FL_1, R \in FL_2$.

A number of the results from the previous section can be reformulated in terms of extended H systems. Moreover, we have the following inclusion (we recall its simple proof from Păun et al. (1998) in order to have an example of an extended H system).

Lemma 5 $REG \subseteq EH_1(FIN, FIN)$.

Proof Consider a regular grammar $G = (N, T, S, P)$ (hence with rules in P of the forms $A \rightarrow aB, A \rightarrow a$, for $A, B \in N$ and $a \in T$). We construct the H system

$$\begin{aligned}\gamma &= (N \cup T \cup \{Z\}, T, A_1 \cup A_2 \cup A_3, R_1 \cup R_2) \\ A_1 &= \{S\} \\ A_2 &= \{ZaY \mid X \rightarrow aY \in P, X \in N, a \in T\} \\ A_3 &= \{ZZa \mid X \rightarrow a \in P, X \in N, a \in T\} \\ R_1 &= \{\#X\$Z\#aY \mid X \rightarrow aY \in P, X \in N, a \in T\} \\ R_2 &= \{\#X\$ZZ\#a \mid X \rightarrow a \in P, X \in N, a \in T\}\end{aligned}$$

The work of γ can be now examined. If a string ZxX is spliced, possibly one from A_2 (this is the case if $x = c \in T$ and $U \rightarrow cX \in P$) using a rule in R_1 , then we get a string of the form $ZxaY$. The symbol Z cannot be eliminated, hence no terminal string can be obtained if one continues to use the resulting string as the first term of a splicing. On the other hand, a string ZxX with $|x| \geq 2$ cannot be used as the second term of a splicing. Thus, the only way to obtain a terminal string is to start from S , to use splicings with respect to rules in R_1 an arbitrary number of times, and to end with a rule in R_2 . Always the first term of a splicing is that obtained by a previous splicing and the second one is from A_2 or from A_3 (at the last step). This corresponds to a derivation in G , hence we have $L(\gamma) = L(G)$.

Combining now the previous results, we get the following theorem.

Theorem 3 *The relations in \bullet Table 3 hold, where at the intersection of the row marked with FL_1 with the column marked with FL_2 there appear either the family $EH_1(FL_1, FL_2)$, or two families FL_3, FL_4 such that $FL_3 \subset EH_1(FL_1, FL_2) \subseteq FL_4$. These families FL_3, FL_4 are the best possible estimations among the six families considered here.*

It is worth noting that the only family that is not equal to a family in the Chomsky hierarchy is $EH_1(LIN, FIN)$.

Two of the relations summarized in \bullet Table 3 are central for the DNA computing based on splicing, $EH_1(FIN, FIN) = REG$ and $EH_1(FIN, REG) = RE$.

Therefore, using a finite extended H system, that is, a system with a finite set of axioms and a finite set of splicing rules, we only obtain the computing power of finite automata.

Table 3

The generative power of extended H systems

	<i>FIN</i>	<i>REG</i>	<i>LIN</i>	<i>CF</i>	<i>CS</i>	<i>RE</i>
<i>FIN</i>	<i>REG</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>
<i>REG</i>	<i>REG</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>
<i>LIN</i>	<i>LIN, CF</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>
<i>CF</i>	<i>CF</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>
<i>CS</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>
<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>	<i>RE</i>

However, working with a regular set of rules that is not finite is not of much interest from a practical point of view since we cannot physically realize an infinite “computer” (in this case, an infinite number of restriction enzymes).

3.4 Universal H Systems

The results in [Table 3](#) hold also for 2-splicing – which is important from a “practical” point of view, as in a test tube both results of a splicing operation are equally possible. From a “practical” point of view, the difficulty suggested by the equalities $EH_2(FIN, FIN) = REG$, $EH_2(FIN, REG) = RE$ can also be avoided, and the idea is to use a finite set of rules, but not to apply them freely, as in a usual extended H system, but impose some control on the strings that can be handled by a specific rule. In this way, characterizations of the computing power of Turing machines are obtained by means of finite H systems. The proofs are constructive, in most cases based on the rotate-and-simulate technique from the proof of Basic Universality Lemma, hence, starting from a universal type-0 grammar, we get a universal H system (a system that simulates any particular H system after introducing a coding of this particular system in the axioms of the universal one). That is why *universality results* are spoken about even when explicitly dealing with results which, mathematically speaking, provide characterizations of Turing computability (of RE languages).

There are many controls that can be imposed to a finite extended H system in order to increase its computing power from the power of finite automata to the power of Turing machines. (This shows that the splicing operation needs very little additional power – more technically: context-sensitivity – in order to reach the power of Turing machines.)

Several of these controls are mentioned here without entering into technical details: (1) permitting contexts (each rule has associated to it some symbols and the rule can be applied to splice two strings only if these strings contain the respective symbols), (2) forbidding contexts (as above, but the associated symbols should not be present in the spliced strings), (3) target languages, with two possibilities, local targets and a global target (in the first case, a language is associated with each rule and the results of a splicing operation must be a string in the language associated with the used rule; in the global case, the target languages associated with different rules are identical), (4) programmed H systems (a next rule mapping is considered, which controls the sequence of rules used), (5) double splicing (similar to the previous restriction, but only couples of consecutive rules are specified; the strings resulting after applying the first rule in a couple are spliced by the second rule), (6) using multisets (counting the copies of strings present in any step of the computation). Also considered were other computing devices based on splicing, using suggestions from the regulated rewriting area (Dassow and Păun 1989), from grammar systems area (Csuhaj-Varju et al. 1994), or from membrane computing (Păun et al. 2009) (the handbook (Păun et al. 2009) contains a comprehensive chapter devoted to membrane systems using string objects processed by splicing). Details and source references for all these ways to get universality by means of controlled finite H systems can be found in Păun et al. (1998).

Therefore, universal computing devices based on the splicing operation can be constructed – at the theoretical level. Implementing such “computers” is, of course, another story. From the computing theory point of view, important insights have been obtained; the universality itself, in any of the cases mentioned above, shows that the computability can be

“reconstructed” on the basis of an operation, splicing, which is much different from the usual operation of rewriting (replacing a short substring of a longer string) that is used in most, if not all, classic computing models: Turing machines, Chomsky grammars, Thue and Post systems, and Markov algorithms. This is significant, for instance, in view of the question “what does it mean to compute in a natural way?”: at the level of DNA, nature mainly “computes” by means of splicing. (In the next section, it will also be seen that the insertion–deletion operation can lead to universality, but such operations are not so far from rewriting.)

3.5 Further Developments

There are many other directions of research and many results related to the splicing operation. One idea is to have variations of the basic operations, starting with those considered in Head (1987) and Pixton (2000) and continuing with many others, either closer to the biological reality or motivated mathematically. A well-investigated class of H systems is that of simple H systems, whose rules are of the form $r_a = a\$a\#$ or $r'_a = \#a\$a$, where a is a symbol. Then, we can consider multiple splicing (crossover) taking place in each step, or we can pass to circular strings; this latter case is both well motivated and interesting and still raises a series of problems that were not solved. Indeed, as we mentioned above, there are open problems also related to the relationship between regular languages and languages in $H_1(FIN, FIN)$ (characterization, decidability, etc.). The splicing was also considered for other data structures than strings, such as trees, arbitrary graphs, arrays of various forms, and even for multisets of symbols.

Furthermore, the architecture of the computing device based on splicing can be of different forms, not only H systems, which directly correspond to formal grammars. Grammar systems and membrane systems (P systems) based on splicing are mentioned above; for instance, test-tube systems, time-varying H systems, two-level systems, and more recently, networks of language processors using splicing were also considered.

On the other hand, many other problems than the computing power were investigated. Descriptive complexity was considered from the very beginning: number of axioms and of rules, length of axioms and size of rules (the maximal length of the strings u_1, u_2, u_3, u_4 in splicing rules, or the vector of lengths of the four strings). Recently, also complexity classes based on H systems were introduced. Universality was proved since the very beginning, but also concrete universal H systems were produced. Splicing was related to Schützenberger recombination of strings by means of *constants* and to other combinatorics on word notions.

Of course, splicing was tested also in laboratory, but this is beyond the scope of this chapter.

For all these topics and for further ones the reader can find information in various titles listed in the bibliography.

4 Computing by Insertion–Deletion

As in the case of splicing, details are not recalled about the way insertion and deletion operations are realized in terms of DNA biochemistry, but a formal language presentation is followed, directly introducing the basic notions related to this approach and then recalling some of the results known in this area. As above, only a sample proof will be sketched.

4.1 Insertion and Deletion Operations

An *ins-del system* is a construct $\gamma = (V, T, A, I, D)$, where V is an alphabet, $T \subseteq V$ (terminal symbols), A is a finite language over V (axioms), and I, D are finite sets of triples of the form (u, α, v) , where u, v, α are strings over V ; the triples in I are called insertion rules, those in D are called deletion rules, and they are used as follows.

For $x, y \in V^*$ we define

$$\begin{aligned} x \Rightarrow_{ins} y &\text{ iff } x = x_1 u v x_2, y = x_1 u w v x_2 \text{ for some } (u, w, v) \in I, x_1, x_2 \in V^* \\ x \Rightarrow_{del} y &\text{ iff } x = x_1 u w v x_2, y = x_1 u v x_2 \text{ for some } (u, w, v) \in D, x_1, x_2 \in V^* \end{aligned}$$

The reflexive and transitive closure of \Rightarrow_α , $\alpha \in \{\text{ins}, \text{del}\}$ is denoted by \Rightarrow_α^* . When this is clear from the context, the subscript *ins* or *del* is omitted.

For a system γ as above we define the language

$$L(\gamma) = \{w \in T^* \mid z \Rightarrow^* w, \quad z \in A\}$$

Thus, we start from an axiom of γ , proceed through a finite number of insertion and deletion operations, and we select the strings consisting of terminal symbols – very similar to the way the language generated by a grammar is defined. Actually, there are papers where an ins-del system has the rules presented in a rewriting style: $(u, \lambda/\alpha, v)$ or even $uv \rightarrow u\alpha v$ for insertion rules and $(u, \alpha/\lambda, v)$ or even $u\alpha v \rightarrow uv$ for deletion rules.

The complexity of an ins-del system is evaluated in terms of the complexity of its rules, that is, the length of strings used as contexts and the length of inserted or deleted strings. More precisely, an ins-del system $\gamma = (V, T, A, I, D)$ is of weight $(n, m; p, q)$ if

$$\begin{aligned} n &= \max\{|\alpha| \mid (u, \alpha, v) \in I\} \\ m &= \max\{|u| \mid (u, \alpha, v) \in I \text{ or } (v, \alpha, u) \in I\} \\ p &= \max\{|\alpha| \mid (u, \alpha, v) \in D\} \\ q &= \max\{|u| \mid (u, \alpha, v) \in D \text{ or } (v, \alpha, u) \in D\} \end{aligned}$$

We denote by $INS_n^m DEL_p^q$, for $n, m, p, q \geq 0$, the family of languages $L(\gamma)$ generated by ins-del systems of weight $(n', m'; p', q')$ such that $n' \leq n$, $m' \leq m$, $p' \leq p$, $q' \leq q$. When one of the parameters n, m, p, q is not bounded, we replace it by $*$. Thus, the family of all ins-del languages is $INS^* DEL^*$. Because the insertion-deletion of the empty string changes nothing, when $n = 0$ we also suppose that $m = 0$, and when $p = 0$ we also suppose that $q = 0$. The meaning of INS_0^0 is that no insertion rule is used, and the meaning of DEL_0^0 is that no deletion rule is used. When $m = 0$ or $q = 0$, we have a context-free insertion or deletion, respectively; if both these parameters are zero, then we get a context-free ins-del system.

This section will be concluded with a few simple examples.

The ins-del system

$$\gamma = (\{a, b\}, \{a, b\}, \{ab\}, \{(a, ab, b)\}, \emptyset)$$

clearly generates the (linear nonregular) language $L(\gamma) = \{a^n b^n \mid n \geq 1\}$. If the set of insertion rules is replaced with $I = \{(\lambda, ab, \lambda)\}$, then the generated language is the Dyck language over the alphabet $\{a, b\}$, excepting the empty string.

As a more complex ins-del system, the following one from Margenstern et al. (2005) can be recalled:

$$\gamma = (\{S, S', a, b\}, \{a, b\}, \{S\}, \{(\lambda, S' a S b, \lambda), (\lambda, S' a b, \lambda), ((\lambda, S S', \lambda)\})$$

Because of the selection of terminal strings, symbols S, S' should not be present in the strings that form the language $L(\gamma)$; such symbols can be removed only by the deletion rule (λ, SS', λ) , which means that always S' is introduced in the right hand of a symbol S . Initially, S is alone; assume that we have a string w_1Sw_2 (initially, $w_1 = w_2 = \lambda$). We have to use the insertion rule $(\lambda, S'aSb, \lambda)$ such that we get $w_1SS'aSbw_2$, otherwise SS' cannot be removed. In this way, we pass to the string w_1aSbw_2 . This process can be repeated. When using the insertion rule $(\lambda, S'ab, \lambda)$, the obtained string, $w_1SS'abw_2$, can be turned to a terminal one. Consequently, we get $L(\gamma) = \{a^n b^n \mid n \geq 1\}$.

4.2 The Power of Ins-Del Systems

Continuing the previous examples, we recall now a counterpart of [Lemma 5](#) for ins-del systems.

Lemma 6 $REG \subset INS^*_\ast DEL_0^0$.

Proof Let L be a regular language and let $M = (K, V, q_0, F, \delta)$ be the minimal deterministic finite automaton recognizing L .

For each $w \in V^*$, we define the mapping $\rho_w : K \rightarrow K$ by

$$\rho_w(q) = q' \text{ iff } (q, w) \vdash^*(q', \lambda), \quad q, q' \in K$$

Obviously, if $x_1, x_2 \in V^*$ are such that $\rho_{x_1} = \rho_{x_2}$, then for every $u, v \in V^*$, ux_1v is in L if and only if ux_2v is in L .

The set of mappings from K to K is finite. Hence the set of mappings ρ_w as above is finite. Let n_0 be their number. We construct the ins-del system $\gamma = (V, V, A, I, \emptyset)$ with

$$A = \{w \in L \mid |w| \leq n_0 - 1\}$$

$$I = \{(w, v, \lambda) \mid |w| \leq n_0 - 1, 1 \leq |v| \leq n_0, |wv| \leq n_0, \text{ and } \rho_w = \rho_{wv}\}$$

From the definition of mappings ρ_w and the definitions of A, I , it follows immediately that $L(\gamma) \subseteq L$.

Assume that the converse inclusion is not true and let $x \in L - L(\gamma)$ be a string of minimal length with this property. Thus $x \notin A$. Hence $|x| \geq n_0$. Let $x = zz'$ with $|z| = n_0$ and $z' \in V^*$. If $z = a_1a_2 \dots a_{n_0}$, then it has $n_0 + 1$ prefixes, namely, $\lambda, a_1, a_1a_2, \dots, a_1 \dots a_{n_0}$. There are only n_0 different mappings ρ_w . Therefore there are two prefixes u_1, u_2 of z such that $u_1 \neq u_2$ and $\rho_{u_1} = \rho_{u_2}$. With no loss in generality it may be assumed that $|u_1| < |u_2|$. By substituting u_2 by u_1 we obtain a string x' that is also in L . As $|x'| < |x|$ and x was of minimal length in $L - L(\gamma)$, we obtain $x' \in L(\gamma)$. However, $|u_2| - |u_1| \leq |u_2| \leq n_0$, so if $u_2 = u_1u_3$, then (u_1, u_3, λ) is an insertion rule in I . This implies that $x' \Rightarrow_{ins} x$, that is, $x \in L(\gamma)$, a contradiction. In conclusion, $L \subseteq L(\gamma)$.

The strictness of the inclusion is obvious (see, for instance, the first example considered in the end of the previous section).

We recall now a few non-universality results, that is, pointing out classes of ins-del systems, which generate families of languages strictly included in RE (references are omitted for those results that also appear in Păun et al. (1998); the proofs are in general based on simulating type-0 grammars in Kuroda normal form or in Geffert normal form).

Theorem 4 *The following relations hold:*

1. $\text{INS}_*^*\text{DEL}_0^0 \subset \text{CS}$ and $\text{LIN} - \text{INS}_*^*\text{DEL}_0^0 \neq \emptyset$, but $\text{INS}_2^2\text{DEL}_0^0$ contains non-semilinear languages.
2. $\text{INS}_*^1\text{DEL}_0^0 \subset \text{CF}$.
3. $\text{INS}_*^0\text{DEL}_1^0 \subset \text{CF}$, $\text{INS}_2^0\text{DEL}_2^0 \subset \text{CF}$, $\text{INS}_1^0\text{DEL}_*^0 \subset \text{REG}$ (Verlan 2007).
4. $\text{REG} \subset \text{INS}_*^*\text{DEL}_0^0$ and each regular language is the coding of a language in the family $\text{INS}_*^1\text{DEL}_0^0$.

There are however a lot of universality results in this area (characterizations of RE languages). Some of them are recalled here.

Theorem 5 *We have $\text{INS}_n^m\text{DEL}_p^q = \text{RE}$ for all the following quadruples (n,m,p,q) (for each of these quadruples we also mention the place where a proof can be found, omitting again the cases whose proof can be found in Păun et al. (1998)): (i) $(1,2;1,1)$, (ii) $(1,2;2,0)$, (iii) $(2,1;2,0)$, (iv) $(1,1;1,2)$ – Tanaka and Yokomori (2003), (v) $(2,1;1,1)$ – Tanaka and Yokomori (2003), (vi) $(2,0;3,0)$ – Margenstern et al. (2005), (vii) $(3,0;2,0)$ – Margenstern et al. (2005), (viii) $(1,1;2,0)$, (ix) $(1,1;1,1)$ – Tanaka and Yokomori (2003).*

There are also a series of characterizations of RE languages by means of operations with languages starting from languages generated by ins-del systems. Only one of them is recalled here, together with some details of its proof, namely, the central result from Păun et al. (2008), which gives a Chomsky–Schützenberger-like characterization for RE languages (note that only insertion rules are used).

Theorem 6 *Each language $L \in \text{RE}$ can be represented in the form $L = h(L' \cap D)$, where $L' \in \text{INS}_3^0\text{DEL}_0^0$, h is a projection, and D is a Dyck language.*

Proof (Sketch) Consider a language $L \subseteq T^*$, generated by a type-0 grammar $G = (N, T, S, P)$ in Kuroda normal form. Assume that the rules of P are labeled in a one-to-one manner with elements of a set $\text{Lab}(P)$.

We construct an ins-del system $\gamma = (V \cup \overline{V}, V \cup \overline{V}, \{S\}, I, \emptyset)$, of weight $(3, 0; 0, 0)$, with

$$V = N \cup T \cup \text{Lab}(P)$$

and with I containing the following insertion rules.

- Group 1: For each rule $r : AB \rightarrow CD$ of type 1 in P we construct the following two insertion rules: (λ, CDr, λ) and $(\lambda, \overline{B}\overline{A}\overline{r}, \lambda)$
- Group 2: For each rule $r : A \rightarrow BC$ of type 2 in P we construct the following two insertion rules: (λ, BCr, λ) and $(\lambda, \overline{A}\overline{r}, \lambda)$
- Group 3: For each rule $r : A \rightarrow a$ of type 3 in P we construct the following two insertion rules: $(\lambda, a\overline{a}r, \lambda)$ and $(\lambda, \overline{A}\overline{r}, \lambda)$, where $\overline{\lambda} = \lambda$

For a rule $r : u \rightarrow v$ in P we say that two rules (λ, vr, λ) and $(\lambda, \overline{u}^R\overline{r}, \lambda)$ in P' are r -complementary, and denote their labels by r_+ and r_- , respectively, (x^R is the reversal of the string x).

We define the projection $h : (V \cup \overline{V})^* \rightarrow T^*$ by $h(a) = a$ for all $a \in T$, and $h(a) = \lambda$ otherwise. Let D be the Dyck language over V , taking as pairs (a, \overline{a}) for $a \in V$.

We have $L(G) = h(L(\gamma) \cap D)$. To begin with some useful notions are introduced.

For any rule $r : u \rightarrow v \in P$, let $U_r(u) = ru\overline{u}^R\overline{r}$; we call this an r -block. Then, this notion is extended to define *U-structures* as follows:

1. An r -block $U_r(u)$ is a U-structure.
2. If U_1 and U_2 are U-structures, then $U_1 U_2$ is a U-structure.
3. Let α_i , $i = 1, 2, 3$, be U-structures or empty, with at least one α_i being non-empty; consider a string of the form $r\alpha_1 u_1 \alpha_2 u_2 \alpha_3 \overline{u}^R \overline{r}$, where $u = u_1 u_2$ is such that $r : u \rightarrow v \in P$. Then, this string, denoted by $U_r(\alpha_1 u_1 \alpha_2 u_2 \alpha_3)$, is a U-structure.
4. Nothing else is a U-structure.

Let us now define a mapping ϕ over $(V \cup \overline{V})^*$ as follows: For any $a \in V - T$, let $a\overline{a} \sim \lambda$, and for any $a \in T$, let $a\overline{a} \sim a$. Then, one can consider a reduction operation over $(V \cup \overline{V})^*$ by iteratively using the binary relation \sim . We define $\phi(w)$ as the string finally obtained as the *irreducible* string in terms of this reduction operation. (Because the symbols from T and from $V - T$ are subject of different “reduction rules,” the irreducible string reached when starting from a given string is unique, hence the mapping ϕ is correctly defined.)

The following lemma holds:

Lemma 7 *Let $S \Rightarrow^{n-1} z_{n-1} (= \alpha u \beta) \Rightarrow z_n (= \alpha v \beta)$ in G , where $r : u \rightarrow v$ is used in the last step. Then, there exists a derivation of γ such that $S \Rightarrow^{2n} \tilde{z}_n$ and $\phi(\tilde{z}_n) = z_n$.*

The following observations are useful for the proof of the inclusion $h(L(\gamma) \cap D) \subseteq L(G)$.

Observation 1 For a rule $r : u \rightarrow v$ in P , let $r_+ : (\lambda, vr, \lambda)$ and $r_- : (\lambda, \overline{u}^R\overline{r}, \lambda)$ be the two r -complementary rules.

1. Any successful derivation of γ requires the use of both r -complementary rules r_+ and r_- .
2. Let \tilde{z} be any sentential form in a derivation of γ that eventually leads to a string in D (we say that such a derivation is successful). Then, it must hold that for any prefix α of \tilde{z} , $\#_{vr}(\alpha) \geq \#_{\overline{u}^R\overline{r}}(\alpha)$, where $\#_x(\alpha)$ denotes the number of occurrences of a string x in α .
3. Applying insertion rules within a U-structure leads to only invalid strings. Indeed, suppose that r_+ and r_- are applied on some occurrence of u appearing in a U-structure $U_r(\delta_1 u \delta_2) = r'\delta_1 u \delta_2 \overline{u}^R \overline{r}'$, where $r' : u \rightarrow v'$. This derives a string $r'\delta_1 v U_r(u) \delta_2 \overline{u}^R \overline{r}'$ that leads to an invalid string (i.e., *not* in D) unless $u = v$. This also occurs in the case where u appears in separate locations in the U-structure.
4. A location in \tilde{z} is called *valid* for two r -complementary rules if it is either immediately before u_1 for r_+ or immediately after u_2 for r_- , by ignoring U-structures in \tilde{z} , where $u = u_1 u_2$. Then, applying insertion rules at valid locations only leads to valid strings. This is seen as follows: From 1, 2, 3 above, the locations for r_+ and r_- to be used are restricted to somewhere in the left and right, respectively, of u . In order to derive a valid string from \tilde{z} , it is necessary to apply r_+ and r_- to u so that these two rules together with u may eventually lead to forming a U-structure.

Now, the following result holds:

Lemma 8 Let $S \Rightarrow^{2n} \tilde{z}$ in γ and $\phi(\tilde{z}) = z (\in (N \cup T)^*)$. Then, one has $S \Rightarrow^n z$ in G .

The proof of the theorem can be completed now.

For any $w \in L(G)$, consider a derivation $S \Rightarrow^* w$. Then, by [Lemma 7](#) there exists a derivation $S \Rightarrow^* \tilde{w}$ in γ such that $\phi(\tilde{w}) = w$. Since ϕ deletes only U-structures and elements of \overline{T} , this implies that $\tilde{w} \in D$ and $h(\tilde{w}) = w \in T^*$. Thus, $w \in h(L(\gamma) \cap D)$. Hence, we have $L(G) \subseteq h(L(\gamma) \cap D)$.

Conversely, suppose that $S \Rightarrow^*$ in γ and $\phi(\tilde{w}) = w (\in T^*)$. Then, by [Lemma 8](#) we have $S \Rightarrow^* w$ in G . Again, $\phi(\tilde{w}) \in T^*$ implies that $\tilde{w} \in D$ and $h(\tilde{w}) = w$. Thus, we have $h(L(\gamma) \cap D) \subseteq L(G)$.

4.3 Further Remarks

As in the case of computing by splicing, there also are several other developments – and a series of open problems – in the case of computing by insertion–deletion, starting with the linguistically motivated models and results (for instance, related to Marcus contextual grammars), and ending with insertion–deletion operations for data structures other than strings. The bibliography below provides several titles that might be useful to the interested reader.

5 Concluding Remarks

Computing by splicing and by insertion–deletion provides convincing evidence that computer science – more specifically computability theory – has much to learn from the biochemistry of DNA. Whether or not this will prove to be useful to practical computer science is still a matter for further research, but from a theoretical point of view, we stand to gain much insight into computability from reasoning in this framework; in particular, it enables everyone to ask the question: “what does it mean to compute in a *natural way*?“

Abstract

Emerging technologies that enable the engineering of nano- or cell-scale systems using biological and/or artificially synthesized molecules as computing and communication devices have been receiving increased attention. This chapter focuses on “bacterial computing,” which attempts to create an autonomous cell-based Turing machine, and “molecular communication,” which attempts to create non-electromagnetic-wave-based communication paradigms by using molecules as an information medium. ➤ [Section 2](#) introduces seminal works for constructing *in vivo* logic circuits, and focuses on research into implementing *in vitro* and *in vivo* finite automata in the framework of DNA-based computing. Furthermore, the first experimental development of a programmable *in vivo* computer that executes a finite-state automaton in bacteria is highlighted. ➤ [Section 3](#) reports on the system design, experimental results, and research trends of molecular communication components (senders, molecular communication interfaces, molecular propagation systems, and receivers) that use bacteria, lipids, proteins, and DNA as communication devices.

1 Introduction

1.1 Brief Introduction to Bacterial Computing

Biological molecules such as DNA, RNA, and proteins are natural devices that store information, activate (chemical) functions, and communicate between systems (such as cells). Research in DNA computing aims to utilize these biological devices to make a computer. One of the ultimate goals is to make an autonomous cell-based Turing machine for genetic and life engineering.

Finite-state automata (machines) is the most basic computational model in the Chomsky hierarchy and is the starting point for building universal DNA computers. Many works have proposed theoretical models of DNA-based computer to develop finite-state automata (Păun et al. 1998), and several experimental research works have attempted to implement finite automata *in vitro* and *in vivo*. For example, Benenson et al. (2001, 2003) successfully implemented the two-state finite automata *in vitro* by sophisticated use of the restriction enzyme (actually, *FokI*), which is cut outside of its recognition site in a double-stranded DNA. However, their method has some limitations for extending to more than two states. Yokomori et al. (2002) proposed a theoretical framework using a length-encoding technique to implement finite automata on DNA molecules. Theoretically, the length-encoding technique has no limitations to implement finite automata of any larger states. Based on the length-encoding technique, Sakakibara and his group (Kuramochi and Sakakibara 2005) attempted to implement and execute finite automata of a larger number of states *in vitro*, and carried out intensive laboratory experiments on various finite automata from two states to six states for several input strings.

On the other hand, Sakakibara and his group (Nakagawa et al. 2005) proposed a method using a protein-synthesis mechanism combined with four-base codon techniques to simulate a computation (accepting) process of finite automata *in vivo* (a codon is normally a triplet of bases, and different base triplets encode different amino acids in protein). The proposed method is quite promising, has several advanced features such as the protein-synthesis process,

is very accurate, overcomes the mis-hybridization problem in the self-assembly computation, and further offers an autonomous computation.

Attempts to implement a finite number of states *in vivo* have also been actively studied in the area of synthetic biology. One of the most significant goals of synthetic biology is the rewiring of genetic regulatory networks to realize controllable systems in a cell. Recently, this technology has been applied to the development of biomolecular computations *in vivo*. Weiss et al. (2003, 2004) explored *in vivo* technology to develop genetic circuits and perform logical computations in cells. They developed cellular units that implement the logical functions NOT, IMPLIES, and AND. These units are combined into genetic circuits for cellular logical computation.

The first half of this chapter overviews seminal works of Weiss et al. (2003, 2004) on the construction of *in vivo* logic circuits, and research by Sakakibara and his group (Kuramochi and Sakakibara 2005; Nakagawa et al. 2005) on implementing finite automata *in vitro* and *in vivo* in the framework of DNA-based computing.

First, the length-encoding technique proposed in Yokomori et al. (2002) and Sakakibara and Hohsaka (2003) is introduced to implement finite automata in test tubes. In the length-encoding method, the states and state transition functions of a target finite automaton are effectively encoded into DNA sequences, a computation (accepting) process of finite automata is accomplished by self-assembly of encoded complementary DNA strands, and the acceptance of an input string is determined by the detection of a completely hybridized double-strand DNA. Second, intensive *in vitro* experiments are shown in which several finite-state automata have been implemented and executed in test tubes. Practical laboratory protocols that combine several *in vitro* operations such as annealing, ligation, PCR, and streptavidin–biotin bonding are designed and developed to execute *in vitro* finite automata based on the length-encoding technique. Laboratory experiments are carried out on various finite automata from two states to six states for several input strings. Third, a novel framework to develop a programmable and autonomous *in vivo* computer using *Escherichia coli* (*E. coli*) is presented, and *in vivo* finite-state automata are implemented based on the framework by employing the protein-synthesis mechanism of *E. coli*. The fundamental idea to develop a programmable and autonomous finite-state automata in *E. coli* is that first an input string is encoded into one plasmid, state-transition functions are encoded into the other plasmid, and those two plasmids are introduced into an *E. coli* cell by electroporation. Fourth, a protein-synthesis process in *E. coli* combined with four-base codon techniques is executed to simulate a computation (accepting) process of finite automata, as proposed for *in vitro* translation-based computations in Sakakibara and Hohsaka (2003). This approach enables one to develop a programmable *in vivo* computer by simply replacing a plasmid encoding a state-transition function with others. Furthermore, the *in vivo* finite automata are autonomous because the protein-synthesis process is autonomously executed in the living *E. coli* cell.

1.2 Brief Introduction to Molecular Communication

The second half of this chapter overviews molecular communication that uses molecules (chemical substances such as proteins and deoxyribonucleic acid (DNA)) as information media and offers a new communication paradigm based on biochemical reactions caused by received molecules (Hiyama et al. 2005a, 2008b; Moritani et al. 2007a; Suda et al. 2005).

Molecular communication has received increasing attention as an interdisciplinary research area that spans the fields of nanotechnology, biotechnology, and communication engineering.

Molecular communication is inspired by the observation of specific features of biological molecular systems that living organisms have acquired through the evolutionary process over billions of years. Communication in biological systems is typically done through molecules (i.e., chemical signals). For instance, multicellular organisms including human beings perform maintenance of homeostasis, growth regulation, kinematic control, memory, and learning through intercellular and intracellular communication using signal-transducing molecules such as hormones (Alberts et al. 1997; Pollard and Earnshaw 2004). Molecular communication aims to develop artificially designed and controllable systems that could transmit biochemical information such as phenomena and the status of living organisms that cannot be feasibly carried with traditional communication using electromagnetic waves (i.e., electronic and optical signals).

In molecular communication, a sender generates molecules, encodes information into the molecules (called information molecules), and emits the information molecules to the propagation environment. A propagation system transports the emitted information molecules to a receiver. The receiver, upon receiving the transported information molecules, reacts biochemically according to the information molecules (this biochemical reaction represents decoding of the information).

Molecular communication is a new communication paradigm and is different from the traditional communication paradigm (● *Table 1*). Unlike traditional communication which utilizes electromagnetic waves as an information medium, molecular communication utilizes molecules as an information medium. In addition, unlike traditional communication in which encoded information such as voice, text, and video is decoded and regenerated at a receiver, in molecular communication information molecules activate some biochemical reactions at a receiver and recreate phenomena and/or chemical status that a sender transmits. Other features of molecular communication include aqueous environmental communication, the stochastic nature of communication, low energy-consumption communication, and high compatibility with biological systems.

● **Table 1**

Comparisons of key features between traditional communication and molecular communication

Key features	Traditional communication	Molecular communication
Information medium	Electromagnetic waves	Molecules
Signal type	Electronic and optical signals	Chemical signals
Propagation speed	Light speed (3×10^5 km/s)	Slow speed (a few $\mu\text{m}/\text{s}$)
Propagation distance	Long (ranging from m to km)	Short (ranging from nm to m)
Propagation environment	Airborne and cable medium	Aqueous medium
Encoded information	Voice, text, and video	Phenomena and chemical status
Behavior of receivers	Decoding of digital info	Biochemical reaction
Communication model	Deterministic communication	Stochastic communication
Energy consumption	High	Extremely low

Although the communication speed/distance of molecular communication is slower/shorter than that of traditional communication, molecular communication may carry information that is not feasible to carry with traditional communication (such as the biochemical status of a living organism) between entities to which traditional communication does not apply (such as biological entities). Molecular communication has unique features that are not seen in traditional communication and is not competitive but complementary to traditional communication.

Molecular communication is an emerging research area and its feasibility is being verified through biochemical experiments. Detailed system design, experimental results, and research trends in molecular communication are described in [Sect. 3](#).

2 Bacterial Computing

2.1 In Vivo Genetic Circuit

Seminal work to develop genetic circuits and perform logical computations in cells was done by Weiss et al. ([2003, 2004](#)). They developed cellular units that implement the logical functions NOT, IMPLIES, and AND. These units were combined into genetic circuits for cellular logical computation. These genetic circuits employed messenger RNA (mRNA), DNA-binding proteins, small molecules that interacted with the related proteins, and DNA motifs that regulated the transcription and expression of the proteins. They further attempted to construct a circuit component library so that genetic circuit design is the process of assembling library components into a logical circuit.

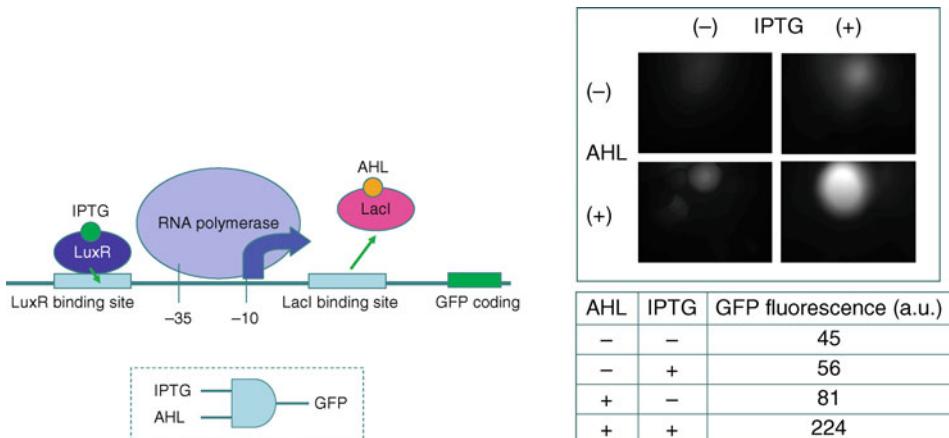

2.1.1 AND Gate

Given a library of circuit components, various genetic circuits are designed by combining and assembling a set of library components. For example, the AND logical function was implemented in cells by using RNA polymerase, activator proteins, inducer molecules, and DNA that encodes the RNA polymerase binding domain, the activator binding domain, and an output gene (Weiss et al. [2003](#)). In this genetic circuit, the input and output signals are represented by the concentrations of some mRNAs or small molecules.

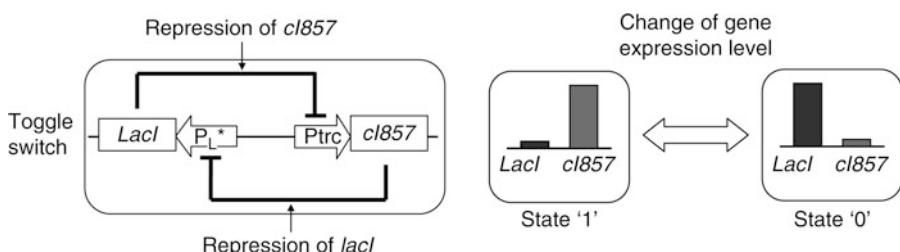

There can be several designs to implement the same logical function AND. Sakakibara et al. ([2006](#)) developed another circuit design for implementing the AND function and performed an *in vivo* experiment to run the AND circuit. As basic components, they used RNA polymerase, activator protein LuxR, repressor protein LacI, two inducer molecules, GFP protein, and DNA that encodes the RNA polymerase binding domain, the activator binding domain, the repressor binding domain, and the GFP gene. In this circuit design, the input signals are two inducers AHL and IPTG, and the output signal is GFP protein. This genetic circuit executes the AND logical function as follows. If only the IPTG inducer is present, the activator LuxR is active with IPTG, binds to the DNA promoter and activates RNA polymerase transcription, but the repressor LacI is still active, it keeps binding to the DNA promoter and hence prevents transcription. If only the AHL inducer is present, the inducer binds to the repressor LacI and changes the conformation of the repressor. The conformation change prevents the repressor from binding to the DNA promoter. However, the activator LuxR is inactive without IPTG and hence does not activate the RNA polymerase transcription. Finally, if both inducers AHL and IPTG are present, the inactive repressor LacI does not bind to the

Fig. 1

(Left) A genetic circuit design for AND function and (right) its experimental results.

**Fig. 2**

(Left) Toggle switch circuit and (right) two states using gene expression levels.

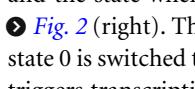

DNA promoter and the activator LuxR activates the RNA polymerase transcription, and therefore RNA polymerase transcribes the GFP gene, yielding the GFP output. The genetic circuit design is illustrated in **Fig. 1** (left) and the experimental results for executing the AND logical function are shown in **Fig. 1** (right).

2.1.2 Toggle Switch

In order to realize a finite number of states *in vivo*, Gardner et al. (2000) proposed the toggle switch mechanism. The toggle switch is composed of two repressors and two constitutive promoters (see **Fig. 2** (left)). Each promoter is inhibited by the repressor that is transcribed by the opposing promoter. The behavior of the toggle switch and the conditions for bistability to represent two states can be formalized using the following equations:

$$\frac{dV_{cl857}}{dt} = \frac{\alpha_1}{1 + V_{lacI}^\beta} - V_{cl857}$$

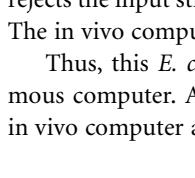

$$\frac{dV_{lacI}}{dt} = \frac{\alpha_2}{1 + V_{cl857}^\gamma} - V_{lacI}$$

where V_{cl857} is the concentration of repressor gene *cl857*, V_{lacI} is the concentration of repressor gene *lacI*, α_1 is the effective rate of synthesis of repressor *cl857*, α_2 is the effective rate of synthesis of repressor *lacI*, β is the cooperativity of repression of promoter *P_{trc}*, and γ is the cooperativity of repression of promoter *P_{L*}*. The bistability of the toggle switch depends on these parameters. The state where *cl857* is expressed and *lacI* is repressed is termed state “1” and the state where *cl857* is repressed and *lacI* is expressed is termed state “0,” as shown in  Fig. 2 (right). The state 1 is switched to state 0 by a thermal pulse of 42°C induction and the state 0 is switched to state 1 by a pulse of IPTG induction, which is a molecular compound that triggers transcription of the lac operon.

2.2 Bacterial Finite-State Machine

2.2.1 Preliminaries

The aim of bacteria-based computing is to develop a computing machine in a living system. Sakakibara and his group (Nakagawa et al. 2005) have attempted to simulate a computation process of finite automata in *Escherichia coli* (*E. coli*) by employing the *in vivo* protein-synthesis mechanism of *E. coli*. (*Escherichia coli* is a typical bacterium living inside our body, in the large intestine.) This *in vivo* computation possesses the following two novel features, not found in any previous biomolecular computer. First, an *in vivo* finite automaton is implemented in a living *E. coli* cell. Second, this automaton increases in number very rapidly according to bacterial growth; one bacterial cell can multiply to over a million cells overnight. This chapter explores the feasibility of *in vivo* computation.

The main feature of the *in vivo* computer based on *E. coli* is that first an input string is encoded into one plasmid, state-transition functions are encoded into the other plasmid, and *E. coli* cells are transformed with these two plasmids by electroporation. Second, a protein-synthesis process in *E. coli* combined with four-base codon techniques is executed to simulate a computation (accepting) process of finite automata, which has been proposed for *in vitro* translation-based computations in Sakakibara and Hohsaka (2003). The successful computations are detected by observing the expressions of a reporter gene linked to mRNA encoding input data. Therefore, when an encoded finite automaton accepts an encoded input string, the reporter gene, *lacZ*, is expressed and hence a blue color is observed. When the automaton rejects the input string, the reporter gene is not expressed and hence no blue color is observed. The *in vivo* computer system based on *E. coli* is illustrated in  Fig. 3.

Thus, this *E. coli*-based computer enables one to develop a programmable and autonomous computer. As known to the authors, this is the first experimental development of an *in vivo* computer and it has succeeded in executing a finite-state automaton using *E. coli*.

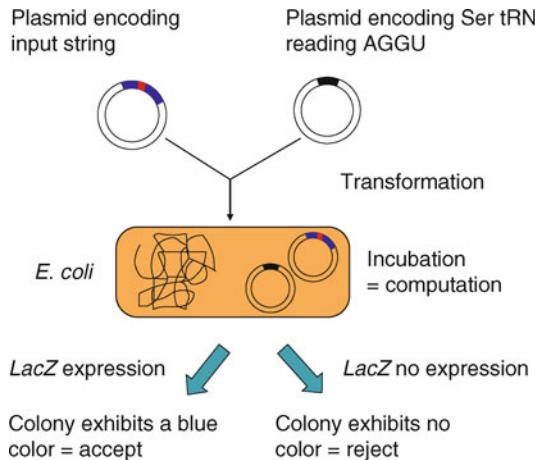

2.2.2 A Framework of a Programmable and Autonomous In Vivo Computer using *E. coli*

Length-Encoding Method to Implement Finite-State Automata

Let $M = (Q, \Sigma, \delta, q_0, F)$ be a (deterministic) finite automaton, where Q is a finite set of states numbered from 0 to k , Σ is an alphabet of input symbols, δ is a state-transition function such that $\delta : Q \times \Sigma \rightarrow Q$, q_0 is the initial state, and F is a set of final states. The length-encoding

Fig. 3

The framework of an *in vivo* computer system based on *E. coli*.

technique (Yokomori et al. 2002) is adopted to encode each state in Q by the length of DNA subsequences.

For the alphabet Σ , each symbol a in Σ is encoded into a single-strand DNA subsequence, denoted $e(a)$, of fixed length. For an input string w on Σ , $w = x_1x_2 \cdots x_m$ is encoded into the following single-strand DNA subsequence, denoted $e(w)$:

$$5' - e(x_1) \underbrace{x_1x_2 \cdots x_k}_{k \text{ times}} e(x_2) \underbrace{x_1x_2 \cdots x_k}_{k \text{ times}} \cdots e(x_m) \underbrace{x_1x_2 \cdots x_k}_{k \text{ times}} - 3'$$

where x_i is one of four nucleotides A,C,G,T, and the subsequences $x_1x_2 \cdots x_k$ are used to encode $k+1$ states of the finite automaton M . For example, when a symbol “1” is encoded into a ssDNA subsequence GCGC and a symbol “0” into GGCC, and we encode three states into TT, a string “1101” is encoded into the following ssDNA sequence:

$$5' - \overbrace{\text{GCGC}}^1 \text{TT} \overbrace{\text{GCGC}}^1 \text{TT} \overbrace{\text{GGCC}}^0 \text{TT} \overbrace{\text{GCGC}}^1 \text{TT} - 3'$$

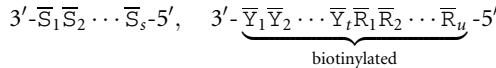

In addition, two supplementary subsequences are appended at both ends for PCR primers and probes for affinity purifications with magnetic beads that will be used in the laboratory protocol:

$$5' - \underbrace{S_1 S_2 \cdots S_s}_{\text{PCR primer}} e(x_1) x_1 x_2 \cdots x_k \cdots e(x_m) x_1 x_2 \cdots x_k \underbrace{Y_1 Y_2 \cdots Y_t}_{\text{probe}} \underbrace{R_1 R_2 \cdots R_u}_{\text{PCR primer}} - 3'$$

For a state-transition function from state q_i to state q_j with input symbol $a \in \Sigma$, the state-transition function $\delta(q_i, a) = q_j$ is encoded into the following complementary single-strand DNA subsequence:

$$3' - \overbrace{\overline{x}_{i+1} \overline{x}_{i+2} \cdots \overline{x}_k}^{k-i \text{ times}} \overbrace{\overline{e(a)}}^j \overbrace{\overline{x}_1 \overline{x}_2 \cdots \overline{x}_j}^j - 5'$$

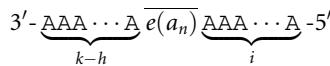

where \bar{X}_i denotes the complementary nucleotide of x_i , and \bar{y} denotes the complementary sequence of y . Further, two more complementary ssDNA sequences are added for the supplementary subsequences at both ends:

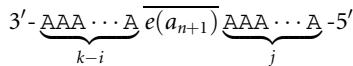

where the second ssDNA is biotinylated for streptavidin–biotin bonding.

Now, all those ssDNAs encoding an input string w and encoding state-transition functions and the supplementary subsequences of probes and PCR primers are put together into a test tube. Then, a computation (accepting) process of the finite automata M is accomplished by self-assembly among those complementary ssDNAs, and the acceptance of an input string w is determined by the detection of a completely hybridized double-strand DNA.

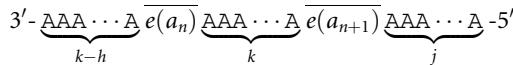

The main idea of the length-encoding technique is explained as follows. Two consecutive valid transitions $\delta(h, a_n) = i$ and $\delta(i, a_{n+1}) = j$ are implemented by concatenating two corresponding encoded ssDNAs, that is,

and

together make

Thus, the subsequence $\underbrace{\text{AAA} \cdots \text{A}}_k$ plays the role of “joint” between two consecutive state-transitions and it guarantees that the two transitions are valid in M .

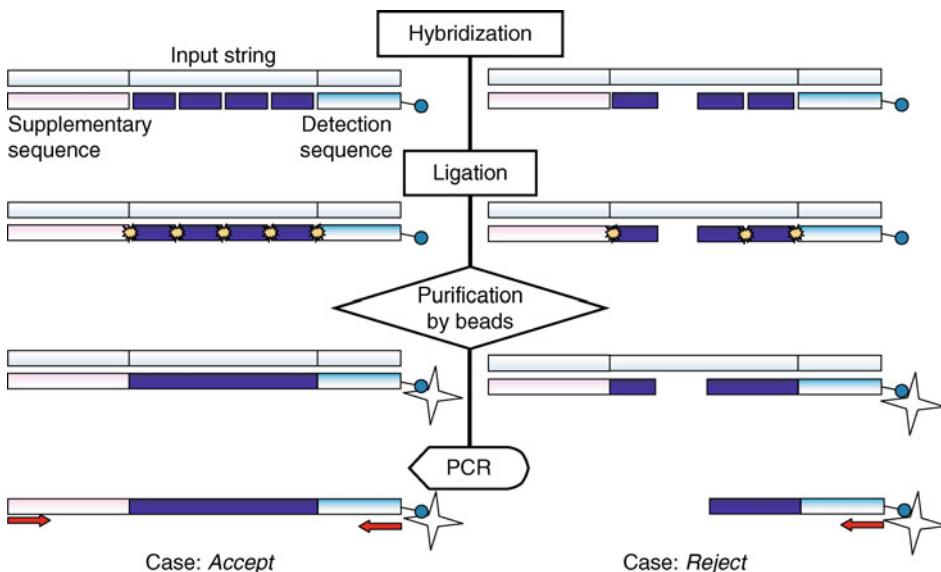

Designing Laboratory Protocols to Execute Finite Automata in Test Tubes

First, the length-encoding method was applied to in vitro experiments to see the effectiveness of the length-encoding techniques for implementing finite-state automata in vitro and in vivo. In order to practically execute the laboratory in vitro experiments for the length-encoding method, the following experimental laboratory protocol was designed, which is also illustrated in Fig. 4:

0. Encoding: Encode an input string into a long ssDNA, and state-transition functions and supplementary sequences into short pieces of complementary ssDNAs.
1. Hybridization: Put all those encoded ssDNAs together into one test tube, and anneal those complementary ssDNAs to be hybridized.
2. Ligation: Put DNA “ligase” into the test tube and invoke ligations at a temperature of 37 °C. When two ssDNAs encoding two consecutive valid state-transitions $\delta(h, a_n) = i$ and $\delta(i, a_{n+1}) = j$ are hybridized at adjacent positions on the ssDNA of the input string, these two ssDNAs are ligated and concatenated.

Fig. 4

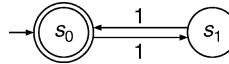

The flowchart of the laboratory protocol used to execute in vitro finite automata consists of five steps: hybridization, ligation, denature and extraction by affinity purification, amplification by PCR, and detection by gel-electrophoresis. The acceptance of the input string by the automata is the left case, and the rejection is the right case.

3. Denature and extraction by affinity purification: Denature double-stranded DNAs into ssDNAs and extract concatenated ssDNAs containing the biotinylated probe subsequence by streptavidin–biotin bonding with magnetic beads.
 4. Amplification by PCR: Amplify the extracted ssDNAs with PCR primers.
 5. Detection by gel-electrophoresis: Separate the PCR products by length using gel-electrophoresis and detect a particular band of the full-length. If the full-length band is detected, that means a completely hybridized double-strand DNA has been formed, and hence the finite automaton “accepts” the input string. Otherwise, it “rejects” the input string. In the laboratory experiments, a “capillary” electrophoresis microchip-based system, called Bioanalyser 2100 (Agilent Technologies), was used in place of conventional gel-electrophoresis. Capillary electrophoresis is of higher resolution and is more accurate than gel electrophoresis using agarose gel.
- #### Simulating Computation Process of Finite Automata Using Four-Base Codons and the Protein-Synthesis Mechanism
- Sakakibara and Hohsaka (2003) have proposed a method using the protein-synthesis mechanism combined with four-base codon techniques to simulate a computation (accepting) process of finite automata. An approach to make an *in vivo* computer is to execute the proposed method in *E. coli* in order to improve the efficiency of the method and further develop a programmable *in vivo* computer. The proposed method is described using the example of the simple finite automaton, illustrated in [Fig. 5](#), which is of two states $\{s_0, s_1\}$,

Fig. 5

A simple finite automaton of two states $\{s_0, s_1\}$, defined on one symbol “1”, and accepting input strings with even numbers of symbol 1 and rejecting input strings with odd numbers of 1s.

defined as one symbol “1”, and accepts input strings with even numbers of symbol 1 and rejects input strings with odd numbers of 1s.

The input symbol “1” is encoded into the four-base subsequence AGGU and an input string is encoded into an mRNA by concatenating AGGU and A alternately, and adding a special sequence AAUAAC that contains a stop codon at the 3'-end. This one nucleotide A in between AGGU is used to encode two states $\{s_0, s_1\}$, which is the same technique presented in Yokomori et al. (2002). The stop codon UAA is used for the decision of acceptance or rejection together with a downstream reporter gene. For example, a string “111” is encoded into an mRNA:

The four-base anticodon (3')UCCA(5') of tRNA encodes the transition rule $s_0 \xrightarrow{1} s_1$, that is a transition from state s_0 to state s_1 with input symbol 1, and the combination of two three-base anticodons (3')UUC(5') and (3')CAU(5') encodes the rule $s_1 \xrightarrow{1} s_0$. Furthermore, the encoding mRNA is linked to the *lacZ*-coding RNA subsequence as a reporter gene for the detection of successful computations. Together with these encodings and the tRNAs containing a four-base anticodon (3')UCCA(5'), if a given mRNA encodes an input string with odd numbers of symbol 1, an execution of the *in vivo* protein-synthesis system stops at the stop codon, which implies that the finite automaton does not accept the input string, and if a given mRNA encodes even numbers of 1s, the translation goes through the entire mRNA and the detection of acceptance is found by the *blue* signal of *lacZ*. Examples of accepting processes are shown in **Fig. 6** (upper): For an mRNA encoding a string “1111,” the translation successfully goes through the entire mRNA and translates the reporter gene of *lacZ* that emits the blue signal (lower). For an mRNA encoding a string “111,” the translation stops at the stop codon UAA, does not reach the *lacZ* region, and produces no blue signal.

If the competitive three-base anticodon (3')UCC(5') comes faster than the four-base anticodon (3')UCCA(5'), the incorrect translation (computation) immediately stops at the following stop codon UAA.

In order to practically execute the laboratory experiments for the *in vivo* finite automata described in this section, the details of the laboratory protocol are described in Nakagawa et al. (2005).

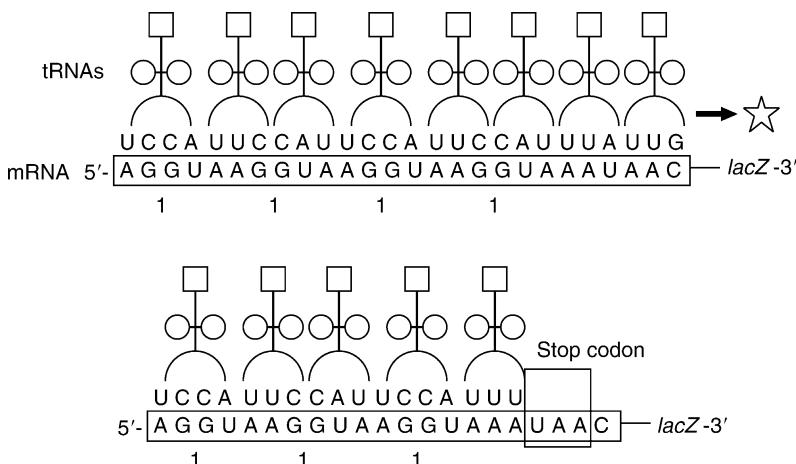

2.2.3 Programmability and Autonomy

Two important issues to consider when developing DNA-based computers are whether they are *programmable* and *autonomous*.

Programmability means that a program is stored as data (i.e., stored program computer) and any computation can be accomplished by just choosing a stored program. In DNA-based computers, it is required that a program is encoded into a molecule different from the main and

Fig. 6

Examples of accepting processes: (Upper) For an mRNA encoding a string “1111,” the translation successfully goes through the mRNA and translates the reporter gene of *lacZ* emitting the blue signal. (Lower) For an mRNA encoding a string “111,” the translation stops at the stop codon UAG, does not reach the *lacZ* region and produces no blue signal.

fixed units of the DNA computer, that molecule encoding program can be stored and changed, and that a change of the molecule encoding program accomplishes any computations.

The main features of the *in vivo* computer enable one to develop a programmable *in vivo* computer. A plasmid encoding a state-transition function can be simply replaced with another plasmid encoding a different state-transition function, and the *E. coli* cell transformed a new plasmid computes a different finite automaton.

With autonomous DNA computers, once one sets a program and input data and starts a computation, the entire computational process is carried out without any operations from the outside. The *in vivo* finite automata are autonomous in the sense that the protein-synthesis process that corresponds to a computation (accepting) process of an encoded finite automata is autonomously executed in a living *E. coli* cell and requires no laboratory operations from the outside (❸ Fig. 7).

2.3 In Vitro and In Vivo Experiments

2.3.1 In Vitro Experiments

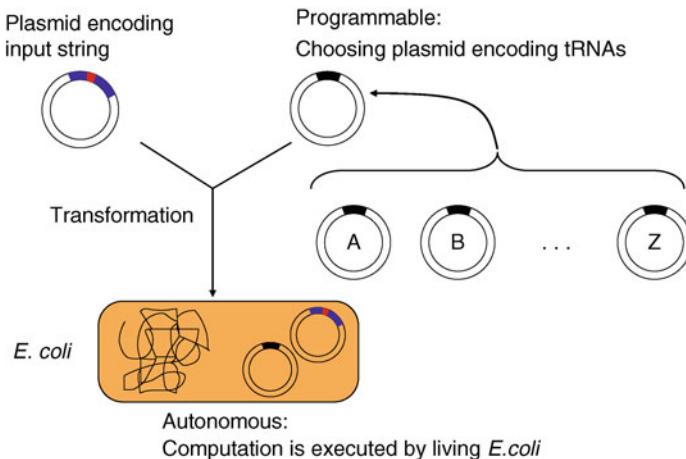

Laboratory *in vitro* experiments have been carried out on various finite automata for several input strings.

Two-States Automaton with Two Input Strings

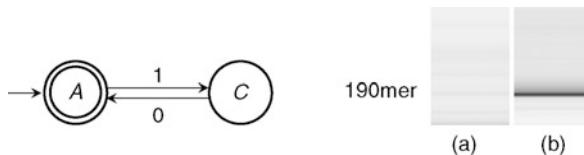

The experiments begin with a simple two-states automaton shown in ❸ Fig. 8 (left) with two input strings, (a) “1101” and (b) “1010.” The language accepted by this automaton is $(10)^+$, and hence the automaton accepts the string 1010 and rejects the other string 1101.

Fig. 7

A programmable and autonomous *in vivo* computer system based on *E. coli*.

**Fig. 8**

(Left) The simple two-states automaton used for this experiment. (Right) The results of electrophoresis are displayed in the gel-like image. Lane (a) is for the input string 1101, and lane (b) for 1010. Since the full-length band (190 mer) is detected only in lane (b), the automaton accepts only the input string (b) 1010.

The results of electrophoresis using the Bioanalyser are displayed in the form of the gel-like image (as shown in Fig. 8 (right)). For these two input strings, the full-length DNA is of 190 bps (mer). Hence, if a band at a position of 190 mer is detected in the results of the electrophoresis, that means a completely hybridized double-strand DNA is formed, and hence the finite automaton “accepts” the input string.

Figure 8 (right) clearly shows that the *in vitro* experiments have successfully identified the correct acceptance of this automaton for two input strings, and hence correctly executed the computation process of the automaton *in vitro*.

Four-States Automaton with Three Input Strings

The second experiment attempts a four-states automaton, shown in Fig. 9 (left) for the three input strings (a) 1101, (b) 1110, and (c) 1010. This four-states automaton accepts the language $(1(0 \cup 1)1)^* \cup (1(0 \cup 1)1)^*0$, and hence it accepts 1110 and 1010 and rejects 1101.

The results are shown in Fig. 9 (right) in the gel-like image. As in the first experiment, the full-length DNA is of 190 bps (mer). Bands at the position of 190 mer are detected in lane

Fig. 9

(Left) The four-states automaton used for this experiment. (Right) The results of electrophoresis are displayed in the gel-like image. Lane (a) is for the input string 1101, lane (b) for 1110, and lane (c) for 1010. Since the full-length band (190 mer) is detected in lanes (b) and (c), the automaton accepts two input strings (b) 1110 and (c) 1010.

(b) and lane (c). Hence, the in vitro experiments have successfully detected that the automaton accepts the two input strings (b) 1110 and (c) 1010.

From Two-States to Six-States Automata with One Input String “111111” of Length 6

The second experiments are five different automata from two states to six states shown in [Fig. 10](#) (upper) for one input string “111111” of length 6. The automaton (2) accepts the language $(11)^*$, that is, strings with even numbers of symbol “1”, (3) accepts the language $(111)^*$, strings repeating three times 1s, (4) accepts the language $(1111)^*$, strings repeating four times 1s, (5) accepts the language $(11111)^*$, strings repeating five times 1s, (6) accepts the language $(111111)^*$, strings repeating six times 1s. Since 6 is a multiple of 2, 3 and 6, the automata (2), (3) and (6) accept the input string 111111 of length 6.

The results are shown in [Fig. 10](#) (lower) in the gel-like image. For the input string 111111, the full-length DNA is of 240 bps (mer). Bands at position 240 mer are detected in lanes (2), (3), and (6) in [Fig. 10](#). Hence, in these in vitro experiments, the automaton (2), (3), and (6) have correctly accepted the input string 111111 and the automaton (4) and (5) have correctly rejected 111111.

2.3.2 In Vivo Experiments

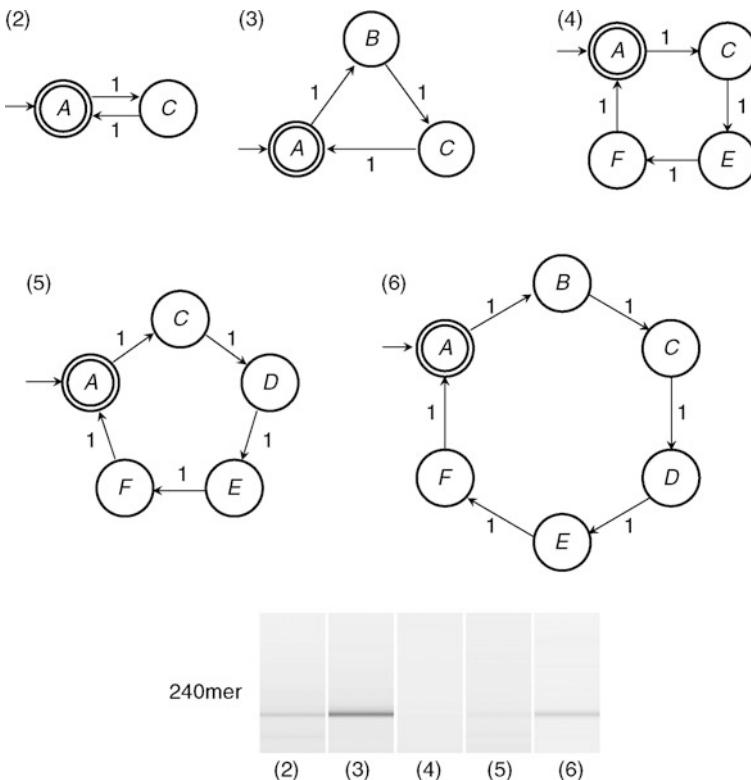

In vivo experiments that followed the laboratory protocols presented in Nakagawa et al. (2005) were done to execute the finite automaton shown in [Fig. 5](#), which is of two states $\{s_0, s_1\}$, defined on one symbol “1,” and accepts input strings with even numbers of symbol 1 and rejects input strings with odd numbers of 1s.

Six input strings, “1,” “11,” “111,” “1111,” “11111,” and “111111,” were tested to see whether the method correctly accepts the input strings “11,” “1111,” “111111,” and rejects the strings “1,” “111,” “11111.”

The results are shown in [Fig. 11](#). Blue-colored colonies that indicate the expression of *lacZ* reporter gene were observed only in the plates for the input strings 11, 1111, and 111111. Therefore, the in vivo finite automaton succeeded in correctly computing the six input strings, that is, it correctly accepted the input strings 11, 1111, 111111 of even numbers of symbol “1” and correctly rejected 1, 111, 11111 of odd number of 1s. To the best of our knowledge, this is the first experimental implementation and in vivo computer that succeeded in executing an finite-state automaton in *E. coli*.

Fig. 10

(Upper) Five different automata from two states to six states used for this experiment.
 (Lower) The results of the electrophoresis are displayed in the gel-like image. Lane (2) is for the automaton (2), (3) for (3), (4) for (4), (5) for (5), and (6) for (6). Since the full-length bands (240 mer) are detected in lanes (2), (3), and (6), the automata (2), (3), and (6) accept the input string 111111.

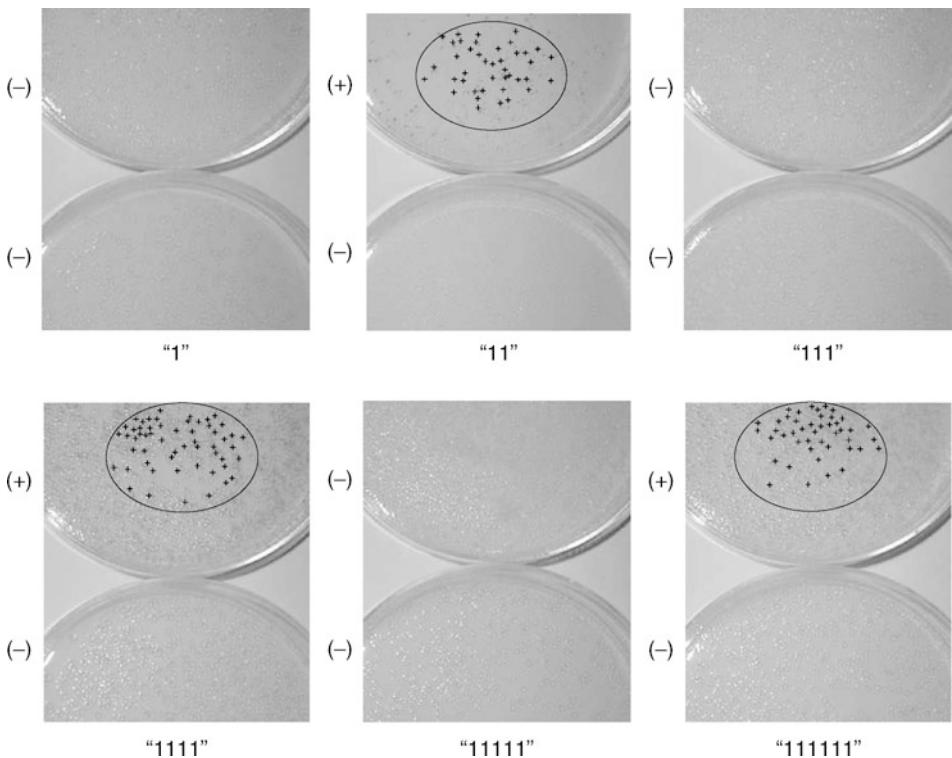

2.4 Further Topics

While a single *E. coli* bacteria cell contains approximately 10^{10} order of active molecules (Weiss et al. 2004), the previous works only utilized a small set of molecules to implement genetic circuits and finite-state automata. The main difficulty is to control such a huge number of molecules and complex wired networks for our purposes to implement bacterial computers. The idea of a “genomic computer” relating to developmental biology and evolution proposed by Istrail et al. (2007) presents some interesting direction to handle hundreds of thousands of regulatory modules that genomes contain for information processing. An animal genome contains many thousands of *cis*-regulatory control modules (called CRMs) that are wired in large networks and constitute genomic computers of information processing capability. Each CRM receives multiple inputs in the form of transcription factors that bind to CRM and execute information processing, such as AND, OR and NOT functions, for their multiple inputs. The idea is very similar to genetic circuits. The interesting features of genomic

Fig. 11

Computation by *E. coli* cells with plasmids of the input strings 1, 11, 111, 1111, 11111, 111111. In each panel, the upper plate (part of a LB plate) shows the result in the presence of the suppressor tRNA with UCCU anticodon in the cell, while the lower plate shows the result of the control experiment with no suppressor tRNA expressed. The signs (+) and (−) indicate the theoretical values about the expressions of the *lacZ* reporter gene: (+) means that the cultured *E. coli* cells must express *lacZ* theoretically, and (−) means it must not express. Circles indicate the blue-colored colonies expressing *lacZ*. Therefore, the *in vivo* finite automaton has correctly computed the six input strings, that is, it correctly accepts the input strings 11, 1111, 111111 of even numbers of symbol “1” and correctly rejects 1, 111, 11111 of odd number of 1s.

computers are: (1) multiplicity of processors and synchronicity, (2) robustness against system failure, and (3) evolvability especially relating to developmental biology.

Another recent interesting approach to utilizing genomes is the genetic memory proposed by Ham et al. (2008) that employs genome rearrangement operations to develop biological memory. They designed and synthesized an inversion switch using the DNA inversion recombination systems to create a heritable sequential memory switch.

One of the important directions of *in vivo* computation is multicellular bacterial computation. One necessary and fundamental mechanism for implementing multicellular computation is the communication between cells for sending and receiving the signals. Such intercellular communication was realized by means of the quorum-sensing mechanism,

which in nature allows the living bacteria to detect cell density. By using such a quorum sensing mechanism, Sakakibara and his group (Sakakibara et al. 2007) constructed a genetic circuit in *E.coli* that provides a one-dimensional cellular automaton. The main purpose was to extend previous works of implementing finite-state automata and develop *in vivo* computational systems higher than finite-state machine in terms of the Chomsky hierarchy. The computational capacity of the cellular automaton is equivalent to the universal Turing Machine. CA are multicellular systems in which uniform cells are allocated on a lattice grid. Each cell has a finite number of states. The state transition is determined by the current state and the states of the neighbor cells. Three mechanisms are required to implement CA in bacteria: (1) sending and receiving signals between cells, (2) sustaining the state, and (3) sensing input signals and changing the state following the state transition rules. To encode signals for mechanism (1), small molecules inducing transcription were used. For mechanism (2), the toggle switch circuit was employed to represent a finite number of states using gene expression. If one gene is expressed and the other is not, the state is 1, and, vice versa, 0. For mechanism (3), the state transition functions were implemented as logic gates using transcriptional regulatory proteins that bind to specific signal molecules (chemicals).

3 Molecular Communication

Molecular communication is a new and interdisciplinary research area; as such, it requires research into a number of key areas. Key research challenges in molecular communication include (1) design of a sender that generates molecules, encodes information onto the molecules (called information molecules), and emits the information molecules, (2) design of a molecular propagation system that transports the emitted information molecules from a sender to a receiver, (3) design of a receiver that receives the transported information molecules and biochemically reacts to the received information molecules resulting in decoding of the information, (4) design of a molecular communication interface between a sender and a molecular propagation system and also between the propagation system and a receiver to allow a generic transport of information molecules independent of their biochemical and physical characteristics, (5) mathematical modeling of molecular communication components and systems.

This section describes system design in detail, experimental results, and research trends in molecular communication.

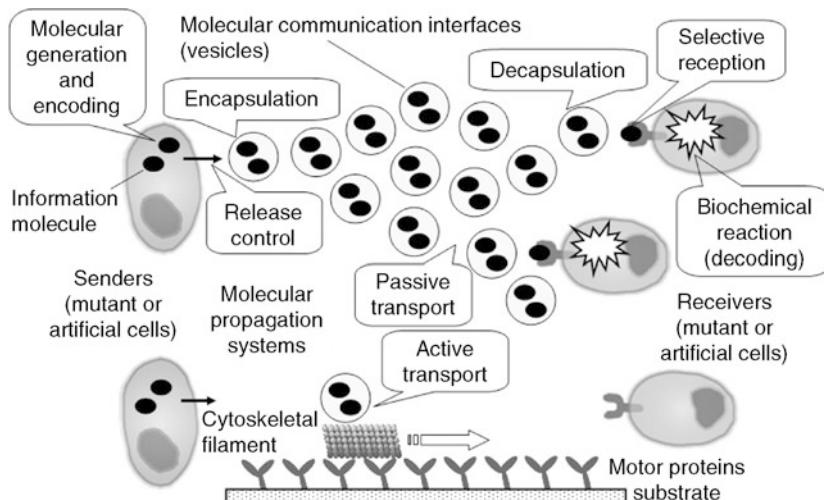

3.1 Overview of the Molecular Communication System

► *Figure 12* depicts an overview of a molecular communication system that includes senders, molecular communication interfaces, molecular propagation systems, and receivers.

A sender generates molecules, encodes information into the molecules (called information molecules), and emits the information molecules into a propagation environment. The sender may encode information into the type of the molecules used or the concentration of the molecules used. Possible approaches to creating a sender include genetically modifying eukaryotic cells and artificially constructing biological devices to control the encoding.

Fig. 12

An overview of a molecular communication system that includes senders, molecular communication interfaces, molecular propagation systems, and receivers.

A molecular communication interface acts as a molecular container that encapsulates information molecules to hide the characteristics of the information molecules during the propagation from the sender to a receiver to allow a generic transport of information molecules independent of their biochemical and physical characteristics. Using a lipid bilayer vesicle (Luisi and Walde 2000) is a promising approach to encapsulate the information molecules. Encapsulated information molecules are decapsulated at a receiver.

A molecular propagation system passively or actively transports information molecules (or vesicles that encapsulate information molecules) from a sender to an appropriate receiver through the propagation environment. The propagation environment is an aqueous solution that is typically found within and between cells. Using biological motor systems (motor proteins and cytoskeletal filaments) (Vale 2003) is a promising approach to actively and directionally transport information molecules.

A receiver selectively receives transported and decapsulated information molecules, and biochemically reacts with the received information molecules (this biochemical reaction represents decoding of the information). Possible approaches to creating a receiver are to genetically modify eukaryotic cells and to artificially construct biological devices to control the biochemical reaction.

3.2 Molecular Communication Interface

A vesicle-based communication interface provides a mechanism for transporting different types of information molecules in diverse propagation environments (Moritani et al. 2006a). The vesicle structure (i.e., a lipid bilayer membrane) compartmentalizes information molecules from the propagation environments and provides a generic architecture for transporting

diverse types of information molecules independent of their biochemical and physical characteristics. The vesicle structure also protects information molecules from denaturation (e.g., molecular deformation caused by enzymatic attacks or changes in pH) in the propagation environment. Key research issues in implementing the vesicle-based communication interface include how vesicles encapsulate information molecules at a sender and how vesicles de-encapsulate the information molecules at a receiver.

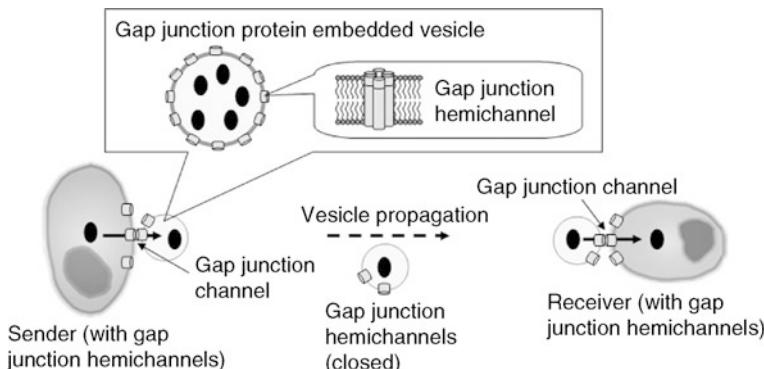

On these grounds, a molecular communication interface that uses a vesicle embedded with gap junction proteins has been proposed (Moritani et al. 2006b, 2007b). A gap junction is an intercellular communication channel formed between neighboring two cells, and it consists of two docked hemichannels (connexons) constructed from self-assembled six gap junction proteins (connexins) (Kumar and Gilula 1996). When a gap junction is open, molecules whose molecular masses are less than 1.5 kDa can directly propagate through the gap junction channel connecting two cells according to the molecular concentration gradient. A gap junction hemichannel is closed unless two hemichannels are docked.

In the molecular communication interface shown in Fig. 13 a sender stores information molecules inside itself and has gap junction hemichannels. When a vesicle with gap junction hemichannels physically contacts the sender, gap junction channels are formed between the sender and the vesicle, and the information molecules are transferred from the sender to the vesicle according to the molecular concentration gradient. When the vesicle detaches from the sender spontaneously, the gap junction hemichannels at the sender and at the vesicle close, and the information molecules transferred from the sender to the vesicle are encapsulated in the vesicle. Encapsulation of information molecules in a vesicle allows a molecular propagation system to transport the information molecules from the sender to a receiver independent of their biochemical and physical characteristics. The receiver also has gap junction hemichannels, and when the transported vesicle physically contacts the receiver, a gap junction channel is formed between the vesicle and the receiver, and the information molecules in the vesicle are transferred into the receiver according to the molecular concentration gradient.

The feasibility of the designed communication interface has been investigated by creating connexin-43 (one of the gap junction proteins) embedded vesicles (Moritani et al. 2006b). Microscopic observations confirmed that calceins (hydrophilic dyes used as model

Fig. 13

A schematic diagram of a molecular communication interface using a vesicle embedded with gap junction proteins.

information molecules) were transferred between connexin-43 embedded vesicles and the transferred calceins were encapsulated into the vesicles (Moritani et al. 2007b). This result indicates that the created connexin-43 embedded vesicle (a molecular communication interface) may encapsulate information molecules and receive/transfer information molecules from/into a sender/receiver through gap junctions.

3.3 Molecular Propagation System

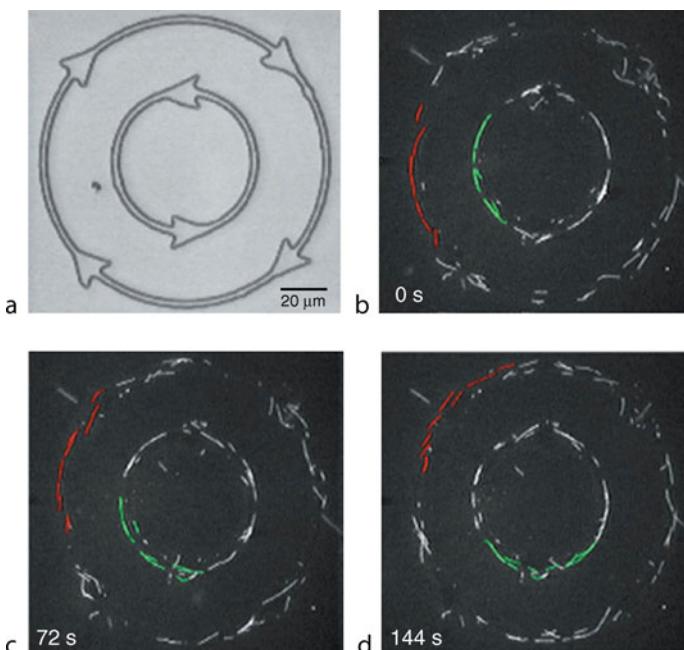

The simplest and easiest approach to transport information molecules (or vesicles that encapsulate information molecules) from a sender to a receiver is to use free diffusion. In biological systems, for instance, neurotransmitters such as acetylcholines diffuse at a synapse (around 100 nm gap between a nerve cell and a target cell), cellular slime molds such as amebas exhibit chemotaxis by detecting the molecular concentration gradient of cyclic adenosine monophosphates (cAMPs) diffused from hundreds of micrometers away, and pheromones secreted from insects can affect receiver insects even if they diffuse over a distance of several meters. Generally, the achievable rates of transmitted information molecules at a receiver are low due to Brownian motion and the dilution effect in the propagation environment; however, these observed facts indicate that diffusion-based passive molecular communication is feasible as long as the receiver sensitivity is high.

On the other hand, biological systems have a directional molecular propagation mechanism as well as nondirectional free diffusion. Motor proteins such as kinesins directionally transport cargo such as subcellular organelles and vesicles almost exactly to their destinations in spite of frequent collisions with disturbance molecules (e.g., water molecules, inorganic ions, organic small molecules, and organic macromolecules) within a biological cell. This mechanism is known as active transport and is realized by motor proteins' enzymatic actions that convert chemical energy called adenosine triphosphate (ATP) into mechanical work during their directional walk along filamentous proteins such as microtubules (MTs) (Alberts et al. 1997; Pollard and Earnshaw 2004). Motor proteins are nanometer-scaled actuators and have received increasing attention as engineering materials because they also work in an artificial environment outside of biological cells where aqueous conditions such as temperature and pH are reasonable (Goel and Vogel 2008; Van den Heuvel and Dekker 2007). For instance, as shown in Fig. 14, directional gliding of MTs was demonstrated by immobilizing kinesins onto a glass substrate etched by lithography (Hiratsuka et al. 2001). This mechanism may be applied to a molecular propagation system that uses gliding MTs as cargo transporters of information molecules. The idea is to load information molecules onto gliding MTs at a sender, to transport (glide) the information molecule-loaded MTs from a sender to a receiver, and to unload the transported information molecules from the gliding MTs at a receiver. Major issues in demonstrating this idea are how to load specified information molecules onto gliding MTs at a sender and how to unload the information molecules from the gliding MTs at a designated receiver in a reversible manner. Note that cargo transporters that utilize avidin–biotin (Bachand et al. 2004; Hess et al. 2001) or antigen–antibody (Bachand et al. 2006; Ramachandran et al. 2006) bindings for cargo loading may not be suitable for cargo unloading because of their tight bindings.

On these grounds, a molecular propagation system that uses the reverse geometry of MT motility on kinesins and also uses DNA hybridization and strand exchange has been proposed (Hiyama et al. 2005b, 2008a, c). The propagation system uses DNA hybridization and strand

Fig. 14

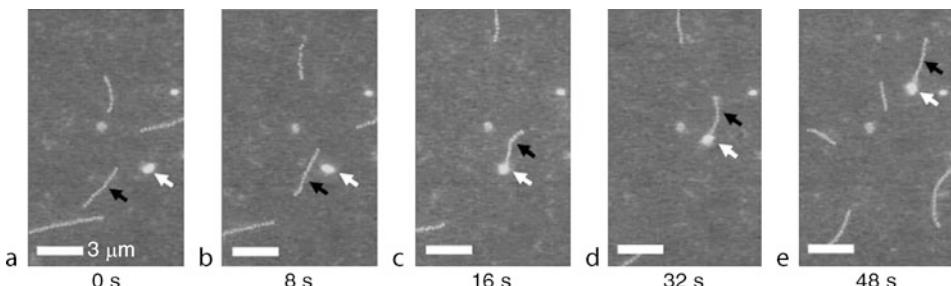

Unidirectional movement of MTs along circular tracks. (a) Transmission electron microscopy (TEM) image of the micro-patterned track equipped with arrow-shaped rectifiers. (b–d) Snapshots of the gliding MTs labeled with fluorescent dyes. MTs in the outer and inner circle are gliding clockwise and counterclockwise, respectively. MTs entering the arrowheads from the wrong direction often make 180° turns and move out in the correct direction. Each panel is reproduced with permission from Hiratsuka et al. (2001); copyright 2001, Biophysical Society.

exchange to achieve autonomous and reversible loading/unloading of specified cargos (e.g., vesicles encapsulating information molecules) at a sender/receiver and MT motility to transport the loaded cargo from a sender to a receiver. In order to use DNA hybridization and strand exchange, each gliding MT, cargo, and unloading site (receiver) is labeled with different single-stranded DNAs (ssDNAs). Note that the length of an ssDNA attached to an MT is designed to be shorter than that of the cargo, and the length of an ssDNA attached to a cargo is designed to be as long as that of the unloading site. Cargo are pooled at a given loading site (a given sender) and the ssDNA for the cargo is designed to be either complementary or noncomplementary to that of the MT. When an MT labeled with an ssDNA passes through a given loading site (● Fig. 15a–b), a cargo labeled with an ssDNA complementary to that of the MT is selectively loaded onto the gliding MT through DNA hybridization (● Fig. 15c), while cargo labeled with a noncomplementary ssDNA remain at the loading site. The cargo loaded onto the MT (i.e., an MT-cargo complex) is transported by MT motility on kinesins toward a given unloading site (● Fig. 15d–e). To achieve autonomous unloading at a given unloading site, the ssDNA attached to each unloading site is designed to be either complementary or noncomplementary to that attached to the cargo. When the MT-cargo complex passes

Fig. 15

Microscopic images of cargo loading and transport. Black and white arrows indicate an MT and a cargo, respectively. Each panel is reproduced with permission from Hiyama et al. (2008a); copyright 2008, Wiley-VCH Verlag GmbH & Co. KGaA.

through an unloading site, the cargo labeled with an ssDNA complementary to the one attached to the unloading site is selectively unloaded from the gliding MT through DNA strand exchange (Hiyama et al. 2008a, c). These results indicate that gliding MTs may load/unload cargo-vesicles at a sender/receiver through DNA hybridization and strand exchange.

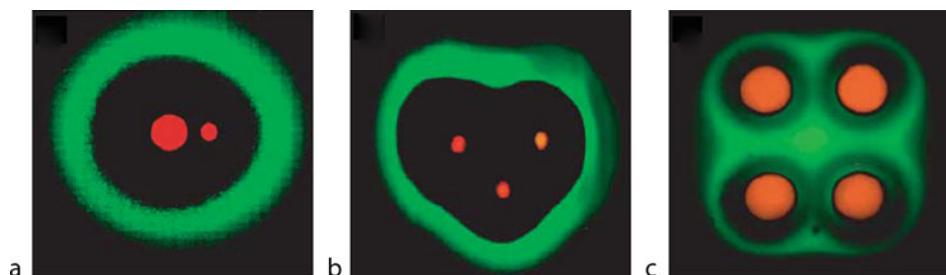

3.4 Senders and Receivers

The most straightforward approach to create senders and receivers in molecular communication is to use living biological cells. In eukaryotic cells, organelles called ribosomes synthesize some proteins that are transported to cell membranes through the vesicle transport between the endoplasmic reticulum (ER) and the Golgi apparatus. Then the transported molecules are secreted into the outside of the cell by exocytosis and diffused away (Alberts et al. 1997; Pollard and Earnshaw 2004). The diffused molecules are selectively captured by cell surface receptors. The received molecules are transduced into intracellular signals that induce cell behavior or are taken inside the cell by endocytosis, resulting in biochemical reactions such as activation of enzymes and expression of genes (Alberts et al. 1997; Pollard and Earnshaw 2004). These facts indicate that it is the fastest way to use living biological cells as senders/receivers in molecular communication, rather than creating senders/receivers artificially, because biological cells inherently have most of the required functionalities as senders/receivers in molecular communication. In that case, the issues to be solved are how to control these inherent functionalities and how to encode information onto molecules.

For instance, *Escherichia coli* (*E. coli*) bacteria produce intercellular messengers such as acyl-homoserine lactones (AHLs) and respond according to the sensed population of surrounding bacteria. It was demonstrated that genetic manipulations for these mechanisms can enable one to artificially control the fluctuation of bacterial population and bioluminescence (Basu et al. 2005; You et al. 2004). This uses a synthetic multicellular system in which genetically engineered “receiver” cells that produce fluorescent proteins were programmed to form ring-like patterns of differentiation based on chemical gradients of AHL signals that were synthesized by “sender” cells. Other patterns, such as ellipses and clovers, were achieved by

Fig. 16

Bacterial pattern formation and molecular communication. Red and green colored portions in each panel represent colonies of “sender” cells and “receiver” cells that received AHL signals sent by sender cells, respectively. Genetically engineered receiver cells formed ring-like patterns such as ellipses (a), hearts (b), and clovers (c) by placing sender cells in different configurations. Each panel is reproduced with permission from Basu et al. (2005); copyright 2005, Macmillan Publishers Ltd.

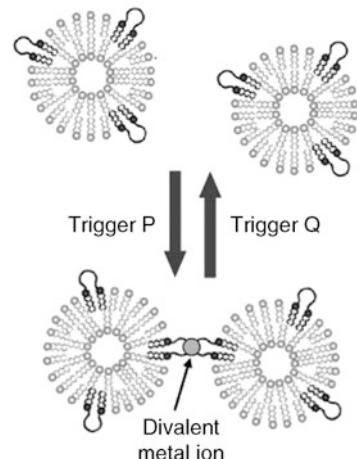

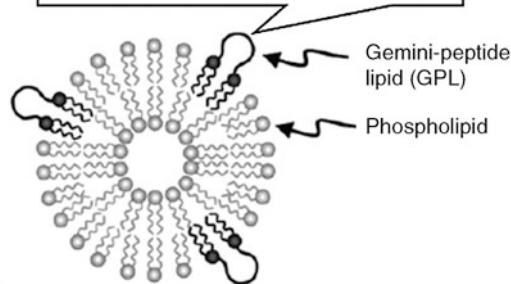

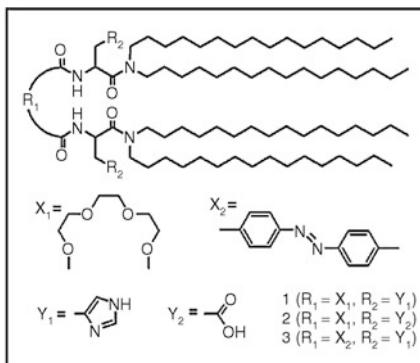

placing senders in different configurations (► Fig. 16). Such a synthetic multicellular system is an example of a molecular communication system that uses bacteria as molecular senders/receivers.

Genetically altered mutant eukaryotic cells can be also used as molecular senders/receivers. In the process of vesicle transport within eukaryotic cells such as yeasts, export molecules are selected and sorted strictly at the ER and recycled between the ER and the Golgi apparatus (Sato and Nakano 2003). If information is encoded onto the type of molecules or the concentration of molecules, the genetically altered cells, which change the sorting and secreting molecules in response to external stimuli such as temperature and light, may act as a sender in molecular communication.

In contrast, another possible approach to creating senders and receivers in molecular communication is to assemble functional molecules that are designed and synthesized artificially. For instance, a synthetic sender/receiver that uses a giant liposome embedded with gemini-peptide lipids has been proposed (Mukai et al. 2009; Sasaki et al. 2006a). A liposome is an artificially created vesicle that has a lipid bilayer membrane structure similar to cell membranes. The gemini-peptide lipids are composed of two amino acid residues, each having a hydrophobic double-tail and a functional spacer unit connecting to the polar heads of the lipid (► Fig. 17a). The liposomes embedded with the same type of gemini-peptide lipids in their lipid bilayer membranes assemble in response to specific triggers such as ions and light (► Fig. 17b) (Iwamoto et al. 2004; Sasaki et al. 2006b). Note that assembled liposomes with gemini-peptide lipids can be dissociated reversibly by applying a complementary trigger (e.g., applying UV-light for liposomal assembly and applying visible light for liposomal dissociation). The reversible liposomal dissociation and assembly mechanisms may be applied to the selective transmission and reception mechanisms of information molecules (or small liposomes that encapsulate information molecules) at a sender and a receiver (Mukai et al. 2009; Sasaki et al. 2006a), respectively (► Fig. 18). The gemini-peptide lipids are used as a molecular tag. A small liposome embedded with molecular tags acts as a container of information molecules (a molecular container) and a giant liposome embedded with a

GPL	Trigger P	Trigger Q
1	Zn ²⁺	K ⁺
2	Ca ²⁺	K ⁺
3	Zn ²⁺ & UV	Zn ²⁺ & VIS

molecular tag acts as a sender/receiver. A sender/receiver is embedded with a specific molecular tag, and a molecular container whose destination is the receiver is also embedded with the same type of molecular tag. When trigger A/B is applied to the sender/receiver and the molecular container, a sender/receiver embedded with a molecular tag that is responsive to the applied trigger transmits/receives the molecular container embedded with the same type of molecular tag (► Fig. 18). This selective transmission/reception mechanism controlled by specific triggers may lead to the creation of not only unicast-type but also multicast- and broadcast-type molecular communication.

As for the biochemical reaction at a receiver, artificial signal transduction systems have been fabricated on a liposomal membrane (Fukuda et al. 2001; Mukai et al. 2009). The artificial signal transduction system is inspired by biological signal transduction that involves ligand–receptor interaction and G-protein-linked pathways. The system is composed of three molecular components: an artificial receptor, an enzyme, and bilayer-forming lipids (► Fig. 19) (Fukuda et al. 2001). In this figure, an azobenzene-containing artificial receptor is embedded in the bilayer-forming lipids (dimyristoylphosphatidylcholine: DMPC) and an enzyme (lactate dehydrogenase: LDH) is immobilized on the bilayer-forming lipids. In the

Fig. 18

A schematic diagram of a sender/receiver using a giant liposome embedded with gemini-peptide lipids and molecular capsules using small liposomes embedded with gemini-peptide lipids. By applying a complementary trigger (e.g., visible light/UV-light exposure) to the system, selective transmission/reception of molecular capsules can be performed at a sender/receiver.

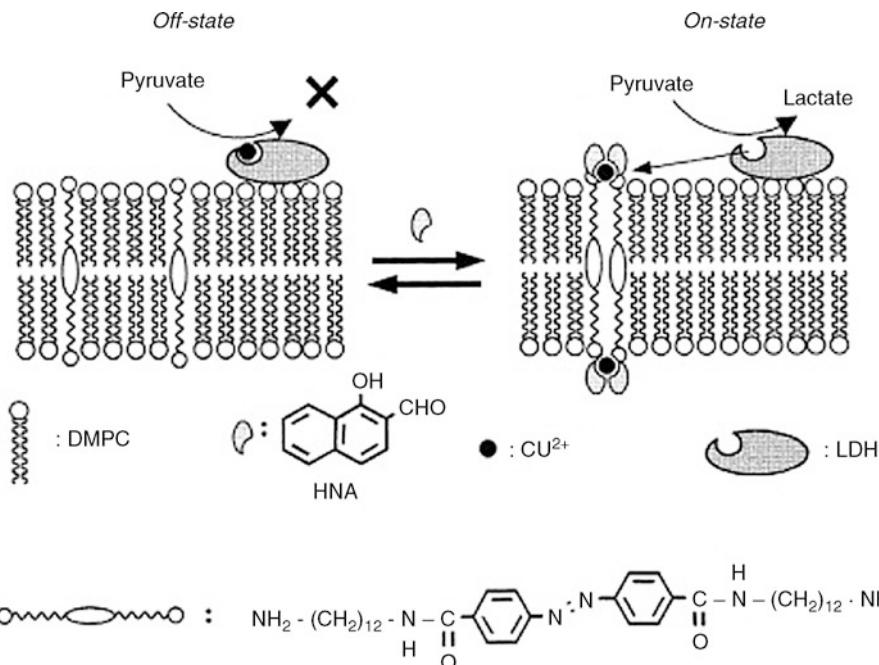

absence of an external signal (1-hydroxy-2-naphthoaldehyde: HNA), Cu^{2+} ions bind to LDH and inhibit LDH activity (corresponding to the off-state). In contrast, in the presence of HNA, Cu^{2+} ions bind to the HNA-receptor complex and activate LDH activity (corresponding to the on-state), resulting in the switching of enzymatic activity through the molecular recognition of the receptor toward the signal. Similar systems can be constructed by using gemini-peptide lipids as photo-responsive molecular tags for liposomal dissociation and assembly. In this case, the photo-responsive molecular tag embedded in the receiver can also act as an artificial receptor in an artificial signal transduction system fabricated on a liposomal membrane (Mukai et al. 2009). The photo-responsive molecular tag drastically changes Cu^{2+} ion-binding affinity through the photoisomerization of azobenzene-spacer units in the GPL type 3. Thus input of a photonic signal (UV-light/visible light exposure) to the molecular tag would be converted to amplified chemical signal output at the enzyme through the translocation of Cu^{2+} ions as a mediator between them. These results indicate that a receiver may biochemically react to the received information molecules by applying a specific trigger.

On the other hand, in the long run it may be possible to create a “white box”-type artificial cell that is only composed of known biological materials and functions. In the field of synthetic biology, some innovative challenges are going on: creating artificial organisms that do not exist or could exist in nature, and creating standardized biological “parts” to turn artisanal genetic engineering into “real” engineering (Bio Fab Group 2006). By combining these technologies, it may be possible to create an artificial cell acting as a sender/receiver in molecular communication from scratch.

Fig. 19

A schematic diagram of an artificial signal transduction system fabricated on a liposomal membrane. The system is composed of an azobenzene-containing artificial receptor, an enzyme (LDH), and bilayer-forming lipids (DMPC), achieving the switching of enzymatic activity through the molecular recognition of the receptor toward an external signal (HNA). 3.5 Research Trends and Future Prospects

Although molecular communication is a new research area, it has received increasing attention in the areas of biophysics, biochemistry, information science, and communication engineering. As summarized in [Table 2](#), various workshops and symposia have been organized worldwide in recent years. The National Science Foundation (NSF) has recognized the importance and impact of molecular communication research, and has already started investigation into funding (NSF 2008). In the middle of 2008, the Institute of Electrical and Electronics Engineers (IEEE) Emerging Technologies Committee launched a new subcommittee to advance the concept of nanoscale networking and molecular communication (IEEE 2008).

Molecular communication research started with experimental approaches to first verify the feasibility, and now it has been extended to theoretical approaches based on information theory. For instance, achievable information rates have been calculated assuming that distinct information molecules are freely diffused (Eckford 2007). Other examples include an information-theoretic model of molecular communication based on cellular signaling (Liu and Nakano 2007), calculating the maximum capacity for the molecular communication channel between a sender and a receiver (Atakan and Akan 2007), and

mathematical modeling of molecular communication among floating nanomachines (acting as senders/receivers) in an aqueous environment based on probabilistic timed finite-state automata (Wiedermann and Petru 2008). These mathematical models are also now in the initial phase of research under many constraints and partly nonrealistic assumptions, but they will become sophisticated soon.

In conclusion, molecular communication is an emerging interdisciplinary research area, and, as such, it requires a lot of research effort and collaboration among biophysicists, biochemists, and information scientists. The authors of this chapter hope that many researchers will participate in and contribute to the development of molecular communication.

Acknowledgments

The first author of this book chapter would like to thank many people who executed and supported the research shown in this chapter, especially Junna Kuramochi, Hirotaka Nakagawa, Kensaku Sakamoto, Takahiro Hohsaka, Takashi Yokomori, and Satoshi Kobayashi. This work was supported in part by special coordination funds for Promoting Science and Technology from the Ministry of Education, Culture, Sports, Science and Technology of the Japanese Government, and through a grant from the Bioinformatics Research and Development of the Japanese Science and Technology Agency.

The second author of this chapter would like to thank Prof. Kazuo Sutoh and Associate Prof. Shoji Takeuchi (The University of Tokyo), Prof. Jun-ichi Kikuchi (Nara Institute of Science and Technology), Prof. Kazunari Akiyoshi and Associate Prof. Yoshihiro Sasaki (Tokyo Medical and Dental University), Prof. Tatsuya Suda (University of California, Irvine), and Mr. Yuki Moritani (NTT DOCOMO, Inc.) for their considerable help with the promotion of molecular communication research.

Abstract

Ciliates are a very diverse and ancient group of unicellular eukaryotic organisms. A feature that is essentially unique to ciliates is the nuclear dualism, meaning that they have two functionally different types of nuclei, the macronucleus and the micronucleus. During sexual reproduction a micronucleus is transformed into a macronucleus – this process is called *gene assembly*, and it is the most involved naturally occurring example of DNA processing that is known to us. Gene assembly is a fascinating research topic from both the biological and the computational points of view.

In this chapter, several approaches to the computational study of gene assembly are considered. This chapter is self-contained in the sense that the basic biology of gene assembly as well as mathematical preliminaries are introduced. Two of the most studied molecular models for gene assembly, *intermolecular* and *intramolecular*, are presented and the main mathematical approaches used in studying these models are discussed. The topics discussed in more detail include the string and graph rewriting models, invariant properties, template-based DNA recombination, and topology-based models. This chapter concludes with a brief discussion of a number of research topics that, because of the space restrictions, could not be covered in this chapter.

1 Introduction

The mathematical study of gene assembly in ciliates was initiated in Landweber and Kari (1999, 2002), where it was noted that the DNA rearrangements performed by ciliates have a strong computational appeal. The first results dealt with the computational capabilities of suitably defined models for gene assembly, using classical approaches from theoretical computer science, especially based on formal languages and computability theory. Shortly afterward, a parallel line of research was initiated in Ehrenfeucht et al. (2001b) and in Prescott et al. (2001a), where the focus was to study various properties of the gene assembly process itself, understood as an information processing process that transforms one genetic structure into another.

This research area has witnessed an explosive development, with a large number of results and approaches currently available. Some of them belong to computer science: models based on rewriting systems, permutations, strings, graphs, and formal languages, invariants results, computability results, etc.; see, for example, Ehrenfeucht et al. (2003a). While others, such as template-based DNA recombination, belong to theoretical and experimental biology; see, for example, Ehrenfeucht et al. (2007) and Angeleska et al. (2007).

In this chapter, several approaches and results in the computational study of gene assembly are reviewed. In [Sect. 2](#), the basic biological details of the gene assembly process as currently understood and experimentally observed are introduced. After mathematical preliminaries in [Sect. 3](#), two of the most studied molecular models for gene assembly (intermolecular and intramolecular) are introduced in [Sects. 4](#) and [5](#). Several mathematical approaches used in studying these models are also discussed. In [Sect. 6](#), some properties of the gene assembly process, called invariants, that hold independently of molecular model and assembly strategy, are discussed. In [Sect. 7](#), models for template-based DNA recombination are presented as a possible molecular implementation of the gene assembly process. The chapter is concluded with a brief discussion in [Sect. 8](#).

2 The Basic Biology of Gene Arrangement in Ciliated Protozoa

All living cells can be classified as belonging to one of two high-level groups: the *prokaryotes* or the *eukaryotes*. The prokaryotes are defined chiefly by their simple cellular organization: within a prokaryotic cell, there are no compartments or subdivisions, all of the intracellular materials (e.g., enzymes, DNA, food, waste) are contained within a single cellular membrane and are free to intermix. By contrast, eukaryotic cells contain nested membranes with many functionally and morphologically distinct organelles, the most well known being the nucleus that contains the DNA, and DNA processing machinery. All bacteria and archaea are prokaryotes while all higher multicellular organisms are eukaryotes.

The *protozoa* are single-celled eukaryotes of striking complexity; each cell functions as a complete, individual organism capable of advanced behaviors typically associated with multicellular organisms. Protozoa are equipped with extensive sensory capabilities and various species can sense temperature, light, and motion, as well as chemical and magnetic gradients. In addition to locomotion via swimming, some types of ciliated protozoa are able to coordinate legs made from fused cilia to walk along substrates in search of food. Many protozoan species are active hunters and possess sensory apparatus enabling them to identify, hunt, and consume prey.

Protozoa are found in nearly every habitat on Earth, and form a critical portion of the microbial food web. Beyond such ecological significance, the study of protozoa is fundamental to evolutionary inquiry as the protozoa represent a significant portion of eukaryotic evolutionary diversity on Earth – through their evolution they have produced unique features, one of which we study further in this chapter.

The *ciliated protozoa* (phylum Ciliophora) are a particularly interesting group due to their unique, and complex, nuclear morphology and genetics. Where most eukaryotic cells contain only one type of nucleus (sometimes in many copies), ciliate cells contain two functionally different types of nucleus: *Macronucleus* (abbreviated as *MAC*) and *Micronucleus* (*MIC*), each of which may be present in various multiplicities. For details on the many other aspects of ciliate biology which are not touched upon here, the reader can refer to Hausmann and Bradbury (1997) and Prescott (2000).

The diversity within the phylum Ciliophora is staggering and even relatively closely related species have extreme evolutionary distances, for example, the ciliates *Tetrahymena thermophila* and *Paramecium caudatum* have an evolutionary distance roughly equivalent to that between rat and corn (Prescott 1994). In this chapter, the discussion is restricted to ciliates of the subclass Stichotrichia for which the unique features that are discussed in this chapter are especially pronounced.

In Stichotrichia there is a profound difference in genome organization between the *MIC* and *MAC* on both a global level (where one considers the organization of chromosomes) and a local level (considering the organization of DNA sequence within individual genes).

On the global level, the *MIC* is diploid (there are exactly two copies of each chromosome) and composed of long chromosomes containing millions of base pairs of DNA. Each of these chromosomes contains a large number of genes, although these genes account for only a very small portion of the total sequence of the chromosomes (approximately 2–5% in stichotrichs). This long, but genetically sparse, chromosome structure is similar to that found in the nuclei of most other eukaryotes.

The global organization of the *MAC* provides a stark contrast to that of the *MIC*: most obviously, the number of copies of chromosomes in *MACs* is very large. For example, typically

more than 1,000 copies in stichotrichs, more than 10,000 in *Stylonichia*, and at the extreme end up to millions of copies of the rDNA-containing chromosome in the stichotrich *Oxytricha trifallax* (also called *Sterkiella histriomuscorum*). Along with much higher number of copies, MAC chromosomes are much shorter than those of the MIC and they contain only 1–3 genes each. Although they are small, these chromosomes are genetically dense – indeed, approximately 85% of a typical chromosome sequence contain genes. Hence, although we have a huge multiplicity of these chromosomes, the total DNA content is still much lower than in the MIC. Thus, the MIC chromosomes are long and “sparse” while the MAC chromosomes are short and “dense.”

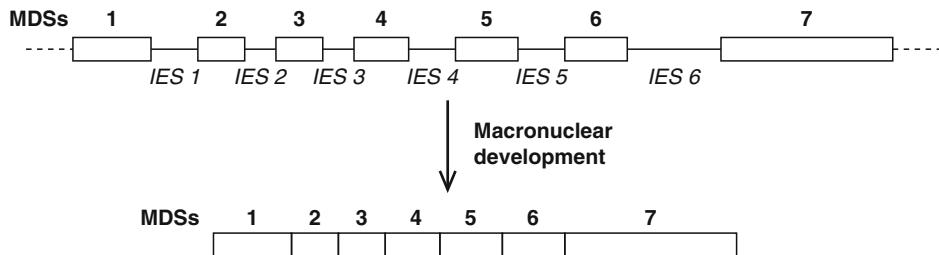

The difference in global genetic organization between the MAC and the MIC is impressive, but turns out to be much less startling than the difference in the local organization of the genes. On the local level, the MAC is a functional nucleus and, like most eukaryotic nuclei, it carries out the day-to-day genetic “housekeeping” tasks of the cell including the production of proteins from the functional MAC genes. In contrast, the genes of the MIC are not functional (not expressible as proteins) due to the presence of many noncoding sequences that break up the genes. Indeed, the macronuclear forms of ciliate genes are heavily modified from the original micronuclear configurations. MIC genes can be divided into two interleaving types of regions: *macronuclear destined segments* or MDSs and *internal eliminated sequences* or IESs. The MDSs are the regions of the MIC gene that end up in the functional MAC version of the gene, while the IESs are interspersed nongenetic regions of sequence that do not appear in the MAC version of the gene, see  Fig. 1. The MDSs are assembled, via overlapping regions called *pointers* to form the macronuclear genes. Each MDS, with the exception of the first and last, is flanked on either side by one of these pointer regions. The outgoing pointer region on one side, which we depict at the right side of MDS n has identical DNA sequence to the incoming pointer region on the left side of MDS $n + 1$. An illustration of this can be seen in  Fig. 2; note that the outgoing pointer of MDS n is identical to the incoming pointer of MDS $(n + 1)$.

In some ciliates, in addition to the appearance of IESs, the MIC genes have the further complication that the MDSs do not appear in the same order as they do in the functional MAC gene. That is, the order of MDSs in the MIC gene is *scrambled* relative to their “orthodox” order in the MAC gene and may even contain segments that are inverted (i.e., rotated 180°). A schematic representation of the gene actin I from *O. trifallax* is shown in  Fig. 3 (see Prescott and Greslin (1992)). Note that the numbers enumerating MDSs refer to the orthodox order of the MDSs in the macronuclear version of the gene, and a bar is used to denote MDSs that are inverted.

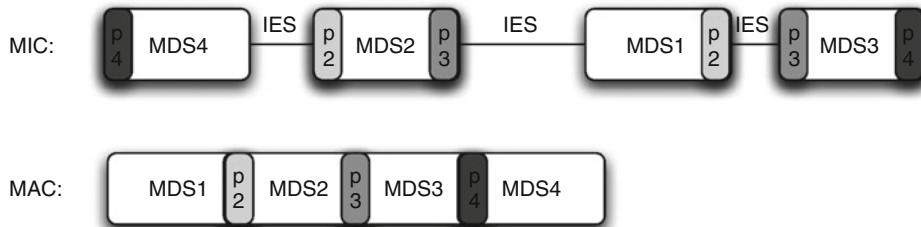

Ciliates reproduce asexually but, during times of environmental stress (e.g., starving due to lack of nutrients) can also undergo the (nonreproductive) sexual activity of *conjugation*. Rather than producing offspring, the purpose of conjugation in ciliates is to give each cell a “genetic facelift” by incorporating new DNA from the conjugating partner cell. The specifics of conjugation are highly species dependent, but almost all ciliate species follow the same basic outline, the generic form of which is illustrated in  Fig. 4. Two cells form a cytoplasmic bridge while meiotically dividing their diploid MICs into four haploid MICs. Each cell sends one haploid MIC across the bridge to the conjugating partner. The cell then combines one of its own haploid MICs with the newly arrived haploid MIC from the partner to form a new fused diploid MIC. Also, each cell destroys its old MAC and remaining haploid MICs, the fused MIC divides into two parts, one of which will be the new MIC and the other one will develop into (will be transformed into) the new MAC.

Fig. 1

A diagram of the arrangement of six IESs and seven MDSs in the micronuclear (top) and the macronuclear (bottom) gene encoding β TP protein. During macronuclear development the IESs are excised and the MDSs are ligated (by overlapping of the ends) to yield a macronuclear gene. MDSs are rectangles. IESs are line segments between rectangles (from Prescott and DuBois (1996)).

**Fig. 2**

Schematic representation of MIC gene (top) and associated MAC gene (bottom) with pointers indicated on the MDSs.

**Fig. 3**

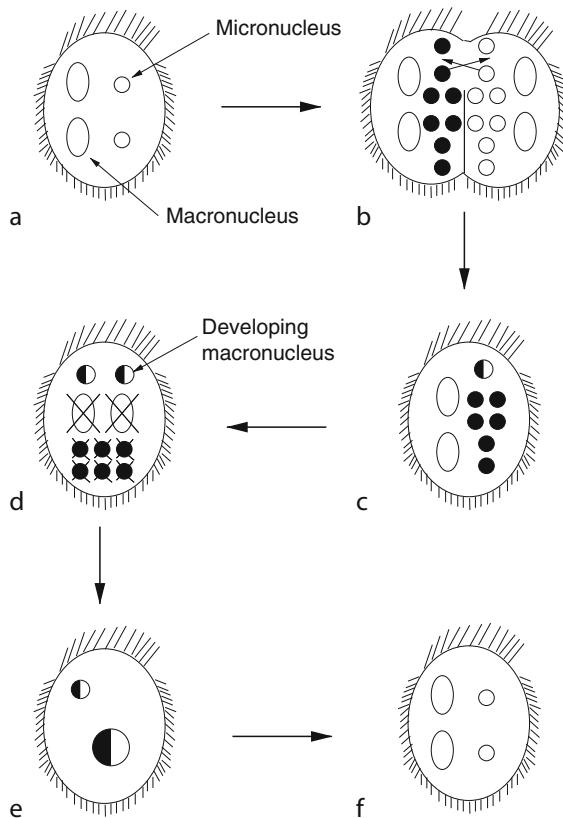

Schematic representation of the structure of the micronuclear gene-encoding actin protein in the stichotrich *Sterkiella nova*. The nine MDSs are in a scrambled disorder (from Prescott and Greslin (1992)).

The topic of interest in this chapter is this transformation of a new MIC into a new MAC. We focus in particular on the transformations of the individual genes – a process called *gene assembly*. This process is fascinating both from the biological and information processing points of view. Indeed, gene assembly is the most complex example of DNA processing known in nature, underscored by the dramatic difference in the structure, and composition, of the MIC and MAC genomes explained above. To form a functional macronuclear gene, all IESs must be excised, all MDSs must be put in their original (orthodox) order with inverted segments switched to their proper orientation.

Fig. 4

Conjugation in stichotrichs: (a) A stichotrich with two macronuclei and two micronuclei. (b) Two stichotrichs have joined and formed a cytoplasmic channel. The two diploid micronuclei have each formed four haploid micronuclei. (c) The two cells exchanged haploid micronuclei, and the two organisms have separated. The exchanged haploid micronucleus has fused with a resident haploid micronucleus forming a new diploid micronucleus (half white and half black). (d) The new diploid micronucleus has divided by mitosis. The unused haploid micronuclei (six) and the two macronuclei are degenerating. (e) One of the new daughter micronuclei has developed into a new macronucleus. The old macronucleus and the unused haploid micronuclei have disappeared. (f) Conjugation has been completed. The micronucleus and macronucleus have divided, yielding the appropriate nuclear numbers (in this case, two MICs and two MACs) (from Ehrenfeucht et al. (2003a)).

Understanding and investigating the computational nature of the gene assembly process, and its biological implications, becomes the central focus of this chapter. For further details on the biology of gene assembly we refer to Jahn and Klobutcher (2000), Prescott (1999, 2000), Möllenbeck et al. (2008), and Ehrenfeucht et al. (2007) and, in particular to Ehrenfeucht et al. (2003a), which contains chapters explaining basic biology, basic cell biology, and the basic biology of ciliates written specifically for motivated computer scientists.

3 Mathematical Preliminaries

In this section we fix basic mathematical notions and terminology used in this chapter.

3.1 Strings

For an alphabet Σ , let Σ^* denote the set of all strings over Σ . Let Λ denote the *empty string*. For a string $u \in \Sigma^*$, we denote by $|u|$ its length, that is, the number of letters u consists of.

A string u is a *substring* of a string v , if $v = xuy$, for some $x, y \in \Sigma^*$. In this case, we denote $u \leq v$. We say that u is a *conjugate* of v if $v = w_1w_2$ and $u = w_2w_1$, for some $w_1, w_2 \in \Sigma^*$.

For an alphabet Σ , let $\bar{\Sigma} = \{\bar{a} \mid a \in \Sigma\}$ be a signed disjoint copy of Σ . The set of all strings over $\Sigma \cup \bar{\Sigma}$ is denoted by $\Sigma^{\pm} = (\Sigma \cup \bar{\Sigma})^*$. A string $v \in \Sigma^{\pm}$ is called a *signed string over Σ* . We adopt the convention that $\bar{\bar{a}} = a$ for each letter $a \in \Sigma$.

Let $v \in \Sigma^{\pm}$ be a signed string over Σ . We say that a letter $a \in \Sigma \cup \bar{\Sigma}$ occurs in v , if a or \bar{a} is a substring of v . Let $\text{dom}(v) \subseteq \Sigma$, called the *domain* of v , be the set of the (unsigned) letters that occur in v .

Example 1 For the alphabet $\Sigma = \{2, 3\}$ of pointers, $\bar{\Sigma} = \{\bar{2}, \bar{3}\}$. Here $u = 233 \in \Sigma^* \subseteq \Sigma^{\pm}$, while $v = 2\bar{3}\bar{2} \in \Sigma^{\pm}$ is a signed string over Σ for which $\text{dom}(v) = \{2, 3\}$ although 3 is not a substring of v .

The signing $a \mapsto \bar{a}$ of letters extends to strings in a natural way: for a signed string $u = a_1a_2 \dots a_n \in \Sigma^{\pm}$, with $a_i \in \Sigma \cup \bar{\Sigma}$ for each i , let the *inversion* of u be

$$\bar{u} = \bar{a}_n\bar{a}_{n-1} \dots \bar{a}_1 \in \Sigma^{\pm}$$

For any set of strings $S \subseteq \Sigma^{\pm}$, we denote $\bar{S} = \{\bar{u} \mid u \in S\}$. For two strings $u, v \in \Sigma^{\pm}$, we say that u and v are *equivalent*, denoted $u \approx v$, if u is a conjugate of either v or \bar{v} .

For an alphabet Σ , let $\|\cdot\|$ be the substitution that unsigns the letters: $\|a\| = a = \|\bar{a}\|$. Mapping $\|\cdot\|$ extends to Σ^{\pm} in the natural way. A signed string v over Σ is a *signing* of a string $u \in \Sigma^*$, if $\|v\| = u$. A signed string u , where each letter from Σ occurs exactly once in u , is called a *signed permutation*.

For two alphabets Σ and Δ , a mapping $f : \Sigma^{\pm} \rightarrow \Delta^{\pm}$ is called a *morphism* if $f(uv) = f(u)f(v)$ and $f(\bar{u}) = \bar{f(u)}$. If $\Delta \subseteq \Sigma$, a morphism $f : \Sigma^* \rightarrow \Delta^*$ is called a *projection* if $f(x) = x$ for $x \in \Delta$ and $f(x) = \lambda$, for $x \in \Sigma \setminus \Delta$.

Example 2 For the alphabet $\Sigma = \{2, 3, 4, 5\}$, there are $2^4 \cdot 4! = 384$ signed permutations. The signed strings 2 3 4 5 and $\bar{4}\bar{2}\bar{5}3$ are among them.

Throughout this chapter we $\{2, 3, \dots\}$ the set of *pointers*.

3.2 Graphs

For a finite set V , let $E(V) = \{\{x, y\} \mid x, y \in V, x \neq y\}$ be the set of all unordered pairs of different elements of V . A (*simple*) *graph* is an ordered pair $G = (V, E)$, where V and E are finite sets of

vertices, and *edges*, respectively. If $e = \{x, y\} \in E$ is an edge, then the vertices x and y are the *ends* of e . In this case, x and y are *adjacent* in G . If $V = \emptyset$, then we denote $G = \emptyset$ and call it the *empty graph*.

For a vertex x in G , let $N_G(x) = \{y \mid \{x, y\} \in E\}$ be the *neighborhood* of x in G . A vertex x is *isolated* in G , if $N_G(x) = \emptyset$.

A *signed graph* $G = (V, E, \sigma)$ consists of a simple graph (V, E) together with a labeling $\sigma : V \rightarrow \{-, +\}$ of the vertices. A vertex x is said to be *positive*, if $\sigma(x) = +$; otherwise x is *negative*. We write $x^{\sigma(x)}$ to indicate that the vertex x has sign $\sigma(x)$.

Let $G = (V, E, \sigma)$ be a signed graph. For a subset $A \subseteq V$, its *induced subgraph* is the signed graph $(A, E \cap E(A), \sigma)$, where σ is restricted to A . The *complement* of G is the signed graph $G^c = (V, E(V) \setminus E, \sigma^c)$, where $\sigma^c(x) = +$ if and only if $\sigma(x) = -$. Also, let $\text{loc}_x(G)$ be the signed graph obtained from G by replacing the subgraph induced by $N_G(x)$ by its complement. For a subset $A \subseteq V$, we denote by $G - A$ the subgraph induced by $V \setminus A$.

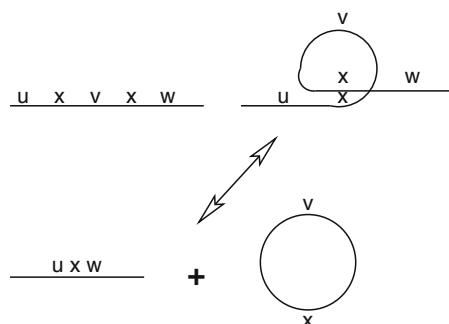

A *multigraph* is a (undirected) graph $G = (V, E, \varepsilon)$, where parallel edges are possible. Therefore, E is a finite set of edges and $\varepsilon : E \rightarrow \{\{x, y\} \mid x, y \in V\}$ is the *endpoint mapping*. We allow $x = y$, and therefore edges can be of the form $\{x, x\} = \{x\}$ – an edge of this form should be seen as a “loop” for x .

4 The Intermolecular Model for Gene Assembly

The very first formal model of the ciliate gene assembly process was the *intermolecular model* proposed in Landweber and Kari (1999, 2002). In this section we introduce a string-based formalization of the model and we refer to Landweber and Kari (1999) for the biological details of the model. Given a string $uxvxw$, where u, x, v, w are nonempty substrings, the authors defined the following intramolecular operation: $uxvxw \rightarrow \{uxw, \cdot vx\}$ where \cdot denotes that the string vx is circular. Intuitively, this models the action of a strand of DNA, $uxvxw$, looping over onto itself and aligning the regions containing the subsequence x . With the x 's aligned, the DNA strand can undergo recombination, yielding the two products uxw and $\cdot vx$. Likewise, the inverse, intermolecular, operation was also defined: $\{uxw, \cdot vx\} \rightarrow uxvxw$. These operations are illustrated in Fig. 5

Fig. 5

The (reversible) recombination of $uxvxw \leftrightarrow \{uxw, \cdot vx\}$ in the intermolecular model for gene assembly of Landweber and Kari (1999, 2002).

Example 3 Consider a hypothetical micronuclear gene with 4 MDSs where the MDSs come in the order $M_1M_2M_4M_3$. If we denote each MDS by its pair of incoming/outgoing pointers and/or markers, we can then denote the whole micronuclear gene as $\delta = (b, p_2)(p_2, p_3)(p_4, e)(p_3, p_4)$. (For more details on formal representation of ciliate genes, see [Sect. 5.](#)) An assembly strategy for this gene in the intermolecular model is the following (we indicate for each operation the pointer on which the molecule is aligned):

$$\begin{aligned}\delta &\xrightarrow{p_3} (b, p_2)(p_2, p_3, p_4) + \cdot(p_4, e)p_3 \xrightarrow{p_4} (b, p_2)(p_2, p_3, p_4, e)p_3p_4 \\ &\xrightarrow{p_2} (b, p_2, p_3, p_4, e)p_3, p_4 + \cdot p_2\end{aligned}$$

As indicated by the formal notation above, the gene gets assembled with copies of pointers p_3 and p_4 following the assembled gene and a copy of pointer p_2 placed on a separate circular molecule. Note that the notation above ignores all IESs of the micronuclear and of the assembled gene.

The obvious difficulty with the intermolecular model is that it cannot deal with DNA molecules in which a pointer is inverted – this is the case, for example, for the actin I gene in *S. nova*. Nevertheless, we can show that inverted pointers can be handled in this model, provided the input molecule (or its MDS–IES descriptor) is available in two copies. Moreover, we consider all linear descriptors modulo inversion. The first assumption is essentially used in research on the intermolecular model, see Kari et al. ([1999](#)), Kari and Landweber ([1999](#)), and Landweber and Kari ([2002](#)). The second assumption is quite natural whenever double-stranded DNA molecules are modeled.

Example 4 Consider the micronuclear actin gene in *Sterkiella nova*, see [Fig. 3](#). Denoting each of its MDSs by the pair of incoming/outgoing pointers and/or markers similarly to our previous example, the gene may be written as

$$\delta = (p_3, p_4)(p_4, p_5)(p_6, p_7)(p_5, p_6)(p_7, p_8)(p_9, e)(\overline{p_3}, \overline{p_2})(b, p_2)(p_8, p_9)$$

Then δ can be assembled in the intermolecular model as follows:

$$\begin{aligned}\delta &\xrightarrow{p_5} (p_3, p_4)(p_4, p_5, p_6)(p_7, p_8)(p_9, e)(\overline{p_3}, \overline{p_2})(b, p_2)(p_8, p_9) + \cdot p_5(p_6, p_7) \\ &\xrightarrow{p_8} (p_3, p_4)(p_4, p_5, p_6)(p_7, p_8, p_9) + \cdot p_8(p_9, e)(\overline{p_3}, \overline{p_2})(b, p_2) + \cdot p_5(p_6, p_7) \\ &\xrightarrow{p_4} (p_3, p_4, p_5, p_6)(p_7, p_8, p_9) + \cdot p_4 + \cdot p_8(p_9, e)(\overline{p_3}, \overline{p_2})(b, p_2) + \cdot p_5(p_6, p_7) \\ &\xrightarrow{p_7} (p_3, p_4, p_5, p_6)p_7p_5(p_6, p_7, p_8, p_9) + \cdot p_4 + \cdot p_8(p_9, e)(\overline{p_3}, \overline{p_2})(b, p_2) \\ &\xrightarrow{p_6} (p_3, p_4, p_5, p_6, p_7, p_8, p_9) + \cdot p_6p_7p_5 + \cdot p_4 + \cdot p_8(p_9, e)(\overline{p_3}, \overline{p_2})(b, p_2) \\ &\xrightarrow{p_9} (p_3, p_4, p_5, p_6, p_7, p_8, p_9, e)(\overline{p_3}, \overline{p_2})(b, p_2)p_8p_9 + \cdot p_6p_7p_5 + \cdot p_4\end{aligned}$$

Assuming that $\overline{\delta}$ is also available, the assembly continues as follows. Here, for a (circular) string τ , we use 2τ to denote $\tau + \tau$:

$$\begin{aligned}
& \delta + \bar{\delta} \longrightarrow \dots \longrightarrow (p_3, p_4, p_5, p_6, p_7, p_8, p_9, e)(\bar{p}_3, \bar{p}_2)(b, p_2)p_8p_9 \\
& \quad + \bar{p}_9 \bar{p}_8(\bar{p}_2, \bar{b})(p_2, p_3)(\bar{e}, \bar{p}_9, \bar{p}_8, \bar{p}_7, \bar{p}_6, \bar{p}_5, \bar{p}_4, \bar{p}_3) \\
& \quad + 2 \cdot p_6p_7p_5 + 2 \cdot p_4 \\
& \xrightarrow{p_2} (p_3, p_4, p_5, p_6, p_7, p_8, p_9, e)(\bar{p}_3, \bar{p}_2)(b, p_2, p_3)(\bar{e}, \bar{p}_9, \bar{p}_8, \bar{p}_7, \bar{p}_6, \bar{p}_5, \bar{p}_4, \bar{p}_3) \\
& \quad + \bar{p}_9 \bar{p}_8(\bar{p}_2, \bar{b})p_2p_8p_9 + 2 \cdot p_6p_7p_5 + 2 \cdot p_4 \\
& \xrightarrow{\bar{p}_2} (p_3, p_4, p_5, p_6, p_7, p_8, p_9, e)(\bar{p}_3, \bar{p}_2, \bar{b})p_2p_8p_9 \\
& \quad + \bar{p}_9 \bar{p}_8\bar{p}_2(b, p_2, p_3)(\bar{e}, \bar{p}_9, \bar{p}_8, \bar{p}_7, \bar{p}_6, \bar{p}_5, \bar{p}_4, \bar{p}_3) \\
& \quad + 2 \cdot p_6p_7p_5 + 2 \cdot p_4 \\
& \xrightarrow{\bar{p}_3} (p_3, p_4, p_5, p_6, p_7, p_8, p_9, e)\bar{p}_3 \\
& \quad + \bar{p}_9 \bar{p}_8\bar{p}_2(b, p_2, p_3)(\bar{e}, \bar{p}_9, \bar{p}_8, \bar{p}_7, \bar{p}_6, \bar{p}_5, \bar{p}_4, \bar{p}_3, \bar{p}_2, \bar{b})p_2p_8p_9 \\
& \quad + 2 \cdot p_6p_7p_5 + 2 \cdot p_4 \\
& \xrightarrow{p_3} p_3(\bar{e}, \bar{p}_9, \bar{p}_8, \bar{p}_7, \bar{p}_6, \bar{p}_5, \bar{p}_4, \bar{p}_3, \bar{p}_2, \bar{b})p_2p_8p_9 \\
& \quad + \bar{p}_9 \bar{p}_8\bar{p}_2(b, p_2, p_3, p_4, p_5, p_6, p_7, p_8, p_9, e)\bar{p}_3 + 2 \cdot p_6p_7p_5 + 2 \cdot p_4 \\
& = 2\bar{p}_9 \bar{p}_8\bar{p}_2(b, p_2, p_3, p_4, p_5, p_6, p_7, p_8, p_9, e)\bar{p}_3 + 2 \cdot p_6p_7p_5 + 2 \cdot p_4
\end{aligned}$$

This calculation shows that the gene is eventually assembled, with p_3 preceding the assembled gene and $p_2p_8p_9$ following it, and that two circular molecules are excised during the assembly.

We refer to [Sect. 5](#) for intramolecular assembly strategies of the actin I gene in *S. nova* and to [Sect. 6](#) for a set of properties that are independent of particular assembly strategies, called invariants. The DNA sequences of all molecules produced by gene assembly are particular invariants of the process. We refer to Harju et al. (2004a) for a detailed discussion on intermolecular assembly strategies and a comparison to intramolecular assemblies.

Consider now contextual versions of the operations. We define rules of the form (p, x, q) (p', x, q') with the intended semantics that p (p' , resp.) and q (q' , resp.) represent contexts flanking x (x' , resp.). These contexts are not directly involved in the recombination process, but instead regulate it: recombination may only take place if x (x' , resp.) is flanked by p (p' , resp.) and q (q' , resp.). Our intramolecular operation now becomes $uxvxw \rightarrow \{uxw, \cdot vx\}$, where $u = u'p, v = qv' = v''p', w = q'w'$, with similar constraints for the intermolecular operation.

It was shown in Landweber and Kari (2002) that iterated nondeterministic application of these contextual rules to an initial axiom string yields a computing system with the generative power of a Turing machine.

5 The Intramolecular Model for Gene Assembly

5.1 Molecular Model

The *intramolecular model* was introduced in Ehrenfeucht et al. (2001b) and Prescott et al. (2001a). It consists of a set of three irreversible molecular operations explaining the excision of IESs and the unscrambling and ligation of MDSs during the MIC–MAC development. All

three operations postulate the folding of a DNA molecule into a specific pattern that allows the alignment of some pointers. Subsequent DNA recombination on those pointers leads to the MDSs (and IESs) being rearranged. Each of the three operations is described in the following.

5.1.1 Loop, Direct-Repeat Excision (in Short, **ld**)

The **ld** operation is applicable to a DNA molecule having two occurrences of a pointer, say p , on the same strand. We say in this case that pointer p has a *direct repeat* along the molecule. The molecule is then folded into a *loop* (► Fig. 6a) so that the two occurrences of p are aligned. Recombination on p is thus facilitated (► Fig. 6b) and as a result, a linear molecule and a circular molecule are obtained, (► Fig. 6c). Each of the two molecules has an occurrence of p .

5.1.2 Hairpin, Inverted-Repeat Excision/Reinsertion (in Short, **hi**)

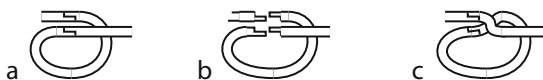

The **hi** operation is applicable to a DNA molecule having two occurrences of a pointer, say p , on different strands of the molecule. We say in this case that pointer p has an *inverted repeat* along the molecule. Then the molecule is folded into a *hairpin* (► Fig. 7a) so that the two occurrences of p have a direct alignment. Recombination on p is thus facilitated (► Fig. 7b), and as a result, a new linear molecule is obtained, where one block of nucleotides has been inverted (► Fig. 7c).

5.1.3 Double Loop, Alternating Direct-Repeat Excision (in Short, **dlad**)

The **dlad** operation is applicable to a DNA molecule having two pointers, say p and q , each with two occurrences. All four pointer occurrences should be on the same strand. Moreover, pointer p has one occurrence in-between the two occurrences of q and one occurrence outside

► Fig. 6

Illustration of the ld-rule. (a) The molecule is first folded into a loop, aligning the two direct repeats of a pointer. (b) Recombination is facilitated on the two occurrences of the pointer. (c) One linear and one circular molecule are produced as a result of the operation (from Harju et al. (2004b)).

► Fig. 7

Illustration of the hi-rule. (a) The molecule is first folded into a hairpin, aligning the two inverted repeats of a pointer. (b) Recombination is facilitated on the two occurrences of the pointer. (c) A new linear molecule is produced as a result of the operation (from Harju et al. (2004b)).

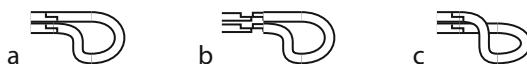

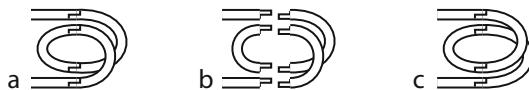

Fig. 8

Illustration of the dlad-rule. (a) The molecule is first folded into a double loop, simultaneously aligning two pairs of pointer occurrences. (b) Recombination is facilitated on both pointer alignments. (c) A new linear molecule is produced as a result of the operation (from Harju et al. (2004b)).

them. (By consequence, the same holds true for pointer q with respect to the two occurrences of pointer p .) The molecule is then folded into a double loop (► Fig. 8a), so that the two occurrences of p and the two occurrences of q are simultaneously aligned. Recombination events on p and on q are facilitated (► Fig. 8b), and as a result, a new linear molecule is obtained, see ► Fig. 8c.

5.1.4 Discussion

The {Id, hi, dlad} model is often referred to as the *intramolecular model*, to stress that in this model, the input to which operations are applied is always a single molecule. (In contrast, the model presented in ► Sect. 4 is referred to as the *intermolecular model*.) It is important to note however that Id yields as an output two molecules. As such, for the intramolecular assembly to succeed, that is, to assemble all MDSs, it is essential that all coding blocks remain within one of the molecules produced by Id. This gives two restrictions for applying Id on a pointer p in a successful gene assembly:

- (i) No MDSs exist in-between the two occurrences of p . (Equivalently, only one, possibly composite, IES exists in-between the two occurrences of p .) We say in this case that we have a *simple* application of Id. As a result, a (possibly composite) IES is excised as a circular molecule and all MDSs remain on the resulting linear molecule.
- (ii) All MDSs are placed in-between the two occurrences of p . We say in this case that we have a *boundary* application of Id. As a result, all MDSs are placed on the resulting circular molecule. The final assembled gene will be a circular molecule. It has been shown in Ehrenfeucht et al. (2001a, 2003a) that using a boundary application of Id can be postponed to the last step of any successful assembly. In this way, in-between the two occurrences of p there is only one (possibly composite) IES, similarly as in the case of simple Id.

The mechanistic details of the alignment and recombination events postulated by the three molecular operations Id, hi, and dlad are not indicated in the original proposal for the intramolecular model. Two mechanisms were later proposed in Prescott et al. (2001b) and in Angeleska et al. (2007). The details of both are discussed in ► Sect. 7.

5.2 String and Graph Representations for Ciliate Genes

We present three different formalizations for the gene assembly process: signed permutations, legal strings, and overlap graphs. The first two of these are linear in the sense that the order of the MDSs can be readily seen from the presentation. On the other hand, from the overlap

graphs the order of the components is more difficult to capture. The gene assembly process will, however, be different in nature for signed permutations as for legal strings as well as for overlap graphs. Permutations need to be sorted while strings and graphs need to be reduced to empty string and graph, respectively. Another formalization in terms of *descriptors* is given in [Sect. 6](#).

5.2.1 Signed Permutations and Legal Strings

Each micronuclear arrangement of MDSs and IESs can be represented as a signed permutation over the alphabet $\{M_1, M_2, \dots, M_\kappa\}$, for an integer $\kappa \geq 1$ corresponding to the number of macronuclear destined sequences that assemble to a functional gene. We identify such a string with a signed permutation over the index set $\{1, 2, \dots, \kappa\}$.

Example 5 Consider the micronuclear arrangement of the actin I gene of *Sterkiella nova*: $M_3 M_4 M_6 M_5 M_7 M_9 \bar{M}_2 M_1 M_8$. This is represented as the signed permutation $\alpha = 3 4 6 5 7 9 \bar{2} 1 8$.

The gene assembly process is equivalent to sorting a signed permutation in proper order, that is, in the order $p(p+1) \dots \kappa 1 \dots (p-1)$ or its inverse for suitable p (and κ , the number of MDSs in the micronuclear gene). If $p = 1$ here, then the MDSs are linearly ordered; otherwise they are cyclically ordered.

Representation by strings will preserve the order of the MDSs that are coded as “pairs of pointers.”

A string $v \in \Sigma^*$ over an alphabet Σ is said to be a *double occurrence string*, if every letter $a \in \text{dom}(v)$ occurs exactly twice in v . A signing of a nonempty double occurrence string is a *legal string*. A letter $a \in \Sigma \cup \bar{\Sigma}$ is *positive* in a legal string $v \in \Sigma^*$, if v contains both a and \bar{a} ; otherwise, a is *negative* in v .

Example 6 Consider the legal string $u = 2 4 3 \bar{2} \bar{5} 3 4 5$ of pointers. Pointers 2 and 5 are positive in u , while 3 and 4 are negative in u . On the other hand, the string $w = 2 4 3 \bar{2} \bar{5} 3 5$ is not legal, since 4 has only one occurrence in w .

Let $u = a_1 a_2 \dots a_n \in \Sigma^*$ be a legal string over Σ with $a_i \in \Sigma \cup \bar{\Sigma}$ for each i . For $a \in \text{dom}(u)$, let $1 \leq i < j \leq n$ be such that $\|a_i\| = a = \|a_j\|$. Then the substring

$$u_{(a)} = a_i a_{i+1} \dots a_j$$

is called the *a-interval* of u . Two different letters $a, b \in \Sigma$ are said to *overlap* in u , if the *a*-interval and the *b*-interval of u overlap: if $u_{(a)} = a_{i_1} \dots a_{j_1}$ and $u_{(b)} = a_{i_2} \dots a_{j_2}$, then either $i_1 < i_2 < j_1 < j_2$ or $i_2 < i_1 < j_2 < j_1$.

Example 7 Let $u = 2 4 3 5 3 \bar{2} \bar{6} \bar{5} 4 6$ be a signed string of pointers. The 2-interval of u is the substring $u_{(2)} = 2 4 3 5 3 \bar{2}$, and hence pointer 2 overlaps with 4 and 5 but not with 3 or 6. Similarly, for example, $u_{(4)} = 4 3 5 3 \bar{2} \bar{6} \bar{5} 4$ and hence 4 overlaps with 2 and 6.

A signed permutation will be represented by a legal string using the following substitution $\varrho_\kappa : \{1, 2, \dots, \kappa\}^* \rightarrow \{2, 3, \dots, \kappa\}^*$

$$\varrho_\kappa(1) = 2, \quad \varrho_\kappa(\kappa) = \kappa, \quad \varrho_\kappa(p) = p(p+1) \text{ for } 2 \leq p < \kappa$$

and $\varrho_\kappa(\overline{p}) = \overline{\varrho_\kappa(p)}$ for each p with $1 \leq p \leq \kappa$.

Example 8 Consider the signed permutation α from Example 5. We have

$$\varrho_9(\alpha) = 34\ 45\ 67\ 56\ 78\ 9\ \overline{3}\ \overline{2}\ 2\ 89.$$

5.2.2 Overlap Graphs

The focus now shifts to representations by graphs. We use signed graphs to represent the structure of overlaps of letters in legal strings as follows: let $v \in \Sigma^*$ be a legal string. The *overlap graph* of v is the signed graph $G_v = (\text{dom}(v), E, \sigma)$ such that

$$\sigma(x) = \begin{cases} +, & \text{if } x \text{ is positive in } v \\ -, & \text{if } x \text{ is negative in } v \end{cases}$$

and

$$\{x, y\} \in E \iff x \text{ and } y \text{ overlap in } v$$

Example 9 Consider the legal string $v = 3\ 4\ \overline{5}\ 2\ \overline{3}\ \overline{2}\ 4\ 5$ of pointers. Then its overlap graph G_v is given in [Fig. 9](#).

Overlap graphs of double occurrence strings are also known as *circle graphs*.

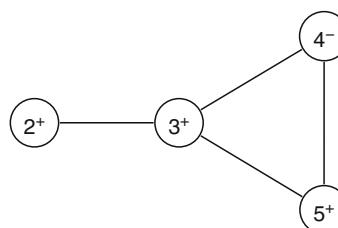

Example 10 Notice that the mapping $w \mapsto G_w$ of legal strings to overlap graphs is not injective. The following eight legal strings of pointers have the same overlap graph (of one edge): $2\overline{3}23, \overline{3}232, 23\overline{2}3, 32\overline{2}3, \overline{2}323, 32\overline{3}2, \overline{2}3\overline{2}3, 32\overline{3}2$. For a more complicated example, we mention that the strings $v_1 = 23342554$ and $v_2 = 35242453$ define the same overlap graph.

5.2.3 Reduction Graph

Recall that legal strings represent the MIC form of genes. We now introduce a graph, called the *reduction graph*, that represents the MAC form of a gene and the other molecules obtained as results of the assembly, given a legal string (the MIC form of that gene). In this way, the

[Fig. 9](#)

The overlap graph of the signed string $v = 3\ 4\ \overline{5}\ 2\ \overline{3}\ \overline{2}\ 4\ 5$.

reduction graph represents the end result after recombination on all pointers. First, we define a *2-edge colored graph* as a tuple (V, E_1, E_2, f, s, t) , where V are the vertices, $s, t \in V$ are called *source* and *target*, and $f: V \setminus \{s, t\} \rightarrow \Gamma$ is a vertex labeling function with Γ a finite set of vertex labels. There are two (not necessarily disjoint) sets of undirected edges E_1 and E_2 . We let $\text{dom}(G)$ be the range of f , and say that 2-edge colored graphs G and G' are *isomorphic*, denoted $G \approx G'$, when they are equal up to a renaming of the vertices. However, we require that the labels of the identified vertices be equal, and that the sources and targets of G and G' be identified.

A reduction graph (Brijder et al. 2006) is a 2-edge colored graph where the two types of edges E_1 and E_2 are called *reality edges* and *desire edges* respectively. Moreover, each vertex, except s and t , is labeled by an element of $\Delta_\kappa = \{2, 3, \dots, \kappa\}$. As an example, consider the representation of legal string $u = \bar{2}\bar{7}47353\bar{4}2656$ over $\Pi_\kappa = \Delta_\kappa \cup \bar{\Delta}_\kappa$ given in [Fig. 10](#). This legal string will be used as our running example.

A reduction graph \mathcal{R}_u for a legal string u is defined in such a way that (1) each occurrence of a pointer of u appears twice (in unbarred form) as a label of a vertex in the graph to represent both sides of the pointer in the representation of u , (2) the reality edges (depicted as “double edges” to distinguish them from the desire edges) represent the segments between the pointers, (3) the desire edges represent which segments should be glued to each other when recombination operations are applied on the corresponding pointers. To enforce this last requirement, positive pointers are connected by crossing desire edges (cf. pointers 4 and 7 in [Fig. 11](#)), while negative pointers are connected by parallel desire edges. The vertices s and t represent the left end and the right end, respectively. Note that, since the reduction graph is fixed for a given u , the end product after recombination is fixed as well. The notion of reduction graph is similar to the breakpoint graph (or reality-and-desire diagram) known from the theory of sorting by reversal, see, for example, Setubal and Meidanis (1997) and Pevzner (2000). A formal definition of reduction graph is found, for example, in Brijder et al. (2006). The reduction graph for string $u = \bar{2}\bar{7}47353\bar{4}2656$ is in [Fig. 11](#).

In depictions of reduction graphs, the vertices (except for s and t) will be represented by their labels, because the exact identities of the vertices are not essential here – we consider reduction graphs up to isomorphism. Note that the reduction graph is defined for the general concept of legal strings. Therefore, the reduction graph represents the end product after recombination of arbitrary sequences of pointers (which by definition come in pairs) – not only those that correspond to sequences of MDSs.

Fig. 10

The representation of $u = \bar{2}\bar{7}47353\bar{4}2656$.

2	$\bar{7}$	4	7	3	5	3	$\bar{4}$	2	6	5	6

Fig. 11

The reduction graph for $u = \bar{2}\bar{7}47353\bar{4}2656$.

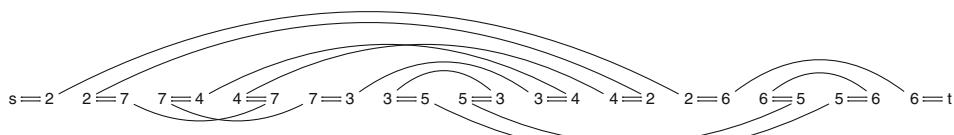

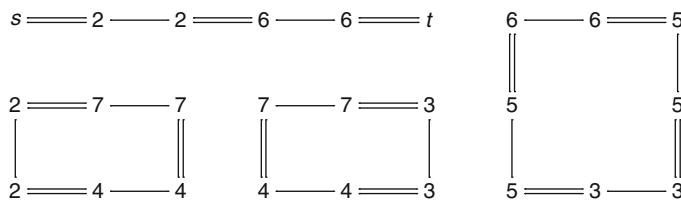

Fig. 12

The reduction graph \mathcal{R}_u of u from the running example.

In the running example, the reduction graph \mathcal{R}_u of u is again depicted in Fig. 12 – we have only rearranged the vertices.

Each reduction graph has a connected component, called the *linear component*, containing both vertices s and t . The other connected components are called *cyclic components*.

5.3 Mathematical Formalizations of the Intramolecular Model

In this section we formalize the gene assembly process involving the three molecular operations **Id**, **hi**, and **dld** in the framework of legal strings and overlap graphs.

5.3.1 Assembly Operations on Strings

Recall that each micronuclear MDS structure can be faithfully represented as a signed permutation α , which in turn has a presentation as a legal string $v = \varrho_\kappa(\alpha)$, where κ is the number of the MDSs in the micronuclear gene, and as an overlap graph G_v with κ vertices.

The assembly operations for strings are described first. The rules are (snr) the *string negative rule*, (spr) the *string positive rule*, and (sdr) the *string double rule*. For simplicity we consider only strings of pointers. Recall that we denote $\Delta_\kappa = \{2, 3, \dots, \kappa\}$ and $\Pi_\kappa = \Delta_\kappa \cup \overline{\Delta}_\kappa$. Below, we assume that $p, q \in \Pi_\kappa$.

- snr_p applies to a legal string of the form $u = u_1 p p u_2$ resulting in

$$\text{snr}_p(u_1 p p u_2) = u_1 u_2 \quad (1)$$

- spr_p applies to a legal string of the form $u = u_1 p u_2 \bar{p} u_3$ resulting in

$$\text{spr}_p(u_1 p u_2 \bar{p} u_3) = u_1 \bar{u}_2 u_3 \quad (2)$$

- $\text{sdr}_{p,q}$ applies to a legal string of the form $u = u_1 p u_2 q u_3 p u_4 q u_5$ resulting in

$$\text{sdr}_{p,q}(u_1 p u_2 q u_3 p u_4 q u_5) = u_1 u_4 u_3 u_2 u_5 \quad (3)$$

We define $\text{dom}(\rho)$ for a string reduction rule ρ by $\text{dom}(\text{snr}_p) = \text{dom}(\text{spr}_p) = \{\|p\|\}$ and $\text{dom}(\text{sdr}_{p,q}) = \{\|p\|, \|q\|\}$ for $p, q \in \Pi_\kappa$.

We adopt the following graphical notations for the applications of these operations:

$$u \xrightarrow{\text{snr}_p} \text{snr}_p(u), \quad u \xrightarrow{\text{spr}_p} \text{spr}_p(u), \quad u \xrightarrow{\text{sdr}_{p,q}} \text{sdr}_{p,q}(u)$$

A composition $\varphi = \varphi_n \dots \varphi_1$ of the above operations φ_i is a *string reduction* of u , if φ is applicable to u . Also, φ is *successful* for u , if $\varphi(u) = \Lambda$, the empty string. Moreover, we define $\text{dom}(\varphi) = \text{dom}(\varphi_1) \cup \text{dom}(\varphi_2) \cup \dots \cup \text{dom}(\varphi_n)$.

Example 11 The rule snr_2 is applicable to the legal string $u = 5\ 2\ 2\ 3\ \bar{5}\ \bar{4}\ 3\ 4$: $\text{snr}_2(u) = 5\ 3\ \bar{5}\ \bar{4}\ 3\ 4$. Moreover, we have

$$5\ 2\ 2\ 3\ \bar{5}\ \bar{4}\ 3\ 4 \xrightarrow{\text{snr}_2} 5\ 3\ \bar{5}\ \bar{4}\ 3\ 4 \xrightarrow{\text{spr}_4} 5\ 3\ \bar{5}\ \bar{3} \xrightarrow{\text{spr}_3} 5\ 5 \xrightarrow{\text{snr}_5} \Lambda,$$

and hence φ is successful for u .

The following is the basic universality result for legal strings.

Theorem 1 (Ehrenfeucht et al. 2000; Brijder et al. 2006) *Each legal string has a successful string reduction.*

5.3.2 Assembly operations on graphs

The assembly operations for graphs will now be described. The rules are (gnr) the *graph negative rule*, (gpr) the *graph positive rule*, (gdr) the *graph double rule*.

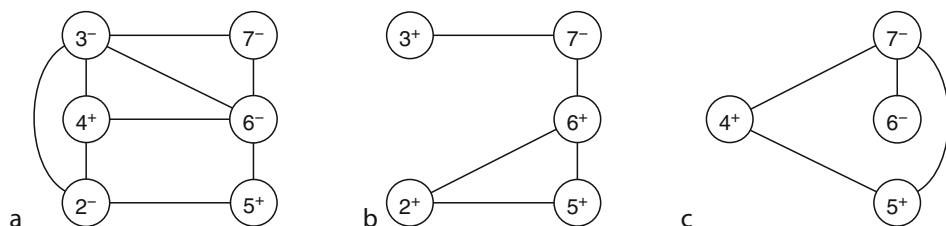

Let x and y be vertices of a signed graph G .

- gnr_x is applicable to G , if x is isolated and negative. The result is $\text{gnr}_x(G) = G - x$.
- gpr_x is applicable to G , if x is positive. The result is $\text{gpr}_x(G) = \text{loc}_x(G) - x$.
- $\text{gdr}_{x,y}$ is applicable to G , if x and y are adjacent and negative. The result is $\text{gdr}_{x,y}(G) = \text{loc}_x \text{loc}_y \text{loc}_x(G) - \{x, y\}$ obtained by complementing the edges between the sets $N_G(x) \setminus N_G(y)$, $N_G(y) \setminus N_G(x)$, and $N_G(x) \cap N_G(y)$.

Example 12 Consider the overlap graph $G = G_w$ for $w = 3\ \bar{5}\ 2\ 6\ 5\ 4\ 7\ 3\ 6\ 7\ 2\ \bar{4}$; see Fig. 13a. The graph $\text{gpr}_4(G)$ is given in Fig. 13b, and the graph $\text{gdr}_{2,3}(G)$ is given in Fig. 13c.

Fig. 13

The graphs (a) $G = G_w$, (b) $\text{gpr}_4(G)$, (c) $\text{gdr}_{2,3}(G)$, where $w = 3\ \bar{5}\ 2\ 6\ 5\ 4\ 7\ 3\ 6\ 7\ 2\ \bar{4}$.

A composition $\varphi = \varphi_n \dots \varphi_1$ of the above graph operations is called a *graph reduction* for a signed graph G , if φ is applicable to G . Also, φ is *successful*, if $\varphi(G)$ is the empty graph.

Example 13 The overlap graph $G = G_w$ given in [Fig. 13a](#) is reduced to the empty graph by the composition $\text{gpr}_5\text{gpr}_6\text{gpr}_7\text{gpr}_4\text{gdr}_{2,3}$.

The above operations are universal for signed graphs.

Theorem 2 (Harju et al. 2004b) *Each signed graph G has a successful graph reduction.*

5.3.3 Equivalence of the Systems

The relation between the systems for strings and graphs is now studied, and we show that there is a correspondence between these operations.

Theorem 3 (Ehrenfeucht et al. 2003b) *Let w be a legal string. Each string reduction $\varphi = \varphi_n \dots \varphi_1$ for w translates into a graph reduction $\varphi' = \varphi'_n \dots \varphi'_1$ for the overlap graph G_w by the translation:*

$$\text{snr}_p \mapsto \text{gnr}_p, \quad \text{spr}_p \mapsto \text{gpr}_p, \quad \text{sdr}_{p,q} \mapsto \text{gdr}_{p,q}.$$

Consequently, if φ is successful for w , then φ' is successful for G_w .

The reverse implication, from graphs to strings, is not as straightforward. Recall first that the mapping from the legal strings to the overlap graphs is not injective.

Denote by $p(w)$ the *first occurrence* of p or \bar{p} in w .

Theorem 4 (Ehrenfeucht et al. 2003b) *Let w be a legal string, and let φ be a successful reduction for G_w . Then there exists a permutation $\varphi'' = \varphi_n \dots \varphi_1$ of φ , which is successful for G_w , and which can be translated to a successful string reduction $\varphi' = \varphi'_n \dots \varphi'_1$ for w by the following translations:*

$$\text{gnr}_p \mapsto \text{snr}_{p(w)}, \quad \text{gpr}_p \mapsto \text{spr}_{p(w)}, \quad \text{gdr}_{p,q} \mapsto \text{sdr}_{p(w),q(w)}.$$

5.4 Properties of Intramolecular Assemblies

Some properties of intramolecular gene assemblies are discussed in this section. Many of these properties hold in all the mathematical models described in [Sect. 5.3](#). In each case however, we choose to describe the results only on a level that allows for the simplest or the most elegant formulation. For more results we refer to Ehrenfeucht (2003a) and Brijder (2008).

5.4.1 Nondeterminism and Confluence

It is easy to show on all model levels, from the molecular level to that of graphs, that for a given gene (permutation, string, graph, resp.), there can be more than one strategy to assemble it.

Different assembly reduction strategies have recently also been confirmed experimentally (Möllenbeck et al. 2008). We say that the intramolecular model is *nondeterministic*. Consider, for example, the signed string associated to the actin I gene in *S. nova*: $u = 3\ 4\ 4\ 5\ 6\ 7\ 5\ 6\ 7\ 8\ 9\ \bar{3}\ \bar{2}\ 2\ 8\ 9$. There are 3060 different sequential strategies to reduce this string (assemble the gene), see Ehrenfeucht et al. (2003a), of which only two are shown in [Table 1](#). Note in particular that these two strategies differ in the number and type of operations used. On the other hand, both strategies are successful, reducing the input string to the empty string. As shown in Theorems 1 and 2, this is true in general: although several operations may be applicable to a given input, successful strategies for that input exist starting with any of those operations. The biological interpretation is that all (potentially many) assembly strategies of a given micronuclear gene, have the same result: the assembled corresponding macronuclear gene. We call such a model *confluent*. Consequently, ciliates “need not remember” a particular sequential strategy which in turn contributes to the robustness of the gene assembly process.

In [Sect. 6](#) it will be proved that the assembly strategies of a given gene share a number of other properties beyond yielding the same assembled gene: the number of molecules (linear and circular) produced throughout the assembly, their nucleotide sequence, whether the assembled gene is linear or circular.

5.4.2 The Structure of MAC Genes with By-products

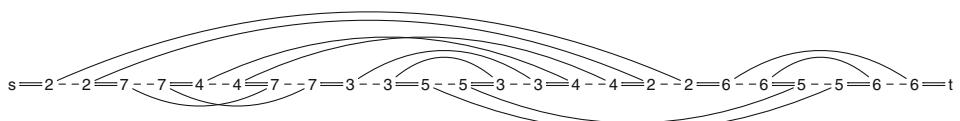

Since legal strings represent the initial configuration (gene in MIC form) and the corresponding reduction graph the end result (the same gene in MAC form and its excised products), it is natural to study the possible forms of reduction graphs. Formally, we now characterize the graphs that are (isomorphic to) reduction graphs.

A graph G isomorphic to a reduction graph must be a 2-edge colored graph (V, E_1, E_2, f, s, t) such that for each p in the range of f , $p \in \mathcal{A}$ and there must be exactly four vertices labeled by p . Each vertex must be connected to exactly one (reality) edge from E_1 , and each vertex, except s and t , must be connected to exactly one (desire) edge from E_2 . Finally, edges from E_2 must connect vertices with a common label. One can call these graphs *abstract reduction graphs*, and let the set of abstract reduction graphs be ARG. It turns out that there are graphs in ARG that are not (isomorphic to) reduction graphs.

To obtain a characterization, one more property of reduction graphs is needed: the ability to linearly order the vertices to resemble its (in general not unique) underlying legal string, as done in [Fig. 11](#). To make this linear order of vertices explicit, we introduce a third set of edges, called *merge edges*, to the reduction graph as done in [Fig. 14](#).

[**Fig. 14**](#)

Merge edges are added to the reduction graph of [Fig. 11](#).

Now, when is a set of edges M for $G \in \text{ARG}$ a set of merge edges? Like desire edges, they have the properties that (1) the edges connect vertices with a common label and (2) each vertex except s and t is connected to exactly one merge edge. Moreover, M and the set E_2 are disjoint – no desire edge is parallel to a merge edge. Finally, the reality edges and merge edges must allow for a path from s to t passing each vertex once. This last requirement is equivalent to the fact that the reality and merge edges induce a connected graph.

If it is possible to add a set of merge edges to the graph, then it is not difficult to see that the graph is isomorphic to a reduction graph \mathcal{R}_u . Indeed, we can identify such a u for this reduction graph by simply considering the alternating path from s to t over the reality and merge edges. The orientation (positiveness or negativeness) of each pointer is determined by the crossing or noncrossing of the desire edges (exactly as we defined the notion of reduction graph).

To characterize reduction graphs we need the notion of a pointer-component graph. Given an abstract reduction graph, a pointer-component graph describes how the labels of that abstract reduction graph are distributed among its connected components.

Definition 1 Let $G \in \text{ARG}$. The pointer-component graph of G , denoted by \mathcal{PC}_G , is a multigraph (ζ, E, ε) , where ζ is the set of connected components of G , $E = \text{dom}(G)$ and ε is, for $e \in E$, defined by $\varepsilon(e) = \{C \in \zeta \mid C \text{ contains vertices labeled by } e\}$.

The pointer-component graph of $G = \mathcal{R}_u$ of Fig. 12 is given in Fig. 15. We have $\zeta = \{C_1, C_2, C_3, R\}$ where R is the linear component and the other elements are cyclic components of \mathcal{R}_u .

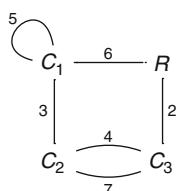

It is shown in Brijder and Hoogeboom (2008a) that, surprisingly, $G \in \text{ARG}$ has a set of merge edges precisely when the pointer-component graph \mathcal{PC}_G is a connected graph. Therefore, we have the following result.

Theorem 5 (Brijder and Hoogeboom 2008a) An abstract reduction graph G is isomorphic to a reduction graph iff \mathbf{PC}_G is a connected graph.

Consider the legal string $u = 2\bar{7}47353\bar{4}2656$ as before and $v = 2\bar{7}426\bar{5}3\bar{4}7356$. It turns out that they have the same reduction graph (up to isomorphism): $\mathcal{R}_u \approx \mathcal{R}_v$ (see Fig. 11). The reason for this is that a reduction graph may have more than one set of merge edges – each one corresponding to a different legal string. Thus, there can be many legal strings giving the same reduction graph. In Brijder and Hoogeboom (2008a) it is shown how for a given legal string u we can obtain precisely the set of all legal strings having the same reduction graph

Fig. 15

The graph $\mathcal{PC}_{\mathcal{R}_u}$ of the graph \mathcal{R}_u in [Fig. 12](#).

(up to isomorphism). In fact, it turns out that this set is exactly the set of all legal strings obtained by applying compositions of the following string rewriting rules.

For all $p, q \in \Pi_\kappa$ with $\|p\| \neq \|q\|$ we define

- The *dual string positive rule* for p is defined by $\text{dspr}_p(u_1 p u_2 p u_3) = u_1 p \bar{u}_2 p u_3$
- The *dual string double rule* for p, q is defined by $\text{dsdr}_{p,q}(u_1 p u_2 q u_3 \bar{p} u_4 \bar{q} u_5) = u_1 p u_4 q u_3 \bar{p} u_2 \bar{q} u_5$

where u_1, u_2, \dots, u_5 are arbitrary (possibly empty) strings over Π_κ . Notice the strong similarities of these rules with the string positive rule and the string double rule. As an example, if we take $u = 2\bar{7}4735342656$ and $v = 2\bar{7}426\bar{5}3\bar{4}7356$ given earlier, then $\text{dsdr}_{4,5} \circ \text{dspr}_3(u) = v$ and hence both legal strings indeed have a common reduction graph.

5.4.3 Intermediate Legal Strings

We now show that we can generalize the notion of reduction graph to allow for representations of any intermediate product during the reduction process. In such an intermediate product, some pointers, represented as a subset D of $\text{dom}(u)$, where u is a legal string, have not yet been used in recombination operations, while the other pointers, in $\text{dom}(u) \setminus D$, have already been used in recombination operations. A reduction graph of u with respect to this set D , denoted by $\mathcal{R}_{u,D}$, represents such intermediate product. As before, we simply ignore the pointers in D – they are put as strings on the reality edges that are now directed edges.

Figure 16 gives an example of $\mathcal{R}_{u,D}$ with $u = 2\bar{7}47353\bar{4}2656$ and $D = \{2, 4\}$ (recall that Λ represents the empty string).

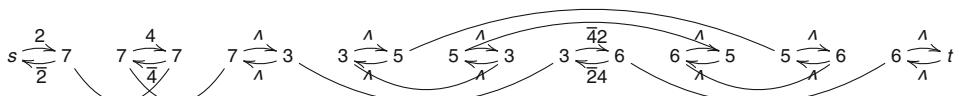

We denote the legal string obtained from a legal string u by removing the pointers from $D \subseteq \text{dom}(u)$ and its barred variants by $\text{rem}_D(u)$. In our example, $\text{rem}_D(u) = \bar{7}7353656$. We define $\text{red}(u, D)$ as the label of the alternating path from s to t . Thus, in our example $\text{red}(u, D) = 2\bar{4}\bar{4}2$. Assuming that gene assembly is intramolecular (all recombination takes place on a single DNA molecule), then the cyclic connected components must have only empty strings as edge labels. In our example, it is easy to obtain an “invalid” intermediate product: take, for example, $D = \{3, 4, 5, 6, 7\}$. Hence, it is not possible to first recombine pointer 2, followed by recombination of the remaining pointers.

Theorem 6 (Brijder et al. 2006) *Let u be a legal string, let φ be a composition of reduction rules with $\text{dom}(\varphi) \subseteq \text{dom}(u)$, and let $D = \text{dom}(u) \setminus \text{dom}(\varphi)$. Then φ is applicable to u iff φ is applicable to $\text{rem}_D(u)$ and $\text{red}(u, D)$ is a legal string with domain D . Moreover, if this is the case, then $\varphi(u) = \text{red}(u, D)$.*

As a consequence of Theorem 6, reductions φ_1 and φ_2 with the same domain have the same effect: $\varphi_1(u) = \varphi_2(u)$ for all legal strings u . Note that in general there are $D \subseteq \text{dom}(u)$ for

Fig. 16

Graph $\mathcal{R}_{u,D}$ with $u = 2\bar{7}47353\bar{4}2656$ and $D = \{2, 4\}$.

which there is no reduction φ of u with $D = \text{dom}(\varphi(u))$. In our example, $\text{red}(u, D)$ is a legal string with domain D and we have, for example, $(\text{snr}_6 \text{sdr}_{3,5} \text{spr}_7)(u) = \overline{2}\overline{4}\overline{4}2 = \text{red}(u, D)$.

5.4.4 Cyclic Components

Since the reduction graph is a representation of the end result after recombination, the cyclic components of a reduction graph represent circular molecules. If we now consider again the intramolecular model of gene assembly, we notice that each such molecule is obtained by loop recombination. Hence, although there can be many different sequences of operations that obtain the fixed end product, the *number* of loop recombination operations (string negative rules in the model) in each such sequence is the same.

Theorem 7 (Brijder et al. 2006) *Let N be the number of cyclic components in the reduction graph of legal string u . Then every successful reduction of u has exactly N string negative rules.*

Example 14 Since \mathcal{R}_u in Fig. 12 has three cyclic components, by Theorem 7, every successful reduction φ of u has exactly three string negative rules. For example, $\varphi = \text{snr}_2 \text{snr}_4 \text{spr}_7 \text{snr}_6 \text{sdr}_{3,5}$ is a successful reduction of u . Indeed, φ has exactly three string negative rules. Alternatively, $\text{snr}_6 \text{snr}_3 \text{snr}_7 \text{spr}_2 \text{spr}_5 \text{spr}_4$ is also a successful reduction of u , with a different number of (spr and sdr) operations.

It turns out that the reduction graph also allows for determining *on which pointers* the string negative rules can be applied using the pointer-component graph (Brijder et al. 2008). For convenience, one can denote $\mathcal{PC}_{\mathcal{R}_u}$ by \mathcal{PC}_u . Also, one can denote $\mathcal{PC}_u|_D$ as the graph obtained from \mathcal{PC}_u by removing the edges outside D . Finally, for a reduction φ , let $\text{snrdom}(\varphi) \subseteq \text{dom}(\varphi)$ be the (unbarred) pointers used in snr rules in φ .

Theorem 8 (Brijder et al. 2008) *Let u be a legal string, and let $D \subseteq \text{dom}(u)$. There is a successful reduction φ of u with $\text{snrdom}(\varphi) = D$ iff $\mathcal{PC}_u|_D$ is a tree.*

In our running example, we see that $D = \{2, 3, 6\}$ induces a (spanning) tree of \mathcal{PC}_u . Therefore, there is a successful reduction φ of u with $\text{snrdom}(\varphi) = D$. Indeed, we have $\text{sdr}_{4,5} \text{spr}_7(u) = 226336$. It is clear that we can extend $\text{sdr}_{4,5} \text{spr}_7$ to a successful reduction that applies string negative rules on 2, 3, and 6. Notice that here snr_3 must be applied *before* snr_6 . In fact in Brijder et al. (2009) it is shown that the possible orders in which the string negative rules can be applied is also deducible from \mathcal{PC}_u by considering rooted trees.

The results above can be carried over to intermediate products; for example, the number of string negative rules from u to $\varphi(u)$ is fixed and is equal to the number of cyclic components of $\mathcal{R}_{u,D}$.

5.5 Simple and Parallel Gene Assemblies

The general formulation of the intramolecular operations allows for the aligned pointers to be arbitrarily far from each other. We discuss in this section a *simple* variant of the model, where

all alignments and folds involved in the operations are *local*. In the simple versions of *ld*, *hi*, and *dlad*, the pointers involved in the recombination are at a minimal distance from each other. It turns out that the simple model is able to explain the successful assemblies of all currently known micronuclear gene sequences, see Cavalcanti et al. (2005), Prescott et al. (2001a), and Langille et al. (2010). In this section we discuss the molecular and the mathematical formulation of the simple model and indicate some interesting properties of the model.

In the second part of this section, a notion of *parallel gene assembly* is discussed. In each (parallel) step of the assembly, we apply a number of well-selected operations simultaneously in such a way that the total number of steps is minimal. In each step, the operations are selected in such a way that their application is independent of the others applied in the same step: All sequential compositions of those operations are applicable to the current graph. Several difficult computational problems arise in this context, including deciding whether a given graph has a parallel assembly of a given length, or deciding whether there are graphs (or even trees) of arbitrarily high parallel complexity.

5.5.1 Simple Gene Assembly

The three intramolecular operations allow in their general formulation that the MDSs participating in an operation may be located anywhere along the molecule. Arguing on the principle of parsimony, a simplified model was discussed already in Prescott et al. (2001a) and then formalized in Harju et al. (2006c), asking that all operations are applied “locally”. In the simple model, the restriction is that there is at most one coding block involved in each of the three operations. This idea was then further developed into two separate models. In one of them, which is referred to as the *simple model* (Langille and Petre 2006), both micronuclear, as well as composite MDSs (obtained by splicing of several micronuclear MDSs) may be manipulated in each of the three molecular operations. In the other, called the *elementary model* and introduced in Harju et al. (2006b, 2008c), the model was further restricted so that only *micronuclear*, but not *composite*, MDSs could be manipulated by the molecular operations. Consequently, once two or more micronuclear MDSs are combined into a larger composite MDS, they can no longer be moved along the sequence. In this section, only the simple model is discussed and for details of the elementary model one can refer to Harju et al. (2006b, 2008c), Langille et al. (2010), and Petre and Rogojin (2008).

We already discussed in [Sect. 5.1](#) that *ld* must always be *simple* in a successful assembly. As such, the effect of *ld* is that it will combine two consecutive MDSs into a bigger composite MDS. For example, consider that M_3M_4 is a part of the molecule, that is, MDS M_4 succeeds M_3 being separated by one IES I . Thus, pointer 4 has two occurrences that flank I : one in the end of MDS M_3 and the other one in the beginning of MDS M_4 . Then *ld* makes a fold as in [Fig. 6a](#) aligned by pointer 4, IES I is excised as a circular molecule and M_3 and M_4 are combined into a longer coding block as shown in [Fig. 6c](#).

In the case of *hi* and *dlad*, the pointers involved can be separated by arbitrarily large sequences; for example, in the actin I gene in *S. nova*, pointer 3 has two occurrences: one in the beginning of M_3 and one, inverted, in the end of M_2 . Thus, *hi* is applicable to this sequence with the hairpin aligned on pointer 3, even though five MDSs separate the two occurrences of pointer 3. Similarly, *dlad* is applicable to the MDS sequence $M_2M_8M_6M_5M_1M_7M_3M_{10}M_9M_4$,

with the double loops aligned on pointers 3 and 5. Here the first two occurrences of pointers 3 and 5 are separated by two MDSs (M_8 and M_6) and their second occurrences are separated by four MDSs (M_3 , M_{10} , M_9 , M_4).

An application of the *hi* operation on pointer p is *simple* if the part of the molecule that separates the two copies of p in an inverted repeat contains only one MDS and one IES. We have here two cases, depending on whether the first occurrence of p is incoming or outgoing, see [Fig. 17a](#).

An application of *dlad* on pointers p , q is *simple* if the sequence between the first occurrences of p and q , as well as the sequence between the second occurrences of p and q consist of either one MDS or one IES. We have again two cases, depending on whether the first occurrence of p is incoming or outgoing, see [Fig. 17b](#).

The simple operations can be formalized as operations on signed permutations, signed strings, and signed graphs. We only give here the definitions for the string-based operations, where the mathematical formulation is more concise. For the other formulations, including the relationships among these models, one can refer to Harju et al. (2006c), Langille et al. (2010), and Brijder and Hoogeboom (2008b).

The *simple hi* operation for pointer p , denoted sspr_p is applicable to strings of the form $u = u_1 p u_2 \bar{p} u_3$, where $|u_2| \leq 1$, resulting in $\text{sspr}_p(u_1 p u_2 \bar{p} u_3) = u_1 \bar{u}_2 u_3$.

The *simple dlad* operation for pointers p , q , denoted $\text{ssdr}_{p,q}$ is applicable to strings of the form $u = u_1 p q u_2 p q u_3$, resulting in $\text{ssdr}_{p,q}(u_1 p q u_2 p q u_3) = u_1 u_2 u_3$.

Let ϕ be a composition of *snr*, *sspr*, and *ssdr* operations such that ϕ is applicable to string u . We say that ϕ is a *simple reduction* for u if either $\phi(u) = \Lambda$ (in which case we say that φ is *successful*), or $\phi(u) \neq \Lambda$ and no simple operation is applicable to $\phi(u)$ (in which case we say that ϕ is *unsuccessful*). For example, the string reduction in [Table 1b](#) is simple, unlike the one in [Table 1a](#).

The simple model has a number of properties that do not hold for the general model. One of them concerns the length of reduction strategies for a given string. While in the general model a string may have reduction strategies of different lengths, see the example in [Table 1](#), the same is not true in the simple model, see the next result of Langille and Petre (2007). Moreover, if we consider *parallel applications of simple operations* (a notion of Langille and Petre (2007) that is not defined in this chapter), we get a new twist: for any given n there exists a string having maximal parallel reductions of any length between n and $2n$.

[Fig. 17](#)

The MDS/IES structures where (a) *simple hi*-rules and (b) *simple dlad*-rules are applicable. The MDSs are indicated by rectangles and their flanking pointers are shown. Between the two MDSs there is only one IES represented by a straight line (From Harju et al. (2006c) and Prescott et al. (2001a)).

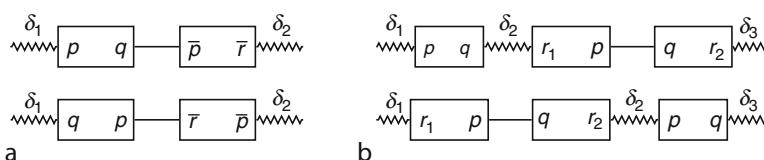

Table 1

Two reduction strategies for the signed string corresponding to the actin I micronuclear gene in *S.nova*

(a)	(b)
$u_1 = \text{spr}_3(u) = \bar{9}\bar{8}\bar{7}\bar{6}\bar{5}\bar{4}\bar{4}\bar{2}289$	$u'_1 = \text{snr}_4(u) = 356756789\bar{3}\bar{2}89$
$u_2 = \text{snr}_4(u_1) = \bar{9}\bar{8}\bar{7}\bar{6}5\bar{2}289$	$u'_2 = \text{sdr}_{5,6}(u'_1) = 37789\bar{3}\bar{2}89$
$u_3 = \text{spr}_8(u_2) = \bar{9}\bar{2}25675679$	$u'_3 = \text{snr}_7(u'_2) = 389\bar{3}\bar{2}89$
$u_4 = \text{spr}_2(u_3) = \bar{9}5675679$	$u'_4 = \text{sdr}_{8,9}(u'_3) = 3\bar{3}\bar{2}2$
$u_5 = \text{sdr}_{5,7}(u_4) = \bar{9}669$	$u'_5 = \text{spr}_2(u'_4) = 3\bar{3}$
$u_6 = \text{snr}_6(u_5) = \bar{9}9$	$u'_6 = \text{spr}_3(u'_5) = \Lambda$
$u_7 = \text{spr}_9(u_6) = \Lambda$	

Theorem 9 (Langille and Petre 2007) *Let u be a signed double occurrence string and ϕ, ψ two reduction strategies for u . Then ϕ and ψ have the same number of operations.*

Regarding the outcome of reduction strategies, the simple model is different from the general model in several respects; for example, there are strings that cannot be reduced in the simple model, unlike in the general model where all strings have reduction strategies. Indeed, no simple operation is applicable to the string $\bar{2}43423$. The following is a result of Langille and Petre (2006).

Theorem 10 (Langille and Petre 2006) *No signed string has both successful and unsuccessful reductions in the simple model.*

On the other hand, the outcome of various strategies for a given string can differ; for example, for $u = 23467856782345$, $u_1 = \text{ssdr}_{2,3} \circ \text{ssdr}_{7,8}(u) = 465645$, whereas $u_2 = \text{ssdr}_{3,4} \circ \text{ssdr}_{6,7}(u) = 285825$. The strings u_1 and u_2 are, however, identical modulo a relabeling of their letters. This observation can be extended to define a notion of *structure* that can be used to prove that the results of various reductions, although different, always have the same structure. For details, one can refer to Langille and Petre (2006), where the discussion is in terms of signed permutations, rather than signed strings.

5.5.2 Parallel Gene Assembly

The notion of parallelism is usually defined in concurrency theory for processes whose application is independent of each other. In other words, a number of processes can be applied in parallel to a signed graph if they can be (sequentially) applied in any order. Adopting this approach, the following gives the definition of parallel application of the three molecular operations on a signed graph. For a similar discussion, albeit technically more tedious, on the level of signed strings, one can refer to Harju et al. (2006a).

Definition 2 (Harju et al. 2006a) *Let S be a set of *gnr*, *gpr*, and *gdr* operations and let G be a signed graph. We say that the rules in S are applicable in parallel to G if for any ordering $\varphi_1, \varphi_2, \dots, \varphi_k$ of S , the composition $\varphi_k \circ \dots \circ \varphi_1$ is applicable to G .*

Based on the definition of parallelism, which presumes that the rules are applicable in any possible order, the following theorem shows that the result is always the same regardless of the order in which they are applied.

Theorem 11 (Harju et al. 2006a) *Let G be a signed graph and let S be a set of operations applicable in parallel to G . Then for any two compositions φ and ψ of the operations of S , $\varphi(G) = \psi(G)$.*

Based on Theorem 11, we can write $S(G) = \varphi(G)$ for any set S of operations applicable in parallel to G and any composition φ of these operations. The notion of parallel complexity is defined as follows.

Definition 3 (Harju et al. 2007) *Let G be a signed graph, and let S_1, \dots, S_k be sets of gnr, gpr, gdr operations. If $(S_k \circ \dots \circ S_1)(G) = \emptyset$, then we say that $S = S_k \circ \dots \circ S_1$ is a parallel reduction for G . In this case the parallel complexity of S is $\mathcal{C}(S) = k$. The parallel complexity of the signed graph G is:*

$$\mathcal{C}(G) = \min\{\mathcal{C}(S) \mid S \text{ is a parallel reduction strategy for } G\}.$$

Deciding whether a given set of graph operations is applicable in parallel to a given graph turns out to be a difficult problem if gdr operations are involved. When at most two gdr operations are involved, then simple characterizations were given in Harju et al. (2008a). The computational complexity of the general problem was upper bounded in the co-NP class, see Alhazov et al. (2009).

It can be easily verified that the parallel complexity of the graphs corresponding to the currently known micronuclear gene sequences is at most two, see Harju et al. (2008b). However, examples of graphs of higher complexity can be given. For example, the graph with the highest known complexity has 24 vertices and can be reduced in six parallel steps. The tree with the highest known parallel complexity has 12 vertices and can be reduced in five parallel steps. One can refer to Harju et al. (2008b) for more examples. Although the parallel complexity of certain types of graphs (e.g., for uniformly signed trees) is known to be finitely bounded, see Harju et al. (2008a), the general problem is currently open and seems to be very difficult. In particular, it seems to require a characterization for the parallel applicability of arbitrary sets of operations, another open problem. The problem is open even in seemingly simpler cases: for trees, or for negative graphs. The computational complexity of deciding whether the parallel complexity of a given graph is upper bounded by a given contact was placed in the NP^{NP} class in Alhazov et al. (2009). Two algorithms for computing the parallel complexity of signed graphs were given in Alhazov et al. (2009, 2010), both with exponential computational complexity. A visual graph editor including support for computing the parallel complexity of signed graphs can be found in Petre and Skogman (2006).

5.6 Gene Assembly by Folding and Unfolding

In this section, gene assembly is considered from a somewhat more general viewpoint. The section is based on Ehrenfeucht et al. (2002). The molecular operations provided by the gene assembly process each involve one molecule. This observation underlies the model of gene assembly as fold-and-recombine computing paradigm. For convenience, we consider

circular graphs to be representations of DNA molecules. Our initial situation is a set of circular DNA molecules represented by bicolored and labeled circular graphs. The fold-and-recombine process is reflected by a two-stage processing of the graphs: (1) fold on vertices representing pointers; (2) unfold using a pairing function. In this setup, gene assembly becomes a dynamic process for recombination graphs.

Graphs with multiple edges and loops are allowed. The vertices denote all pointers of the gene. We consider bicolored graphs, where color 1 is used to indicate an IES and color 2 is used to indicate an MDS. To represent the sequence of nucleotides comprising various (IES or MDS) segments we use a labeling of the edges.

Each edge will be oriented in both directions: $a = (x, y)$ and $\bar{a} = (y, x)$ are *reverse pairs*. Let V be a set of vertices, and consider E as a set of edge symbols such that $E = \{e_1, \dots, e_n, \bar{e}_1, \dots, \bar{e}_n\}$ with $\bar{e}_i = e_i$. A (*general*) *bicolored graph* G consists of an *end point map* $\varepsilon_G = \varepsilon: E \rightarrow V \times V$ such that $\varepsilon(\bar{e}) = \varepsilon(e)$ for all $e \in E$; a *labeling* $f_G = f: E \rightarrow \Sigma^*$ for an alphabet Σ , with $f(\bar{e}) = \bar{f}(e)$ for all $e \in E$; a *coloring* $h_G = h: E \rightarrow \{1, 2\}$ such that $h(e) = h(\bar{e})$ for all $e \in E$.

For simplicity, we write $e = (x, y)$ for $\varepsilon(e) = (x, y)$. An edge $e = (x, y) \in E$ is a *loop*, if $x = y$. The *valency* $\text{val}_G(x)$ of a vertex x is the number of edges leaving x . A bicolored graph is *even* if its valencies are all even. A bicolored graph G is a *recombination graph*, if $\text{val}_G(x) \in \{2, 4\}$ for all x , and every vertex of valency 4 is balanced: two incident edges have color 1 and the other two have color 2; see Fig. 18a.

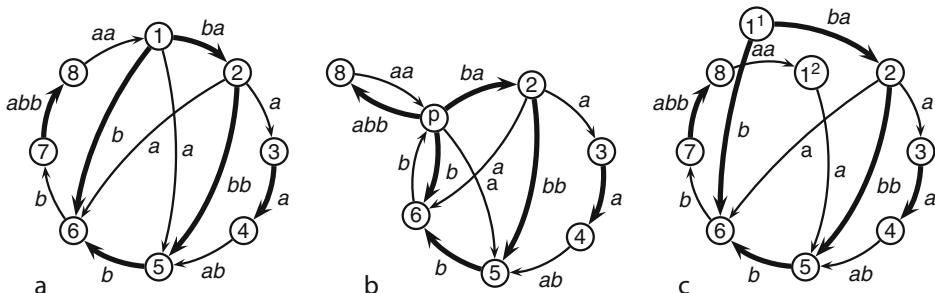

For each vertex x in an even bicolored graph G let ψ_x be a bijection that maps incoming edges to outgoing edges respecting inversions, such that $\psi_x(\overline{\psi_x(e)}) = \bar{e}$ and $\psi_x(e) = \bar{e}$ if and only if e is a loop. Then the map $\psi: x \mapsto \psi_x$ is a *pairing*. Each recombination graph G has the *natural pairing* ψ where e and $\psi_x(e)$ have the same color whenever $\text{val}_G(x) = 4$.

5.6.1 Folding and Unfolding

A pair $p = \{x, y\} \in E(V)$ will be called a *pointer* with *ends* x and y . A set P of mutually disjoint pointers is a *pointer set*. The p -*folded graph* $G * p$ is obtained by identifying the ends of p ; see Fig. 18a, b. For a pointer set $\{p, q\}$, $G * p * q = G * q * p$. This allows one to define, for a pointer set $P = \{p_1, \dots, p_m\}$, the P -*folded graph* $G * P$ as $G * p_1 * \dots * p_m$.

Fig. 18

(a) A recombination graph, where color 1 is represented by thick edge. (b) The p -folded graph $G * p$ for $p = \{1, 7\}$. (c) The ψ -unfolded graph $G \diamond_{\psi} 1$ with the natural pairing (from Ehrenfeucht et al. (2002)).

Let G be an even bicolored graph with a pairing ψ . For a vertex x , let $e_{11}, e_{12}, \dots, e_{m1}, e_{m2}$ be the incoming edges with $\psi_x(e_{il}) = \bar{e}_{l2}$. In the ψ -unfolded graph, the vertex x is replaced by the new vertices x^1, \dots, x^m and the edges are redirected according to the pairing ψ_x ; see [Fig. 18c](#), where the redirection is determined by the colors.

Notice that if G is a recombination graph, so is $G \diamond_\psi x$. Also, if $x \neq y$, then $G \diamond_\psi x \diamond_\psi y = G \diamond_\psi y \diamond_\psi x$. Therefore, we can write $G \diamond_\psi A = G \diamond_\psi x_1 \diamond_\psi \dots \diamond_\psi x_m$ for a subset $A = \{x_1, \dots, x_m\}$.

For an even bicolored graph G with a pairing ψ , let $F(G) = \{x \in V_G \mid \text{val}_G(x) \geq 4\}$. Then the graph $G \diamond_\psi F(G)$ is called the ψ -unfolded graph of G .

Lemma 1 (Ehrenfeucht et al. 2002) *If G is an even bicolored graph with a pairing ψ , then its ψ -unfolded graph is a disjoint union of cycles.*

Let G be a bicolored graph with a pointer set P , and let ψ be a pairing of the P -folded graph $G * P$. We denote $G \circledast_\psi P = (G * P) \diamond_\psi P$. We shall write $G \circledast P$ for $G \circledast_\psi P$, if $G * P$ is a recombination graph and ψ is its natural pairing.

Lemma 2 (Ehrenfeucht et al. 2002) *Let G be a disjoint union of bicolored cyclic graphs. Let P be a pointer set of G , and let ψ be a pairing of $G * P$. Then $G \circledast_\psi P$ is a disjoint union of bicolored cyclic graphs.*

5.6.2 Assembled Graphs of Genomes

Let G be a bicolored cyclic graph with $V_G = \{x_1, \dots, x_n\}$ and the edge set $E_G = \{e_1, \dots, e_n, \bar{e}_1, \dots, \bar{e}_n\}$, where $e_i = (x_i, x_{i+1})$ and $x_{n+1} = x_1$. A vertex x_i is a *boundary vertex* of G , if $h_G(e_{i-1}) \neq h_G(e_i)$, where $i - 1$ is modulo n . A path π is a *segment*, if its edges have color 1 and the ends of π are boundary vertices. For a disjoint union $G = \sum_{i=1}^m G_i$ of bicolored cyclic graphs G_i , we let its boundary vertex set be the union of corresponding sets of the components.

A pair $\mathcal{G} = (G, P)$ is called a *genome*, if G is a disjoint union of bicolored cyclic graphs and P is a pointer set of G containing boundary vertices only; see [Fig. 19](#).

The *assembled genome* of a genome $\mathcal{G} = (G, P)$ is $A(\mathcal{G}) = (G \circledast P, \emptyset)$, and it is a genome. Each segment of the unfolded graph $\gamma \circledast P$ is a *gene*.

Fig. 19

The genome (G, P) with $P = \{p, q\}$ for $p = \{2, 9\}$ and $q = \{5, 8\}$. The labels correspond to the MDSs M_1, M_2, N_1 and P_1, P_2 . The labels corresponding to IESs are omitted (from Ehrenfeucht et al. (2002)).

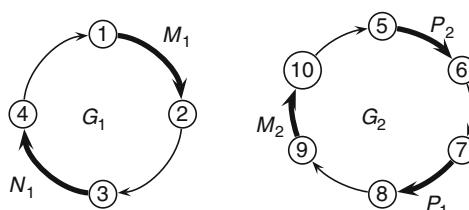

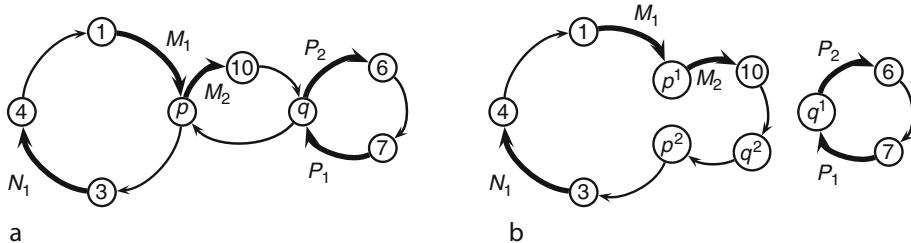

Fig. 20

Let \mathcal{G} be the genome of Fig. 19. Then $\mathcal{G} * P$ is given in (a). Unfolding gives $\mathcal{G} \circledast P$ in (b). The genes of \mathcal{G} are $g_1 : 1 \rightarrow p^1 \rightarrow 10$ (with the value $M_1 M_2$), $g_2 : 7 \rightarrow q^1 \rightarrow 6$ (with the value $P_1 P_2$), and $g_3 : 3 \rightarrow 4$ (with the value N_1) (from Ehrenfeucht et al. (2002)).

For $\mathcal{G} = (G, P)$, a sequence $\mathcal{S} = (P_1, P_2, \dots, P_m)$ of subsets of P is an *assembly strategy* of \mathcal{G} , if $\{P_1, \dots, P_m\}$ is a partition of P . One can show that in a genome $\mathcal{G} = (G, P)$, if $P_1, P_2 \subseteq P$ are disjoint, then $(G \circledast P_1) \circledast P_2 = G \circledast (P_1 \cup P_2) = (G \circledast P_2) \circledast P_1$. This gives the following general invariance property.

Theorem 12 (Ehrenfeucht et al. 2002) *Every assembly strategy $\mathcal{S} = (P_1, P_2, \dots, P_m)$ of a genome produces the same assembled genome $\mathcal{G} = (G, P)$: $G \circledast P = G \circledast P_1 \circledast P_2 \circledast \dots \circledast P_m$.*

A pointer set $R \subseteq P$ of $\mathcal{G} = (G, P)$ is *intracyclic*, if any two parts g' and g'' of each gene g that lie in the same connected component of G , lie in the same connected component of $G \circledast R$. The unfolding of a genome is illustrated in Fig. 20.

Theorem 13 (Ehrenfeucht et al. 2002) *For each genome \mathcal{G} , there exists an intracyclic assembly strategy $\mathcal{S} = (P_1, P_2, \dots, P_m)$ such that $1 \leq |P_i| \leq 2$ for all i .*

We can also show that the following stronger result holds.

Theorem 14 (Ehrenfeucht et al. 2002) *Let $\mathcal{G} = (G, P)$ be a genome for a connected $G \circledast P$. Then there is a genome $\mathcal{G}' = (G', P')$, where G' is connected, such that $A(\mathcal{G}) = A(\mathcal{G}')$, and \mathcal{G}' has an assembly strategy $\mathcal{S} = (P_1, P_2, \dots, P_m)$ of \mathcal{G}' for which $1 \leq |P_i| \leq 2$ for all i , and each $G \circledast \bigcup_{i=1}^j P_i$ is a cyclic graph for each j .*

6 Invariant Properties of Gene Assembly

As discussed already in this chapter, both an intermolecular model and an intramolecular model exist for gene assembly. Moreover, both models are nondeterministic: For a given gene, there may be several assembly strategies and also, a gene may be assembled either on a linear, or on a circular molecule. As such, a natural question is that of *invariants*: What properties of the assembled gene and of the assembly process hold for all assembly strategies of both models? For example, for a given gene, is the set of molecules excised during the assembly an invariant of the process? The same question for whether or not the assembled gene is linear or cyclic, and for whether or not the obtained structure of the IESs is fixed for given gene is also open.

An affirmative answer to these questions was given already in Ehrenfeucht et al. (2001a) for the intramolecular model, showing that these properties are invariants of the intramolecular model. We follow here a presentation of Petre (2006), where the result is given in a stronger form, showing that the properties above are invariants of *any model based on the paradigm of pointer-directed assembly*. This result may also be deduced based on the graph-theoretical framework of Ehrenfeucht et al. (2002). The presentation given in this section is in terms of strings and permutations. One can refer to Petre (2006) for more details, examples, and full proofs.

6.1 Gene Structure

In this section, we introduce a novel formal representation for the gene structures of ciliates, able to track the transformations witnessed by a gene from its micronuclear form to its assembled form. A gene is first represented as a signed permutation over the alphabet of MDSs by denoting their sequence and orientation. Our notation is then extended to denote also the IESs and all the pointers.

It can be recalled that $u, v \in \Sigma^*$ are called *equivalent*, denoted $u \approx v$, if u is a conjugate of either v or \bar{v} . Two finite sets $X_1, X_2 \subseteq \Sigma^*$ are called *equivalent*, denoted $X_1 \approx X_2$, if they have the same number of elements and for any $x_i \in X_i$ there is $x_j \in X_j$ such that $x_i \approx x_j$, with $i, j = 1, 2, i \neq j$. Intuitively, if u denotes a circular DNA molecule and $u \approx v$, then v denotes the same molecule, potentially starting from a different nucleotide and/or in the reverse direction. Similarly, if X_1 denotes a set of circular molecules and $X_1 \approx X_2$, then X_2 denotes the same set of molecules.

We denote the MDSs of the given gene by letters from the alphabet $\mathcal{M}_n = \{M_1, M_2, \dots, M_n\}$ in the order they occur in the macronuclear gene, where $n \geq 1$. Thus, the sequence of MDSs in the macronuclear gene is $M_1 M_2 \dots M_n$. On the other hand, the sequence of MDSs in the micronuclear gene is in general a signed permutation over \mathcal{M} .

Example 15 The MDSs of the micronuclear gene actin I in *S. nova* may be represented as the signed permutation $M_3 M_4 M_6 M_5 M_7 M_9 \bar{M}_2 M_1 M_8$, see Prescott and DuBois (1996). In this gene, MDS M_2 is inverted.

We call \mathcal{M}_n -descriptor any signed permutation over \mathcal{M}_n . We say that μ is an *assembled \mathcal{M}_n -descriptor* if μ or $\bar{\mu}$ is of the form $M_i \dots M_n M_1 \dots M_{i-1}$, for some $1 \leq i \leq n$.

Consider now the alphabet of IESs $\mathcal{I}_n = \{I_0, I_1, \dots, I_n\}$. For any $J \subseteq \mathcal{M}_n \cup \mathcal{I}_n$, a signed permutation over J will be called an \mathcal{MIJ}_n -descriptor.

Let π_n be the projection $\pi_n : (\mathcal{M}_n \cup \mathcal{I}_n)^* \rightarrow \mathcal{M}_n^*$. We say that $\delta \in (\mathcal{M}_n \cup \mathcal{I}_n)^*$ is an *assembled \mathcal{MIJ}_n -descriptor* if $\pi_n(\delta)$ is an assembled \mathcal{M}_n -descriptor.

We can associate an \mathcal{MIJ}_n -descriptor to any \mathcal{M}_n -descriptor as follows. Let $\mu = \tilde{M}_{i_1} \tilde{M}_{i_2} \dots \tilde{M}_{i_n}$ be an \mathcal{M}_n -descriptor, where $\tilde{M}_{i_k} \in \{M_{i_k}, \bar{M}_{i_k}\}$ and i_1, i_2, \dots, i_n is a permutation over $\{1, 2, \dots, n\}$. Then the \mathcal{MIJ}_n -descriptor associated to μ is $\tau_\mu = I_0 \tilde{M}_{i_1} I_1 \tilde{M}_{i_2} I_2 \dots \tilde{M}_{i_n} I_n$. We denote by I_0, I_1, \dots, I_n the noncoding blocks separating the MDSs. We say in this case that τ_μ is a *micronuclear \mathcal{MIJ}_n -descriptor*.

Example 16 (i) The \mathcal{MIJ}_9 -descriptor associated to the actin I gene in *S. nova*, see Example 15, is $I_0 M_3 I_1 M_4 I_2 M_6 I_3 M_5 I_4 M_7 I_5 M_9 I_6 \bar{M}_2 I_7 M_1 I_8 M_8 I_9$.

(ii) $\delta = I_0 \bar{I}_3 \overline{M}_3 \overline{M}_2 \overline{M}_1 I_2 I_1$ is an assembled \mathcal{M}_3 -descriptor.

The \mathcal{MI}_n -descriptors can now be extended to include also the information about the position of pointers in the gene. Consider then the alphabet $\mathcal{P}_n = \{2, 3, \dots, n\}$ and denote the markers by b and e . Denote $\Sigma_n = \mathcal{M}_n \cup \mathcal{I}_n \cup \mathcal{P}_n \cup \{b, e\}$ and let π_n be the projection $\pi_n : \Sigma_n^* \rightarrow (\mathcal{M}_n \cup \mathcal{I}_n)^*$. We say that $\sigma \in \Sigma_n^*$ is a Σ_n -descriptor if it has one of the following forms:

- (i) $\sigma = \alpha_0 p_1 p_1 \alpha_1 p_2 p_2 \dots p_k p_k \alpha_k \alpha_0 \alpha_k \neq \Lambda$ or
- (ii) $\sigma = p_1 \alpha_1 p_2 p_2 \dots p_{k-1} p_{k-1} \alpha_k p_1$

where $k \geq 0$, $p_i \in \mathcal{P}_n \cup \overline{\mathcal{P}}_n$, $\alpha_i \in (\Sigma_n \setminus \mathcal{P}_n)^*$, for all $0 \leq i \leq k$ and moreover, $\pi_n(\sigma)$ is a \mathcal{MI}_n -descriptor. In case (i), we call σ *linear*, and in case (ii) we call it *circular*. We say that σ is *assembled* if $\pi_n(\sigma)$ is an assembled \mathcal{MI}_n -descriptor.

Example 17 (i) $\sigma_1 = 22M_233M_3 eI_2\bar{I}_3 bM_122$ is an assembled circular Σ_3 -descriptor.

- (ii) $\sigma_2 = I_022M_233I_1\bar{2}\bar{2}\bar{M}_1\bar{b}I_233 M_3eI_3$ is a linear micronuclear Σ_3 -descriptor.
- (iii) $\sigma_3 = 22M_23M_3eI_2\bar{I}_3 bM_122$ is not a Σ_3 -descriptor.

Every MDS of micronuclear ciliate genes is flanked at its both ends by a pointer or a marker. We denote the pointers flanking MDS M_i by writing $iiM_i(i+1)(i+1)$. For M_1 and M_n we write bM_122 and nnM_ne , respectively. We use a double letter notation for pointers in order to deal with splicing in a simple way in [Sect. 6.2](#). Formally, to associate a Σ_n -descriptor to an \mathcal{MI}_n -descriptor, consider the morphism $\phi_n : (\mathcal{M}_n \cup \mathcal{I}_n)^* \rightarrow \Sigma_n^*$ defined as follows: $\phi_n(I) = I$, for all $I \in \mathcal{I}_n$; $\phi_n(M_i) = iiM_i(i+1)(i+1)$, for all $2 \leq i \leq n-1$; $\phi_n(M_1) = bM_122$ and $f(M_n) = nnM_ne$. For any \mathcal{MI}_n -descriptor δ , we say that $\phi_n(\delta)$ is the Σ_n -descriptor *associated* to δ . It can be said that $\phi_n(\delta)$ is a *micronuclear* Σ_n -descriptor if δ is a micronuclear \mathcal{MI}_n -descriptor. Note that all micronuclear Σ_n -descriptors are linear.

Example 18 The micronuclear Σ_9 -descriptor of the actin I gene in *S.nova*, see Example 16, is $I_033M_344I_144M_455I_266M_677I_355M_566I_477M_788I_599M_9eI_6\overline{33M}_2\bar{2}\bar{2}I_7bM_122I_888M_899I_9$.

For any micronuclear Σ_n -descriptor σ and any $p \in \mathcal{P}_n$, σ contains two occurrences from the set $\{pp, \bar{p}\bar{p}\}$: pp represents the pointer in the beginning of MDS M_p and at the end of M_{p-1} , while $\bar{p}\bar{p}$ is its inversion.

6.2 Invariants

In this section, we give a number of invariants of the gene assembly process: the circularity of the assembled gene (whether or not the gene is assembled on a circular molecule), with the IES-context of the gene (the sequence of IESs preceding and succeeding the assembled gene), but also with the set of molecules excised during assembly. It is worth emphasizing that we establish all these properties based solely on the generic paradigm of pointer-directed assembly, independently of the specificities of either the intra-, or the inter-molecular model.

During the pointer-directed assembly, ciliates allegedly align their DNA molecules along their pointers, and through recombination they sort the MDSs in the orthodox order. It is essential to observe that in this process, the two strands of any pointer p will be separated: One strand will remain with the block preceding the pointer, while the other strand will remain

with the block succeeding the pointer. The single strands will then recombine with the complementary strands obtained by separating in a similar way the second occurrence of p in the gene. This splicing on pointers can be formalized by a word-cutting operation defined in the following.

Let σ be a Σ_n -descriptor. If σ is linear, $\sigma = \alpha_0 p_1 p_1 \alpha_1 p_2 p_2 \alpha_2 \dots \alpha_{k-1} p_k p_k \alpha_k$, with $p_i \in \mathcal{P}_n \cup \overline{\mathcal{P}}_n$, $\alpha_i \in (\Sigma_n \setminus \mathcal{P}_n)^\pm$, then $W_\sigma = \{\alpha_0 p_1, p_k \alpha_k, p_i \alpha_i p_{i+1} \mid 1 \leq i < k\}$. If σ is circular, $\sigma = p_1 \alpha_1 p_2 p_2 \alpha_2 \dots \alpha_{k-1} p_k p_k \alpha_k p_1$, then $W_\sigma = \{p_i \alpha_i p_{i+1}, p_k \alpha_k p_1 \mid 1 \leq i < k\}$. For any set $S \subseteq \Sigma_n^\pm$, we denote $W_S = \cup_{\sigma \in S} W_\sigma$. Note that the set W_σ is equivalent to the set of edges of genome graphs (☞ Sect. 5.6) and to the reality edges of reduction graphs (☞ Sect. 5.2).

It is important to note that we do not conjecture that ciliates split their genes by cutting simultaneously on each pointer, to yield on the scale of 10^5 MDSs and IESs, followed then by a precise reassembly of all these blocks. Indeed, it is difficult to imagine that such a mechanism would lead to the precise effective assembly that we see in ciliates. Here we merely represent those pointer-delimited coding and noncoding blocks that will be eventually reshuffled to assemble the gene. Our main result states that, given the fixed order in which MDSs must be assembled, the pointer-directed assembly of all the other blocks (IESs) is uniquely determined by the micronuclear structure of the gene.

Example 19 For the Σ_9 -descriptor σ in Example 18, we have

$$W_\sigma = \{I_03, 3M_34, 4I_14, 4M_45, 5I_26, 6M_67, 7I_35, 5M_56, 6I_47, 7M_78, 8I_59, \\ 9M_9eI_6\bar{3}, \bar{3}\overline{M_22}, \bar{2}I_7bM_12, 2I_88, 8M_89, 9I_9\}.$$

Our invariant theorem may be stated now as follows.

Theorem 15 (Petre 2006) *Let σ be a micronuclear Σ_n -descriptor.*

- (i) *There exists a set \mathcal{A}_σ of Σ_n -descriptors such that*
 - (a) $W_\sigma \cup \overline{W_\sigma} = W_{\mathcal{A}_\sigma} \cup \overline{W_{\mathcal{A}_\sigma}}$
 - (b) *there exists an assembled Σ_n -descriptor in \mathcal{A}_σ*
- (ii) *For any other set S of Σ_n -descriptors, if S satisfies conditions (a)-(b) above, then $S \approx \mathcal{A}_\sigma$*

Moreover, \mathcal{A}_σ consists of exactly one linear Σ_n -descriptor and possibly several circular ones.

Theorem 15 may be stated informally by saying that the final result of gene assembly, including the molecule where the assembled gene is placed, as well as all the other noncoding molecules excised in the process, is unique.

Example 20 Consider the Σ_9 -descriptor σ associated to gene actin I in *S.nova* in Example 18, with W_σ given in Example 19. It follows from Theorem 15 that the results of assembling the gene are

$$\{I_03\bar{3}\bar{I}_6\bar{e}\overline{M_9}\overline{99M_8}\overline{88M_7}\overline{77M_6}\overline{66M_5}\overline{55M_4}\overline{44M_3}\overline{33M_2}\overline{22M_1}\bar{b}\bar{I}_722I_888I_599I_9, 4I_14\}.$$

Thus, the noncoding block $4I_14$ is excised as a circular molecule and the gene is assembled linearly in the inverse order from $\overline{M_9}$ to $\overline{M_1}$ with the noncoding block $I_03\bar{3}\bar{I}_6$ preceding it and $\bar{I}_722I_888I_599I_9$ succeeding it.

Note that Theorem 15 holds both for the intra-molecular and the inter-molecular models for gene assembly. Consequently, the set of molecules generated by the assembly cannot be

used to distinguish between different assembly strategies, either intramolecular, or intermolecular. Instead, to (in)validate either model, one could experimentally identify the sets of molecules generated at various stages of the assembly and verify it against the predictions made by the two models.

Our results hold also in a more general way. We have proved that the final result \mathcal{A}_σ of assembling a micronuclear Σ_n -descriptor σ is unique modulo conjugation and inversion. As a matter of fact, our proofs apply unchanged also to the following variant proved in Brijder et al. (2006) for the intramolecular model. Let $P \subseteq \mathcal{P}_n$. There exists a unique (modulo conjugation and inversion) set $\mathcal{A}_{P,\sigma}$ of Σ_n -descriptors with the following property: $M_{p-1}ppM_p \leq \alpha$ for some $\alpha \in \mathcal{A}_{P,\sigma} \cup \overline{\mathcal{A}_{P,\sigma}}$ if and only if $p \in P$. In other words, if the assembly is to be done only on a given set P (that may be different from the total set \mathcal{P}_n), then the result is unique. To prove the result, it is enough to replace the morphism ϕ_n in [Sect. 6.1](#) with a morphism $\phi_{P,n}$ that only inserts pp in case $p \in P$. This extension of Theorem 15 does not contradict the non-determinism of gene assembly: The ciliate may choose to reduce the pointers in any order. The result above only says that after assembling on a *fixed* set of pointers, the result, including the excised molecules, is unique.

7 Template-Guided Recombination

In the previous sections, we have considered models that take an abstract view of the gene assembly process in ciliates. A lower, implementation-oriented, level of abstraction is considered next in which we attempt to begin addressing the question of how the assembly process takes place *in vivo*. Our quest for the discovery of the “biological hardware” responsible for implementing assembly begins with a simple examination of how MDSs might overlap to fit together, in the correct order, while also removing IESs. As has been noted above, each MDS is flanked by pointer sequences – that is, looking at the level of DNA sequence, there will be a proper suffix of MDS n that is equal to a proper prefix of MDS $n + 1$. Considering this type of structure for an entire gene of several MDSs, a computer scientist will immediately recognize the *linked list data structure*: the core of the MDS is the data while the pointer sequence indicates the “address” of the next data item (MDS). The initial state of MDSs, distributed throughout the MIC, is reminiscent of the nonlinear distribution of linked list data in heap memory. It is worth noting that the ciliate data structure is, in fact, significantly more sophisticated than a classic linked list; whereas each element of a linked list contains two separate components, an area for a data payload and an area for a pointer to the next element, the ciliate version of the linked list actually combines these two elements. Since the pointers always lie within the MDSs, the pointer to the next MDS is also part of the “data” contained in the MDS and is fully integrated into the assembled gene.

Completing the process of gene assembly, starting with the MIC and ending with the MAC, can be seen as implementing a linked-list specification. However, it does not appear that the pointers alone are guiding this implementation process as some of them may be too short to serve as unique pointers to the following MDSs. Yet the pointer sequences are still always present. A natural question to be answered by any suggested implementation of gene assembly is thus: “what role do the pointers play and why are they present?”

A realistic, biologically implementable, model must incorporate a number of principal features. It must be *irreversible*, it must be *self-propagating* or *reusable*, it cannot be sequence specific, that is, it cannot rely on the presence of certain fixed sequences, as a huge variety of pointer sequences are known (instead it must be *configuration specific*), and it must have some

mechanism for identifying the MDS/IES boundary and hence the pointers. The basic DNA template model of *template-guided recombination* was introduced in Prescott et al. (2001b) to address exactly these requirements that will be clarified in more detail after describing the model.

7.1 DNA Template-Guided Recombination

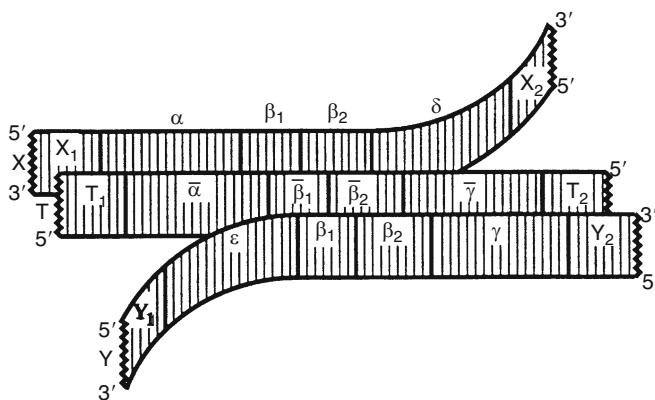

We consider here a schematic view of DNA as a picket fence with the sugar-phosphate backbones running horizontally along the top and bottom of the strand and the hydrogen bonds running vertically between the backbones. Suppose now that one wishes to assemble two strands of DNA, X and Y, having the sequences $X_1\alpha\beta\delta X_2$ and $Y_1\epsilon\beta\gamma Y_2$, respectively, where $\beta = \beta_1\beta_2$. In order to guide this assembly, we assume the existence of a DNA template T of the form $T_1\alpha\beta\gamma T_2$, which is placed in-between the two target strands X and Y, as seen in [Fig. 21](#). Note that we use the notation $\bar{\alpha}$ to denote the Watson–Crick complement of the DNA sequence α and that, in [Fig. 21](#), the $\alpha\beta$ region of X is now aligned with $\bar{\alpha}\beta$ on the template; similarly, $\beta\gamma$ of Y is aligned with its complement on the template. At the same time, the sequence of δ , beginning from the first nucleotide, must not be complementary to γ and, in a similar way, ϵ must not be complementary to α . It is important to note that X and Y need not be physically disconnected independent strands but may instead be different regions of a single, connected, strand of DNA.

The template-guided recombination now takes place in these principal steps:

- The hydrogen bonds in the $\alpha\beta_1$ region of X and the $\bar{\alpha}\beta_1$ in the template are broken and switch from binding the backbones within X and Y vertically to binding complementary sequence horizontally between X and Y; likewise for the second half of the template. In our fence analogy, the vertical pickets within DNA double-strands are replaced by floors and roofs across DNA strands, as pictured in [Fig. 22](#).
- Cuts are now made in the backbones of the roof/floor assembly (at the ends of the roof/floor structures) to yield the free-standing structure of [Fig. 23](#).
- The same cuts also yield a new copy of the original template strand, shown in [Fig. 24](#), and the strands $Y_1\epsilon\beta_1$ and $\beta_2\delta X_2$ (not pictured) that are left free to float away.

[Fig. 21](#)

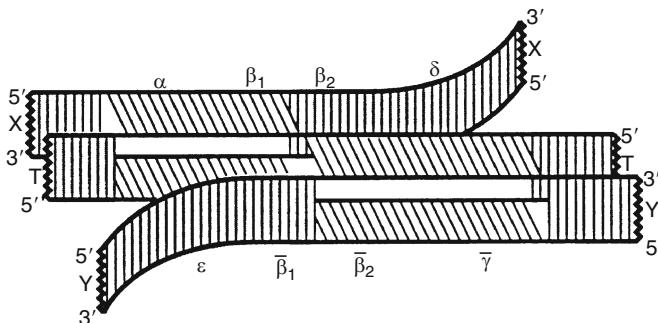

Sequences $X_1\alpha\beta\delta X_2$ and $Y_1\epsilon\beta\gamma Y_2$ stacked with DNA template $T_1\alpha\beta\gamma T_2$ in-between (from Prescott et al. (2001b)).

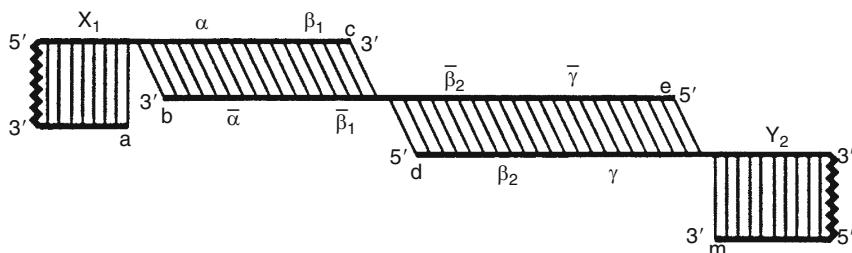

- The roof and floor structures of [Fig. 23](#) rotate to align the cut backbones that are then healed (via ligation) yielding the complete double-stranded DNA $X_1\alpha\beta\gamma Y_2$, which is the recombination of the prefix $X_1\alpha\beta_1$ of X and the suffix $\beta_2\gamma Y_2$ of Y – thus X and Y have been recombined.
- Likewise, the roof and floor structures of [Fig. 24](#) rotate, align, and ligate to yield $T_1\bar{\alpha}\bar{\beta}\bar{\gamma}T_2$ – thus the template is reconstituted.

Fig. 22

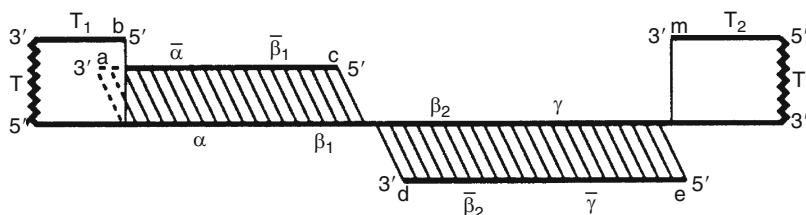

Hydrogen bonds switch from being vertical pickets holding individual strands together to forming floors and roofs across strands (from Prescott et al. (2001b)).

**Fig. 23**

One of the products resulting from cuts made in the backbones of the configuration of [Fig. 22](#) (from Prescott et al. (2001b)).

**Fig. 24**

The reconstituted template, resulting from cuts made in the backbones of the configuration of [Fig. 22](#) (from Prescott et al. (2001b)).

It can be seen clearly that the model, when considered in symbolic terms (as often done in computer science), meets our requirements for a biologically implementable system. The process of template-guided recombination may be described by the following implication:

$$\alpha\beta\delta + \alpha\beta\gamma + \epsilon\beta\gamma \Rightarrow \alpha\beta\gamma + \alpha\beta\gamma + \epsilon\beta_1 + \beta_2\delta$$

where $\beta_1\beta_2 = \beta$. On the left side, we have the first term consisting of the required subsequences for X , the second term is the template, and the third term is the required subsequence of Y . On the right side, the first term expresses the form of X recombined with Y , the form of the reconstituted template, and the last two terms are the forms of the “loose ends.” Note that we must have the components on the left side present in order for the reaction to take place. If they are present, this equation describes *what* happens, though not how it happens, and what we obtain is the four products on the right side. Note carefully that from this moment on, no three components of the right-hand side have the form required of the three components of the left-hand side – thus the process is irreversible (one-way).

Examining the right side, we see $\alpha\beta\gamma$ twice, demonstrating that the template in this model is self-propagating: we begin with one component $\alpha\beta\gamma$ on the left-hand side and after a single iteration we get two such components. Hence as the process progresses iteratively, we have an explanation of the growth of the number of available templates. Thus even if we begin with only a single copy of the template, we very quickly end up with an “abundance” of templates. This is necessary as we recall from [Sect. 2](#) on ciliate biology that many copies of the MIC chromosomes are present during the polytene chromosome stage so that multiple copies of each template are required to successfully assemble a full MAC genome.

Further, it is clear that the whole three-step process does not depend on *specific* sequences α, β, γ ; indeed, all that matters is the relationship between the sequences that causes the formation of a particular configuration.

Considering this process carefully, the true nature of pointers becomes apparent: Pointers are sequence segments within which the transfer of roofs, and dually the transfer of floors, takes place. Consequently, the most essential backbone cuts of the recombination process will take place in the pointer region. Pointers are records of transfers. Hence, in our scheme, pointers are the regions denoted $\beta = \beta_1\beta_2$ while $\alpha\beta$ and $\beta\gamma$ correspond to MDSs M_i and M_{i+1} .

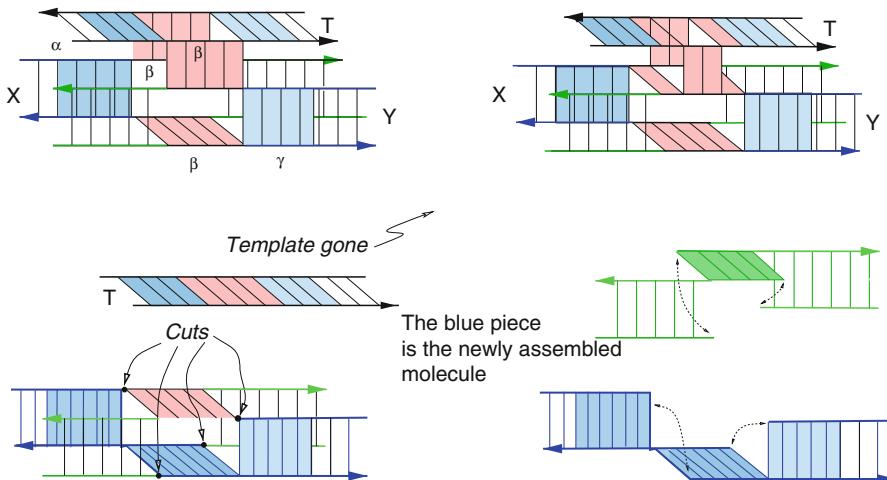

7.2 RNA Template-Guided Recombination

A variant of DNA template-guided recombination has been proposed in Angeleska et al. ([2007](#)), which considers *RNA templates*. Following through the steps of the DNA template model, one can see that a portion of the template strand ends up being incorporated into the final assembled product; this presents no problem for DNA templates but is infeasible with RNA templates since DNA and RNA backbones are incompatible. Rather than proposing a template which sits “in-between” the strands to be assembled, the RNA template model suggests a template that “hangs above” the strands to be recombined, guiding the recombination but never directly participating in it.

Consider DNA strands $\alpha\beta\delta$ and $\epsilon\beta\gamma$ again containing the MDSs $\alpha\beta$ and $\beta\gamma$ and a double-stranded RNA template molecule $\alpha\beta\gamma$. We stack the two substrate strands in tandem, as in the DNA model, but place the template horizontally above, rather than between, the substrates as in [Fig. 25](#). The $\bar{\beta}$ sequence of the RNA template begins to form hydrogen bonds with the sequence β in one of the substrates; note that while the backbones are incompatible,

Fig. 25

Reading left to right, top to bottom: The RNA template forms hydrogen bonds with β and $\bar{\beta}$ in the substrate strands, causing the formation of a floor between strands. When the RNA template is removed, a roof structure is now formed. Four cuts are made, followed by backbones swinging back into position and being healed to form the assembled strand (from Angeleska et al. (2007)).

it is certainly possible for RNA and DNA to share hydrogen bonds across two strands. The complementary strand of the template RNA similarly binds to the other substrate strand. With the internal “picket fence” hydrogen bonds of the substrate strands broken, the complementary portions at the bottom of each strand now form a floor of hydrogen bonds. If the RNA template is now removed, the complementary strands at the top of the substrates will form a roof of hydrogen bonds. Cutting the DNA backbones in the four places indicated in **Fig. 25** and rotating, followed by healing (ligation), the broken backbones similarly to the DNA model yields a correctly assembled DNA strand.

Note carefully that the RNA template is not integrated into the resulting structure; rather, the RNA template served only to break up the hydrogen bonds in the β region of the substrate strands, inducing the formation of a floor of hydrogen bonds between the two substrates, which then induced the formation of a complementary roof structure following the removal of the RNA template.

Yet another similar approach requires only a single-stranded RNA template, which is placed “diagonally” between the two DNA picket fence strands (details are given in Angeleska et al. (2007)).

The development of theoretical models of template-guided recombination has helped to direct biological inquiry into core questions surrounding gene assembly. It is natural, from a biological perspective, to ask where templates might originate. Both the RNA and DNA template-guided models suggest that templates are composed of sequence that is highly similar to that in the old MAC. Recent experimental results in the ciliate *Oxytricha trifallax* (*Sterkiella histriomuscorum*), guided by the insight provided in the theoretical models, support the hypothesis that short MAC-specific RNA templates are involved in gene assembly (Nowacki

et al. 2008). We also point out that the appendix of Angeleska et al. (2007) contains a straightforward RNA-template-combination explanation for the molecular operations Id , hi , and dlad introduced in [Sect. 5](#), which are the basis of the intramolecular models presented in this chapter.

7.3 Template-Guided Recombination on Words and Languages

We move now to consider theoretical research on the template model. Together with combinatorial models discussed in preceding sections, the theoretical work concerning the template model provided both some new insights into the nature of gene assembly and a whole spectrum of novel and interesting notions, models, and results for theoretical computer science.

A formal language theoretic version of the basic *DNA template-guided recombination* (abbreviated TGR) operation of Prescott et al. (2001b) was first studied in Daley and McQuillan (2005b). For words $x, y, z, t \in \Sigma^*$ and natural numbers $n_1, n_2 \geq 1$, we denote by z , the product of the recombination of x and y , guided by template t , by $(x, y) \vdash_{t, n_1, n_2} z$. More specifically, if $x = u_1\alpha\beta v_1$, $y = v_2\beta\gamma u_2$, $t = \alpha\beta\gamma$ with $\alpha, \beta, \gamma, u_1, u_2, v_1, v_2 \in \Sigma^*$, $|\alpha|, |\gamma| \geq n_1$ and $|\beta| = n_2$, then we may write the TGR product $z = u_1\alpha\beta\gamma u_2$. If $T, L \subseteq \Sigma^*$ are languages, then $\pitchfork_{T, n_1, n_2}(L)$ is defined by

$$\pitchfork_{T, n_1, n_2}(L) = \{z : \exists x, y \in L, t \in T \text{ such that } (x, y) \vdash_{t, n_1, n_2} z\}$$

The shorthand notation $\pitchfork_T(L)$ is used whenever n_1, n_2 are understood. We note that the restriction on pointer length, $|\beta| = n_2$, is not as strict as it appears since it has been proven equivalent to the restriction $|\beta| \geq n_2$ in Daley and McQuillan (2005b).

Given the nature of biochemical reactions, it is natural to consider an iterated version of TGR as well: let $\pitchfork_{T, n_1, n_2}^0(L) = L$ and for all $i \geq 1$, let

$$\pitchfork_{T, n_1, n_2}^i(L) = \pitchfork_{T, n_1, n_2}^{i-1}(L) \cup \pitchfork_{T, n_1, n_2}(\pitchfork_{T, n_1, n_2}^{i-1}(L))$$

Then we also define $\pitchfork_{T, n_1, n_2}^*(L)$ as

$$\pitchfork_{T, n_1, n_2}^*(L) = \bigcup_{i \geq 0} \pitchfork_{T, n_1, n_2}^i(L)$$

Finally, let \mathcal{L}, \mathcal{T} be classes of languages and $n_1, n_2 \geq 1$. We define the following closure classes:

$$\begin{aligned}\pitchfork_{\mathcal{T}, n_1, n_2}(\mathcal{L}) &= \{\pitchfork_{T, n_1, n_2}(L) : T \in \mathcal{T}, L \in \mathcal{L}\} \\ \pitchfork_{\mathcal{T}, n_1, n_2}^*(\mathcal{L}) &= \{\pitchfork_{T, n_1, n_2}^*(L) : T \in \mathcal{T}, L \in \mathcal{L}\}\end{aligned}$$

The families of finite languages are denoted by `FIN` and regular languages by `REG`, and we recall that a family of languages is said to be a full AFL if it is closed under homomorphism, inverse homomorphism, intersection with regular languages, union, concatenation, and Kleene plus.

On initial inspection of TGR, there appears to be a similarity with the well-known model of splicing systems, but this relationship has been shown to be superficial in Daley and McQuillan (2005b). Before the relevant formal result is stated, we recall the basic operational scheme of splicing systems.

A *splicing scheme* or *H scheme* is a pair $\sigma = (\Sigma, R)$ where Σ is an alphabet and $R \subseteq \Sigma^* \# \Sigma^* \$ \Sigma^* \# \Sigma^*$ is a set of splicing rules where $\$, \#$ are not elements of Σ . For a rule $r \in R$, we

define the relation $(x, y) \models_r z$ if $r = u_1 \# u_2 \$ u_3 \# u_4$, $x = x_1 u_1 u_2 x_2$, $y = y_1 u_3 u_4 y_2$, $z = x_1 u_1 u_4 y_2$, for some $u_1, u_2, u_3, u_4, y_1, y_2, x_1, x_2 \in \Sigma^*$.

For a language $L \subseteq \Sigma^*$ and an H scheme $\sigma = (\Sigma, R)$, we define $\sigma(L) = \{z \in \Sigma^* : \exists x, y \in L, r \in R \text{ such that } (x, y) \models_r z\}$ and extend to iterated splicing as follows: let $\sigma^0(L) = L$ and $\sigma^i(L)$ be defined by $\sigma^i(L) = \sigma^{i-1}(L) \cup \sigma(\sigma^{i-1}(L))$ for all $i \geq 1$. Finally, as expected,

$$\sigma^*(L) = \bigcup_{i \geq 0} \sigma^i(L)$$

For classes of languages \mathcal{L}, \mathcal{R} , let $H(\mathcal{L}, \mathcal{R}) = \{\sigma^*(L) : L \in \mathcal{L}, \sigma = (\Sigma, R), R \in \mathcal{R}\}$.

Lemma 3 (Daley and McQuillan 2006) *For all $n_1, n_2 \geq 1$, for all full AFLs \mathcal{L} :*

$$\mathcal{L} = \dot{\cap}_{\text{FIN}, n_1, n_2}^*(\mathcal{L}) = H(\mathcal{L}, \text{FIN}),$$

while for all finite languages and templates:

$$\text{FIN} \subset \dot{\cap}_{\text{FIN}, n_1, n_2}^*(\text{FIN}) \subset H(\text{FIN}, \text{FIN}) \subset \text{REG}$$

Despite this result, it has been shown in Daley and McQuillan (2005b) that every regular language is the coding of a language in $\dot{\cap}_{\text{FIN}}^*(\text{FIN})$ demonstrating a relatively modest computational power for single-application TGR.

To investigate the computational power of the iterated case, it is necessary to define the notion of a “useful” template; we say that a template $t \in T$ is *useful* on L, n_1, n_2 if there exists $u_1 \alpha \beta v_1, v_2 \beta \gamma u_2 \in \dot{\cap}_{T, n_1, n_2}^*(L)$ with $|\alpha|, |\gamma| \geq n_1$, $|\beta| = n_2$, $u_1, u_2, v_1, v_2 \in \Sigma^*$ and $t = \alpha \beta \gamma$. If every template $t \in T$ is useful on L, n_1, n_2 , then we say that T is useful on L, n_1, n_2 . The following results, demonstrating the surprisingly limited power of iterated TGR, were shown in Daley and McQuillan (2006):

Theorem 16 (Daley and McQuillan 2006) *Let $n_1, n_2 \geq 1$, \mathcal{L} be a full AFL and $L, T \in \mathcal{L}$. If T is useful on L, n_1, n_2 , then $\dot{\cap}_{T, n_1, n_2}^*(L) \in \mathcal{L}$.*

Corollary 1 (Daley and McQuillan 2006) *Let $n_1, n_2 \geq 1$. For all full AFLs \mathcal{L} , $\dot{\cap}_{\text{REG}, n_1, n_2}^*(\mathcal{L}) = \mathcal{L}$.*

The problem of template equivalence, viz. “Given sets of templates T_1, T_2 , are $\dot{\cap}_{T_1}$ and $\dot{\cap}_{T_2}$ identical operations?” has been considered in Domaratzki (2007), which gives a characterization of when two sets of templates define the same TGR operation in formal language theoretic terms, leading to the following decidability result.

Theorem 17 (Domaratzki 2007) *Let $n_1, n_2 \geq 1$ and $T_1, T_2 \subseteq \Sigma^*$ ($|\Sigma| \geq 3$) be regular sets of templates. Then it is decidable whether or not $\dot{\cap}_{T_1, n_1, n_2}(L) = \dot{\cap}_{T_2, n_1, n_2}(L)$ for all $L \subseteq \Sigma^*$.*

Several variants of TGR have been studied as well, including a computationally universal version with added deletion contexts (Daley and McQuillan 2005a) and a purely intramolecular version that resembles a templated version of the `ld` operation (Daley et al. 2007) discussed above.

In addition to the very literal formalization of TGR considered in this section, the underlying theoretical model has also inspired work at a more abstract level.

7.4 Covers from Templates

The process of gene descrambling may be abstractly formulated in simple terms as a procedure that takes MDSs from the MIC and connects them, via overlap, to form the MAC. The template-guided recombination model discussed above provides a concrete suggestion of how this process might be implemented; one can view a template, T , as a sort of magnet, which glues together regions of MIC chromosomes containing MDSs to form orthodox MAC genes. Returning to a more abstract level, we now consider the set of all MDSs as our primary object of study. In this view, a template is now a request: “with this set of segments(MDSs), please cover me”: and therefore our core question is now “given a set of segments, how can a particular word be covered with these segments?” This leads naturally to the study of various properties of coverings, and the notion of uniqueness of coverings formalized as *scaffolds* presented in Ehrenfeucht and Rozenberg (2006).

An *interval* is a set of integers of the form $\{n, n+1, \dots, n+m\}$, where $n \in \mathbb{Z}$, and $m \in \mathbb{N}$. For a given alphabet Σ , we define a *segment* as a function $f:A \rightarrow \Sigma$, where A is an interval, and denote the set of all segments over Σ by \mathcal{S}_Σ . Since f is a function, we alternatively view segments as sets of ordered pairs of the form $(n, f(n))$, called *elements off*, with n called the *location* of $(n, f(n))$; thus, elements of f are ordered through their locations. This point of view is very convenient as it provides a set-theoretical calculus of segments: we can consider inclusions, union, intersections, differences, . . . of segments. Also, in this way, a set of segments is a family of sets.

For a set $C \subseteq \mathcal{S}_\Sigma$ and a segment $f \in \mathcal{S}_\Sigma$, we say that C *covers* f if $f = \bigcup C$. Intuitively, f is covered by C if each element of f is present in at least one segment of C , and all elements of all segments of C are present in f . Note that in general an element of f may be present in several segments of C , that is, the segments of C may overlap. One may also have redundant segments in C , that is, segments which cover only elements of f that are already covered by other segments of C . We thus say that a cover C of f is *tight* if for every $z \in C$, $C - \{z\}$ is not a cover of z .

Often covers are chosen from a subset of \mathcal{S}_Σ . Given such an $F \subseteq \mathcal{S}_\Sigma$, and a cover C of f with $C \subseteq F$ we say that C is a *small cover* of f (with respect to F) if $|C| \leq |Z|$ for all $Z \subseteq F$ covering f . Note that the property of being a small cover is a global property: C is a small cover of f with respect to F if any other cover Z of f , $Z \subseteq F$, has at least as many segments as C . The set of all small covers of f with respect to F is denoted $SC_F(f)$, and the *small index* of f (with respect to F) is the cardinality of the small covers of f (with respect to F). For any small cover C of f with respect to F , we get a natural order $C(1), \dots, C(m)$ of C , where m is the small index of f , and the order is determined by increasing locations of first elements of the segments of C .

Example 21 Let $\Sigma = \{a, b, c\}$ and $f \in \mathcal{S}_\Sigma$ be defined by

$$f = \{(3, a), (4, b), (5, b), (6, a), (7, c)\}$$

which may be abbreviated as $f = (3, abbac)$ since f begins at location 3.

Consider the sets $F = \{(3, ab), (4, bb), (4, bba), (5, bac), (6, ac)\}$ and $C = \{(3, ab), (4, bb), (6, ac)\}$. It is clear that C covers f and is tight, since no element of C can be removed while still covering f ; however, with respect to F , C is not small since $|C| = 3$ and the set $\{(3, ab), (5, bac)\} \subseteq F$ also covers f and has cardinality 2.

From the point of view of the original biological motivation, the segment f represents a scrambled MAC gene while the set F is the collection of MIC gene fragments available for assembly. We now proceed to investigate the structure of f by considering the family of all small covers of f with respect to some fixed F .

Let $f \in \mathcal{S}_\Sigma$, $F \subseteq \mathcal{S}_\Sigma$ be such that it contains a cover of f , and let m be the small index of f with respect to F . Let $1 \leq i \leq m$. The i th kernel of f with respect to F (denoted $\text{ker}_{i,F}(f)$) is defined by

$$\text{ker}_{i,F}(f) = \left(\bigcap_{C \in SC_F(f)} C(i) \right) - \bigcup_{\substack{C \in SC_F(f) \\ j \neq i}} C(j)$$

We now define the *scaffold* of f (with respect to F) as the set $\{\text{ker}_{1,F}(f), \dots, \text{ker}_{m,F}(f)\}$ of all kernels of f .

Theorem 18 (Ehrenfeucht and Rozenberg 2006) *For each $1 \leq i \leq m$, $\text{ker}_{i,F}(f)$ is a nonempty segment.*

For any segment f , the choice of F determines a certain natural class of “maximal” subsegments of f ; namely, those subsegments that are not strict subsegments of other subsegments. Let $P_F(f)$ be the set of all subsegments of f that belong to F . We say that a segment $g \in P_F(f)$ is *long* (with respect to F) if it is not properly included in any other segment in $P_F(f)$. The set of all long segments of f (with respect to F) is denoted by $LP_F(f)$. Additionally, we call a cover long if it consists solely of long segments.

Attention can now be turned to the study of the canonical class of covers that have both the “long” and “small” property. For each $1 \leq i \leq m$, let $LP_F(f,i) = \{y \in LP_F(f): \text{ker}_{i,F} \subseteq y\}$. That is, we categorize the long segments of f with respect to F according to containment of kernels. Since $LP_F(f,i)$ is an ordered set, we let $rt_F(f,i)$ (resp., $lt_F(f,i)$) be the maximal, or rightmost (resp., minimal, or leftmost) element of $LP_F(f,i)$. The following result provides a method for constructing “canonical” small covers of f .

Theorem 19 (Ehrenfeucht and Rozenberg 2006) *The sets $\{rt_F(f,1), \dots, rt_F(f,m)\}$ and $\{lt_F(f,1), \dots, lt_F(f,m)\}$ are long small covers of f with respect to F .*

More detailed analysis of the structure of scaffolds is given in Ehrenfeucht and Rozenberg (2006).

7.5 Topology-Based Models

An important question that arises from considering template-guided recombination concerns the three-dimensional structure of DNA undergoing multiple recombination events. Recently, two new approaches to this question have been undertaken. The physical structure of the DNA

strand undergoing recombination is directly considered in Angeleska et al. (2007) through the use of virtual knot diagrams. Micronuclear genes are represented in a schematic form that explicitly denotes only the relative locations of the pointer sequences. Consider, for example, the Uroleptus gene *USGI* (Chang et al. 2006) that has the following MDS descriptor: $M_1M_3M_4M_5M_7M_{10}M_{11}M_6M_8M_2M_9$. The corresponding legal string is the following: 2 3 4 5 6 7 8 10 11 11 6 7 8 9 2 3 9 10. It is now possible to interpret this sequence as a Gauss code. Each symbol in a Gauss code must occur exactly twice and to each code we associate a virtual knot diagram in a similar manner to the construction of the recombination graphs exposed above:

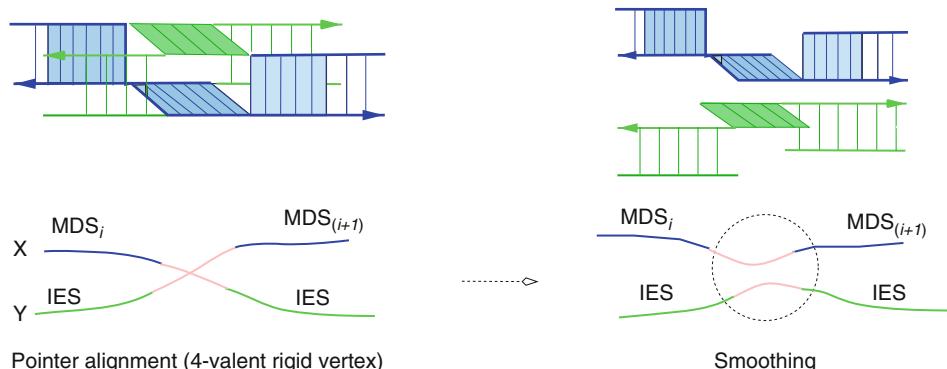

- For each symbol occurring in the code, we place a (disconnected) crossing in the plane and label the crossing with the corresponding symbol. A crossing may be thought of as similar to a vertex with predetermined order of the incident edges of degree 4 in a graph.
- We choose an arbitrary point in the plane to denote as the base point.
- Following a chosen direction, we connect crossings according to the order in the Gauss code. In our example, we would draw arcs from the base point to crossing 2, crossing 2 to crossing 3, crossing 3 to crossing 4, crossing 4 to itself, crossing 4 to crossing 5, and so forth. Each crossing corresponds to a “roof-floor” structure depicted in Fig. 26 left.
- We connect the remaining arc leaving the final crossing back to the base point.

Note that during the construction of the virtual knot diagram, it might happen that we have to cross an already sketched arc. This crossing is not labeled and does not correspond to a required pointer-guided homologous recombination, therefore it is called a “virtual crossing.” The virtual crossings correspond to a cross-over embedding of the DNA in space when one helix crosses over another.

The virtual knot diagram is now relabeled with each crossing receiving the label of its associated pointer and indicating inverted pointers with a bar. The process of assembly is now reduced to one of *smoothing* the crossings of the virtual knot diagram (see Fig. 26 right). The smoothing of a crossing consists of eliminating the crossing by splicing together the arcs of the crossing according to the pointers: if the pointers are not inverted, we splice the arcs together

Fig. 26

Roof-floor structure of a crossing in a virtual knot diagram (from Angeleska et al. (2007)).

following the orientation; if the pointers are inverted, we splice the arcs together opposite to the orientation. The result of a simultaneous smoothing of all crossings is a virtual link diagram with no real crossings remaining; note that the link may be composed of multiple components. If the arcs of the virtual knot diagram are labeled with the respective MDS and IES names (see Angeleska et al. (2007)), then we have the following theorem.

Theorem 20 (Angeleska et al. 2007) *For every labeled virtual knot diagram derived from a representation of a scrambled gene G, there exists a simultaneous smoothing yielding a link with a component C containing a subarc labeled with all MDSs in orthodox macronuclear order.*

Note that the basic mechanism of gene assembly through the smoothing of virtual knot diagrams was already introduced in Ehrenfeucht et al. (2002) in terms of a graph-based model, which was also briefly discussed in [Sect. 5.6](#). This model is based on the notion of recombination graph representing pointers as vertices, and MDSs and IESs as edges between the vertices standing for their flanking pointers. The recombination graph is first subject to a process of *graph folding* yielding a structure similar to the virtual knot diagram. A subsequent step of *graph unfolding* is similar to that of *smoothing* above and yields a representation of the assembled gene and of all the molecules excised during gene assembly. In this way, the approach of virtual knot diagrams from Angeleska et al. (2007) is a translation of the graph-theoretic approach from Ehrenfeucht et al. (2002) into a topological framework. This allows one to apply a rich set of techniques from both graph theory and knot theory to the investigation of gene assembly.

One significant issue that has not yet been addressed concerns the thermodynamics of template-guided recombination. For template-guided recombination to be implemented as suggested in the theoretical models requires some intricate positioning and biochemical operations; specifically, it requires the juxtaposition of three nucleic acid strands in space followed by a strand branch migration process as is observed *in vivo* (see, e.g., Dennis et al. (2004) and Zerbib et al. (1998)) and *in vitro* (see, e.g., Yan et al. (2002) and Yurke et al. (2000)). In order for such a branch migration process to start, it is possibly necessary that some of the cuts in the molecule ([Fig. 25](#) bottom left) appear early in the process. On the other side, it is possible to suppose that the juxtaposition of the molecules is artificially created by as-yet undiscovered enzymatic mechanics. Yet another possibility would be a simple argument indicating the thermodynamic favorability of the process. In the absence of such complex additional enzymatic machinery, template-guided recombination must rely upon diffusion processes within the cell to juxtapose the template and substrate strands. It is a well-known theorem in mathematics that random walks in three-space need never pass through the same point twice, so the likelihood of juxtaposing three molecules, in three-space, seems low. An alternative knot theory-based model presented in Daley et al. (2010) attempts to reduce the complexity of this problem by considering the effects of individual recombinations on the structure of the substrate DNA.

When circular DNA undergoes recombination, it is supercoiled due to twist applied by the recombination machinery (Krasnow et al. 1983; White 1992). Where linear DNA has unbound ends that are free to rotate and relax, thus removing the induced twist, circular DNA cannot relax in this fashion after recombination. Instead, the relaxation of the DNA strand induces supercoiling of the DNA molecule. The connection between linking, twist, and writhe of the DNA has been observed decades ago (White 1992), therefore, multiple recombinations on a closed circle of DNA can lead to a knotted, supercoiled strand.

It is suggested in Daley et al. (2010) that DNA is assembled in a closed circular topology where the twist induced by a template-guided recombination (or multiple recombinations)

causes a new, potentially knotted and supercoiled, topology to form. This new topology could facilitate the juxtaposition of the “next” regions of DNA to be assembled.

8 Discussion

In this chapter, we have discussed a number of topics related to research on the computational nature of gene assembly in ciliates, including the two main models for gene assembly. Among others, we have discussed their mathematical formalizations, invariant properties, template-based DNA recombination, and topology-based models for gene assembly. Due to space restrictions, all lines of research could not be discussed; for the sake of completeness, some of the topics that were not covered are now mentioned briefly.

The organization of the micronuclear genes into broken and shuffled MDSs, separated by IESs, is one of the characteristic features of the ciliates. To explain the evolutionary origin of this organization, a somewhat geometrical hypothesis based on a novel proposal for DNA repair is suggested in Ehrenfench et al. (2007).

Approaches based on formal languages have been introduced for both the intermolecular model and the intramolecular model, leading to very diverse research topics: computability, language equations, closure properties, hierarchies of classes of languages, etc. A typical approach is to consider contextually based applications of string rewriting rules; see, for example, Landweber and Kari (1999) for the intermolecular model. A derivation relation and an axiom are introduced, thus obtaining an acceptance mechanism: Start with a multiset of strings, for example, consisting of several copies of the input string and eventually derive a multiset containing the axiom. It can be proved that such a mechanism is a universal computing device. A similar result can be obtained also based on the intramolecular model, see Ishdorj et al. (2007), where the multisets are replaced with single strings. The idea is to concatenate several copies of the input string rather than having them in a multiset. A generating, rather than accepting, computing device inspired by gene assembly was also considered in Dassow and Vaszil (2006). Defining non-contextual string-based rewriting rules inspired by the molecular operations in either model leads to language operations and to questions related to closure properties, or solutions of language equations, see Daley et al. (2003a), Dassow and Holzer (2005), and Freund et al. (2002), and also Dassow et al. (2002) for a more general framework. Language operations inspired by the template-based DNA recombination were considered in Daley and McQuillan (2005b) and in Domaratzki (2007).

The original, non-contextual, intramolecular and intermolecular operations were generalized to the synchronized insertion and deletion operations on linear strings in Daley et al. (2003a). Let α, β be two nonempty words in an alphabet Σ^* . The synchronized insertion of β into α is defined as $\alpha \oplus \beta = \{uxvxw \mid \alpha = uxw, \beta = vx, x \in \Sigma^+, u, v, w \in \Sigma^*\}$. While the synchronized deletion of β from α is defined as $\alpha \ominus \beta = \{uxw \mid \alpha = uxvxw, \beta = vx, x \in \Sigma^+, u, v, w \in \Sigma^*\}$. All language families in the Chomsky hierarchy were shown to be closed under synchronized insertion while only the families of regular and recursively enumerable languages were closed under synchronized deletion. The existence of a solution was shown to be decidable for language equations of the form $L \odot Y = R$ and $X \odot L = R$ where \odot is one of the synchronized insertion or synchronized deletion operations and L, R are regular languages. The same problems are undecidable in the case that L is a context-free language.

More general results considering families of languages defined by reversal-bounded counter machines are also given in Daley et al. (2003a) along with results for a similarly generalized version of the *hi* operation. Generalized versions of the *ld* and *dld* operations are considered in Daley et al. (2003b) while families of languages defined by closure under these generalized operations are examined in Daley et al. (2004).

Two novel classes of codes based on synchronized insertion were defined and studied in Daley and Domaratzki (2007): the synchronized outfix codes (\oplus -codes) defined by the equation $(L \oplus \Sigma^+) \cap L = \emptyset$ and the synchronized hypercodes (\otimes -codes) defined by $(L \otimes \Sigma^+) \cap L = \emptyset$ (where \otimes is the transitive closure of \oplus , namely synchronized scattered insertion). The \oplus -codes and \otimes -codes are shown to be completely disjoint from the regularly studied classes of $*$ -codes and it is demonstrated that it is decidable if a regular language is an \oplus -code while the same property is undecidable for linear context-free languages. It is, however, decidable if an arbitrary context-free language is an \otimes -code while this same property is, unsurprisingly, undecidable for context-sensitive languages.

A different computability approach was developed in Alhazov et al. (2008), where the process of gene assembly is used to solve an NP-complete problem. Conceptually, this is important since gene assembly is confluent, see [Sect. 5](#), that is, it yields a computing device that answers “yes” to all legal inputs. A way around the problem is to make the device highly nondeterministic by extending its set of legal inputs. For example, strings with more than two occurrences of each letter may be allowed. With this modification, a suitably defined model can be introduced to solve the Hamiltonian path problem (HPP) by mimicking gene assembly on an encoding of the input to HPP, see Alhazov et al. (2008). The intermolecular model also leads to solutions to computational problems, see Ishdorj et al. (2008) for a solution to the satisfiability problem. Yet another approach based on Boolean circuits was investigated in Ishdorj and Petre (2008). Algorithmic questions related to finding a gene assembly strategy were considered in Ilie and Solis-Oba (2006).

The topological model of gene assembly with virtual knot diagrams raises new mathematical questions. Considering that a virtual knot diagram could represent the physical structure of the micronuclear DNA at the time of recombination, in Angeleska et al. (2009) it was shown that for every such virtual knot diagram there is an embedding of the molecule in space, and there is smoothing of the vertices (recombination along the pointers) such that the resulting molecule is always unlinked. Further, it was shown that the smoothing guided by the pointers differs from the existent smoothing notions defined earlier for virtual knot diagrams (Kauffman 1999). This opens completely new problems on virtual knot diagrams that have not been studied before.

Research on the computational nature of gene assembly is an example of genuinely interdisciplinary research that contributed to both computer science, through a whole range of novel and challenging models of computation, and to biology, by increasing our understanding of the biological nature of gene assembly – it has even led to formulating biological models of this process based on the notion of template-guided recombination.

Abstract

This chapter summarizes the efforts that have been made so far to build a huge memory using DNA molecules. These efforts are targeted at increasing the size of the address space of a molecular memory and making operations on a specified word in the address space more efficient and reliable. The former issue should be solved by careful design of the base sequences of the address portions. The latter issue depends on the architecture of a molecular memory and the available memory operations. Concrete examples of molecular memories described in this chapter are classified into *in vitro* DNA memory, DNA memory on surfaces, and *in vivo* DNA memory. This chapter also describes the technology for designing base sequences of DNA molecules.

1 Introduction

Soon after Adleman published his seminal work on DNA computing (Adleman 1994) and Lipton (1995) gave a more general framework for solving nondeterministic polynomial time (NP)-complete problems using DNA, Baum wrote a technical comment in *Science* on building a huge memory using DNA molecules (Baum 1995). He claimed that it was possible to build an associative memory vastly larger than the brain. More concretely, he wrote that it was not completely implausible to imagine vessels storing 10^{20} words, which is comparable to standard estimates of brain capacity as 10^{14} synapses each storing a few bits. Among various proposals for constructing a molecular memory, he considered a scheme that stores DNA molecules consisting of an address portion and a data portion. In order for the scheme to work as an ordinary random access memory, each address portion should be accessible only by the sequence that is complementary to the sequence of the address portion. He even mentioned the use of an error correcting code to avoid accidental bonding due to approximate match.

This chapter summarizes the efforts that have been made so far toward achieving Baum's dream. Those efforts are targeted at increasing the size of the address space of a molecular memory and making operations on a specified word in the address space more efficient and reliable. As Baum pointed out, the former issue should be solved by careful design of base sequences of address portions. The latter issue depends on the architecture of a molecular memory and available memory operations. Sequence design is also affected by the required memory operations.

The next section describes the technology for designing base sequences of DNA molecules. It is one of the most fruitful technological achievements in the research field of DNA computing, and can be used in various application fields including biotechnology and nanotechnology. The following section then summarizes a series of memory operations that have been devised for constructing various kinds of molecular memories. Concrete examples of molecular memories are then described in the sections that follow, classified into *in vitro* DNA memory, DNA memory on surfaces, and *in vivo* DNA memory.

2 Sequence Design

This section describes sequence design in DNA computing. Sequence design is the search for sequences satisfying given constraints or having a high value for a given evaluation function.

First, this section describes the thermodynamics of DNA molecules and the constraints to be satisfied in DNA computing. Then, various strategies for sequence design are described.

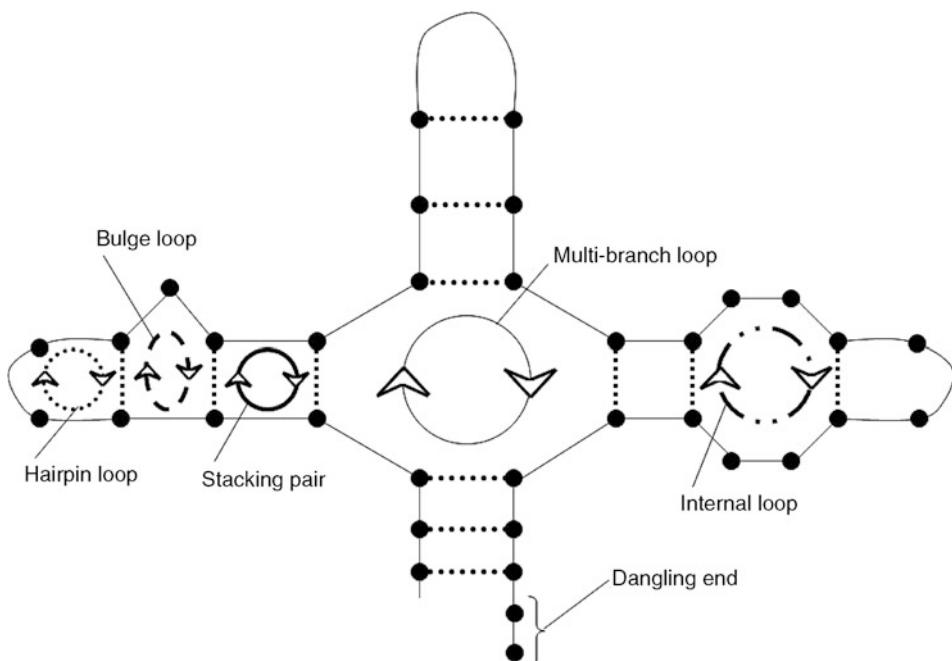

2.1 Thermodynamics of DNA Molecules

Deoxyribonucleic acid (DNA) is a polymer consisting of three units: bases, deoxyribose, and phosphoric acids. In DNA, the bases comprising the nucleotides are adenine (A), thymine (T), cytosine (C), and guanine (G); in RNA, thymine is replaced by uracil (U). The pairs between A and T and between C and G are called Watson–Crick base pairs (Watson and Crick 1953). The former has two hydrogen bonds and the latter has three, making it more stable. Other pairs (called “mismatches”) such as G-T are generally less stable than the Watson–Crick base pairs. On the basis of these selective hydrogen bonds, a DNA sequence and its complementary strand form a double-stranded structure in an antiparallel direction at low temperature (Watson and Crick 1953), which is called hybridization. For example, sequence 5'-AGGCTTACCC-3' hybridizes with its complement 3'-TCCGATGG-5' and forms a double-stranded structure. A double strand melts into two single strands at high temperature, which is called denaturation.

A secondary structure of DNA is defined as a set of base pairs. DNA sequences can form various secondary structures consisting of stacking pairs, various loops, and dangling ends (see [Fig. 1](#)).

■ Fig. 1

Example of DNA secondary structure. The dots represent the bases, while the thin and dotted lines represent the backbones and hydrogen bonds, respectively.

The stability of double-stranded DNA depends on the temperature, the DNA concentration, and the buffer solution. The free energy change (ΔG) is the commonly used indicator of stability for DNA complexes. ΔG is the free energy change when the sequence folds into the structure from a random coil. In particular, ΔG_T denotes the free energy change at temperature T . The lower the free energy, the more stable the structure, so more sequences form into a structure in solution. The free energy of an entire structure is the sum of the free energies of all the local substructures (Zuker and Stiegler 1981). The minimum free energy (ΔG_{\min}) is the minimum value of free energy for any structure. Thus, the structure with the minimum free energy must be the most stable in solution. Stability can be well approximated using the minimum free energy calculation. In fact, the minimum free energy is often used for secondary structure prediction of single-stranded RNA (Zuker and Stiegler 1981). The minimum free energy can be calculated using dynamic programming.

Another indicator for the stability of a double-stranded DNA is the melting temperature, T_m , which is defined as the temperature at which single and double strands are in equilibrium with a 1:1 ratio. A pair of sequences with a high melting temperature is stable, while one with a low melting temperature is unstable. The melting temperature is calculated using (Borer et al. 1974)

$$T_m = \frac{\Delta H}{R \ln(C_t/\alpha) + \Delta S}, \quad (1)$$

where R is the gas constant, C_t is the total oligo concentration. ΔH and ΔS are enthalpy and entropy change from a random coil, respectively. Parameter α is set to one for self-complementary strands and to four for non-self-complementary strands.

Parameters ΔH , ΔS and ΔG are called “thermodynamic parameters” and are calculated on the basis of the nearest-neighbor model (SantaLucia 1998). For example, the ΔG of double-stranded DNA 5'-AGTG-3'/3'-TCAC-5' is calculated using

$$\Delta G \text{ (5'-AGTG-3'/3'-TCAC-5')} = \text{initiation} + \text{symmetry} + \Delta G \text{ (5'-AG-3'/3'-TC-5')} + \Delta G \text{ (5'-GT-3'/3'-CA-5')} + \Delta G \text{ (5'-TG-3'/3'-AC-5')}$$

where “*initiation*” is a contribution by terminal base pairs and the value differs depending on whether the terminal base pair is an A-T pair or G-C pair. The term “*symmetry*” describes whether the sequence is a palindrome or not. The thermodynamic parameters of a substructure, such as 5'-GT-3'/3'-CA-5', are called “nearest-neighbor parameters” or “nearest-neighbor thermodynamics.” Nearest-neighbor parameters are determined by the sequence forming the substructure and must be estimated in advance through thermodynamic analysis. ◉ [Table 1](#) shows an example of reported nearest-neighbor parameters for Watson–Crick base pairs (Allawi and SantaLucia 1997; Tanaka et al. 2004). If the SantaLucia parameters (in the rightmost column of the table) are used, the ΔG of 5'-AGTG-3'/3'-TCAC-5' is calculated as $(0.98 + 1.03) + 0 + (-1.28) + (-1.44) + (-1.45) = -2.16 \text{ kcal/mol}$.

All possible nearest-neighbor parameters have already been estimated for Watson–Crick base pairs (SantaLucia 1998; Sugimoto et al. 1996; SantaLucia et al. 1996), internal mismatches (Aboul-ela et al. 1985), G-A mismatches (Li et al. 1991; Li and Agrawal 1995), G-T mismatches (Allawi and SantaLucia 1997), A-C mismatches (Allawi and SantaLucia 1998a), C-T mismatches (Allawi and SantaLucia 1998b), G-A mismatches (Allawi and SantaLucia 1998c), N-N mismatches (N represents A, T, C, or G) (Peyret et al. 1999), dangling ends (Senior et al. 1988; Bommarito et al. 2000), and bulge loops (Tanaka et al. 2004). The thermodynamic parameters for various loops are calculated approximately as a function of loop length; shorter loops have lower free energy while longer loops have higher free energy.

Table 1

Nearest-neighbor thermodynamic parameters for Watson–Crick base pairs

Sequence	ΔH (Tanaka et al. 2004) (kcal/mol)	ΔS (Tanaka et al. 2004) (eu)	ΔG (Tanaka et al. 2004) (kcal/mol)	ΔG (Allawi and SantaLucia 1997) (kcal/mol)

2.2 Design Constraint

2.2.1 Uniform Melting Temperature

DNA sequences used in DNA computing should hybridize with their complements at the same efficiency to prevent hybridization bias. Thus, making the melting temperature uniform among pairs of complementary sequences is important for obtaining uniform hybridization efficiency. The melting temperature is calculated using formula (1).

Another indicator for the melting temperature is the GC content, which is the ratio of the sum of the number of G and C nucleotides over the total number of nucleotides in the sequence. Double strands with a higher GC content tend to have a higher melting temperature because the hydrogen bond between G and C is more stable than that between A and T. Thus, the GC content can be used to approximately calculate the melting temperature. In DNA computing, sequences are often designed such that their GC content is 50%.

2.2.2 Specific Hybridization

Specific hybridization, which is also called intended/expected/planned hybridization/interaction, denotes the hybridization between an intended pair of sequences while nonspecific hybridization, or unintended/unexpected/unplanned hybridization/interaction, denotes the hybridization between an unintended pair of sequences. Nonspecific hybridization causes various problems in DNA computing, including errors in the computation, failure in the construction of intended DNA nanostructures, and misdiagnosis in DNA microarrays.

Therefore, in DNA computing, multiple sequences need to be designed, such that they do not hybridize nonspecifically with each other, while in RNA secondary structure design, a single sequence needs to be designed that folds into the desired secondary structure (Hofacker 2003; Andronescu et al. 2003, 2004; Dirks et al. 2004). Specific sequences are sequences between which only specific hybridizations can form. Since the number of combinations increases exponentially with the number of sequences, designing specific sequences is an NP-hard problem and is equivalent to the independent set problem (Frutos et al. 1997).

To design specific sequences, we must design sequences among which specific hybridizations are stable and nonspecific ones are unstable. Thus, specific-sequence design requires a metric for stability between two sequences. The most often used criterion for stability is the *h*-measure proposed by Garzon et al. (1997, 1998). The *h*-measure for sequences x_i , x_j is defined as

$$|x_i, x_j| := \min_{-n < k < n} H(x_i, \sigma^k(\bar{x}_j)), \quad (2)$$

where $H(*, *)$ denotes the Hamming distance, σ^k denotes the right (left) shift for $k > 0$ ($k < 0$), k denotes the number of the shift, and \bar{x}_j is the sequence which is Watson–Crick complementary to x_j . The *h*-measure is based on the fact that the stability depends on the number of base pairs: a double strand with a certain number of base pairs is more stable than one with fewer base pairs. Therefore, if the *h*-measure between two sequences is large, the double strand that they form tends to be unstable.

2.2.3 Preventing Secondary Structures

Secondary structures often prevent the sequence from hybridizing to the correct complementary sequence. Thus, we must avoid sequences that form stable secondary structures unless they are specifically designed to form them. The mfold program (Zuker 2003) is commonly used to calculate the stability of secondary structures.

2.2.4 Other Constraints

1. Repeated Bases

Repeated bases have a harmful effect on specific hybridization. For example, guanine-rich motifs can form four-stranded complexes (Sen and Gilbert 1988, 1990). Thus, sequences are often designed not to have repeated bases.

2. Forbidden Subsequences

When a restriction enzyme, which cuts off the sequence at specific sites, is used, the recognition sequence must appear only at an intended site. Otherwise, sequences will be cut off at some unintended site. Therefore, recognition sequences are forbidden except for intended sites.

3. Three-Base Constraint

To prevent nonspecific hybridization, several strategies have been devised that use only three kinds of bases (A, T, and C) for sequence design (Cukras et al. 1999; Faulhammer et al. 2000; Braich et al. 2000, 2002). The reason for omitting base G is that it can form G-C and G-T base-pairings. In addition, Whiplash polymerase chain reaction (PCR) needs to use only three bases because the fourth base is used as stopper sequences to stop the

polymerase extension at the designated position (Hagiya et al. 1999). This constraint is effective to some extent for the specific hybridization. However, omitting G greatly reduces the variety of sequences.

2.3 Strategy for Sequence Design

This subsection summarizes strategies for producing sequences that satisfy the design criteria discussed in the previous section. Many strategies have been proposed for searching appropriate sequences.

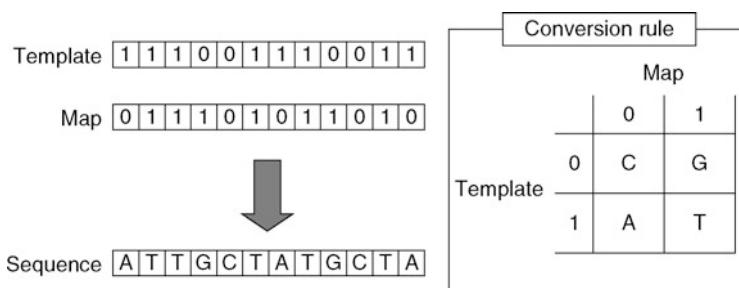

In the coding theory research area, researchers have focused on a classical problem: maximize the size of a set consisting of equi-length code words so that the Hamming distances between them are above a certain threshold. This problem resembles the sequence design problem: design sequences so that the Hamming distances between them are above a certain threshold. Thus, the theoretical analyses and achievements in coding theory can be used for DNA sequence design.

On the basis of coding theory, sequences are produced by crossing two binary codes of length n , namely a template and map. First, the positions for [AT] and [GC] are determined using a template $t = t_1t_2\dots t_n$ ($t_i \in \{0, 1\}$), where 0 indicates [GC] and 1 indicates [AT]. Since the number of occurrences of 0 in the template is equal to the number of G and C in a DNA sequence, the GC content of DNA sequences can be adjusted by controlling the occurrences of 0 in a template. Either A or T is chosen for template positions $t_i = 1$ and either G or C for positions $t_i = 0$ using a map $m = m_1m_2\dots m_n$ ($m_i \in \{0, 1\}$). The conversion rule is to convert 0 in a template and 0 in a map into C, 0 and 1 into G, 1 and 0 into A, and 1 and 1 into T. For example, the sequence “ATTGCTATGCTA” is produced by conversion of codes T=“111001110011” and M=“01101011010” (see Fig. 2).

The problem is to find as many templates and maps as possible such that sequences obtained from them satisfy certain criteria such as uniform GC content or maximal Hamming distance. Frutos et al. proposed a strategy for designing sequences that satisfy a Hamming distance constraint (Frutos et al. 1997). Although the design procedure does not consider frameshift hybridization, their study is a pioneering work in DNA sequence design using coding theory. Li et al. developed a similar design strategy based on the Hamming distance without the frameshift (Li et al. 2002).

Fig. 2

Conversion from two binary codes into a DNA sequence. The bases of the sequence are determined on the basis of the conversion rule.

Marathe et al. clarified the lower and upper bounds on the maximum size of DNA sequences that satisfy the constraints on the basis of the Hamming distance without the frameshift (Marathe et al. 2001). Their study was based on several achievements in coding theory. As Brenneman and Condon pointed out (Brenneman and Condon 2002), however, the upper bound is probably still unknown when the Hamming distance is considered with the frameshift.

Liu et al. proposed a design strategy that considers frameshift hybridization in accordance with the h -measure (Liu et al. 2003). To prevent low h -measure values, they kept equal 01 content in the map. This strategy is based on the observation that deviation in the occurrence of 0 or 1 in the map tends to reduce the h -measure value. Although the heuristics may be partially effective, they are not sufficient because this strategy does not completely guarantee the exclusion of maps, which can cause a low h -measure value.

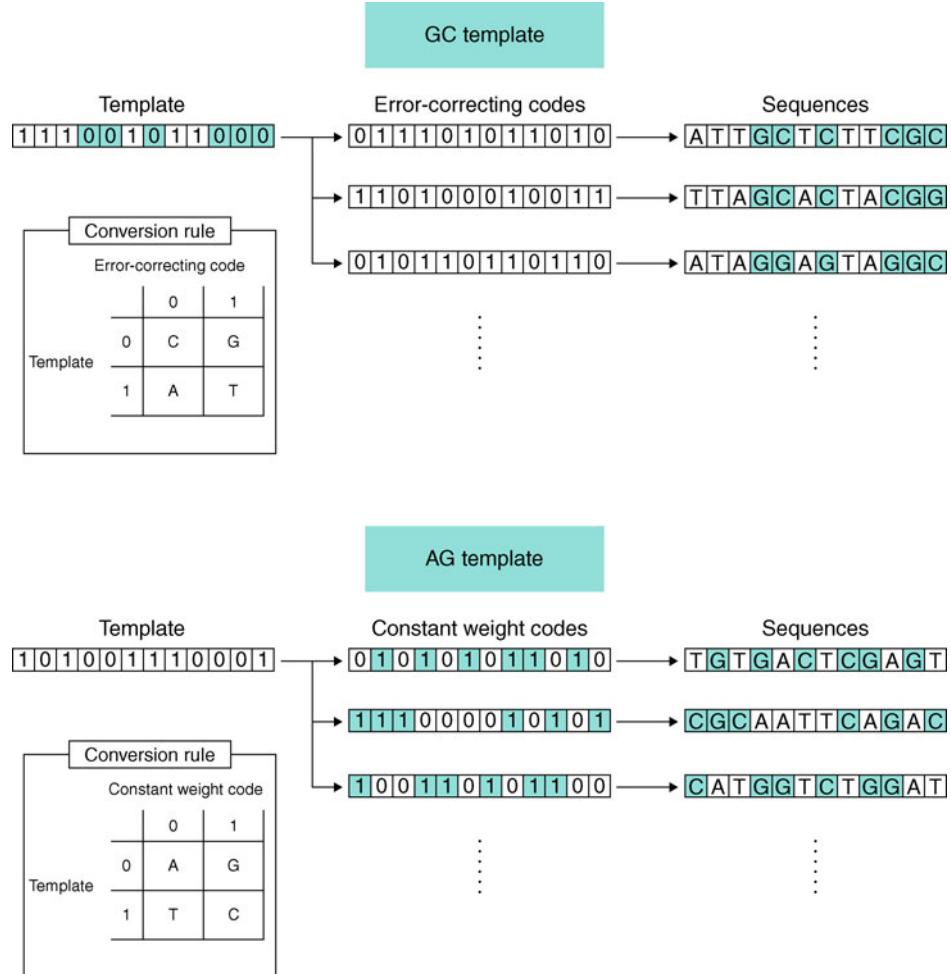

A more sophisticated method, called the “template method,” was proposed by Arita and Kobayashi (2002). In this method, an error-correcting code is used as a map (see  Fig. 3). The error-correcting code is the code for which codewords have at least k mismatches with each other. It has been already investigated in traditional coding theory. For example, a BCH code of length 15 provides at least 128 words with a minimum of five mismatches. Thus, the template method needs to design a template that satisfies a specified constraint. The constraint imposed by Arita and Kobayashi was that the number of mismatches must be larger than a threshold. The template method has two strengths: (i) frameshift hybridization is considered and (ii) mismatches between sequences and concatenations of two sequences are considered. Templates satisfying the specified constraint are found by an exhaustive search, although the number of candidates is dramatically reduced by theoretical consideration. As a result, sets of templates of length up to 30 can be designed.

This template method was later extended by using an AG-template, which determines the position of [AG] rather than [GC] (Kobayashi et al. 2003). The mismatches obtained by using AG-templates outnumber those by using GC-templates. However, using an AG-template does not guarantee uniform GC content. This problem was solved by using a constant weight code in which the codewords have the same number of occurrences of 1 ( Fig. 3). Thus, maps (i.e., constant weight codes) guarantee the uniform GC content instead of templates.

Another important strategy is a *de novo* design proposed by Seeman (1990). The *de novo* design generates sequences for which each subsequence of length l appears at most once. Let one consider a sequence CATGGGAGATGCTTAG as an example of $l = 6$. Any subsequence of length 6 such as CATGGG appears only once in this sequence. The first design step is to choose a sequence of length l that is not included in a given list of prohibited subsequences and to add this sequence to the prohibited list. This sequence is prolonged to the right by concatenating a letter in such a way that the resulting sequence of length $l+1$ does not have any sequence in the prohibited list as its suffix is of length l . Sequences generated by repeating this process are guaranteed not to have two identical subsequences of length l in it. This constraint is motivated by the fact that consecutive complementary bases are likely to form stable structures. However, there is no guarantee that the *de novo* design prevents nonspecific hybridization. For example, although sequences AAAAACAAAAAA and AAAAAGAAAAAA do not share any 6-mer subsequence, the Hamming distance between them is one, resulting in cross-hybridization between one sequence and the complement of the other. Therefore, the sequences produced by the *de novo* design must be checked using another program such as mfold (Zuker 2003) before their practical use.

Fig. 3

Template method with GC template (upper part) and AG template (lower part).

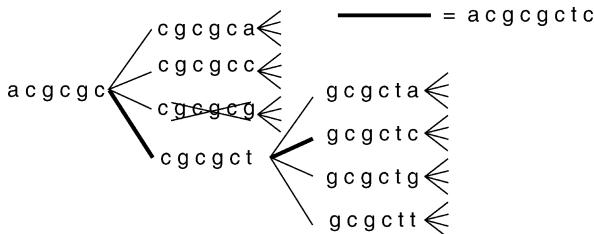

Feldkamp et al. developed a software program with a GUI called *DNASequenceGenerator* for the construction of sets of DNA sequences (Feldkamp et al. 2001). The program can design sequences that satisfy uniqueness (i.e., *de novo* design), uniform melting temperature, and GC content, and that prevent palindromes, start codons and restriction sites. It creates *de novo* sequences using a graph representing DNA sequences (see [Fig. 4](#)). Each path in the graph represents a DNA sequence. The program cuts off from the graph forbidden sequences defined by users and sequences already used. Consequently, *de novo* sequences can be designed.

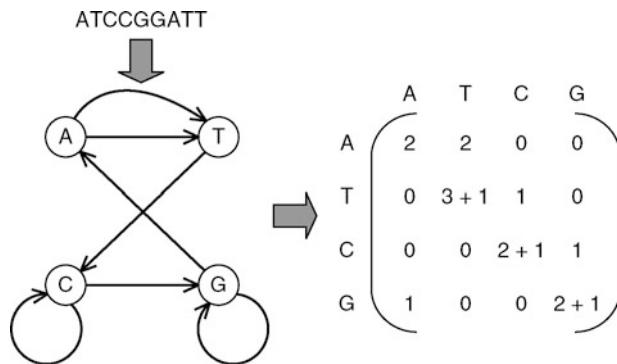

Pancoska et al. developed a design algorithm for sequences with the same melting temperature that uses an Eulerian graph (Pancoska et al. 2004). The algorithm first constructs an Eulerian graph and an adjacency matrix from a given sequence (see [Fig. 5](#)). The key idea is that every Euler path has the same occurrence of each nearest-neighbor parameter. Thus, if we calculate the melting temperature using formula (1), all sequences represented by Euler

Fig. 4

Graph representation of DNA sequences. Each path represents a DNA sequence.

**Fig. 5**

Transformation from a DNA sequence into the Eulerian graph and the adjacency matrix.

paths have the same melting temperature. Consequently, sequences with the same melting temperature can be designed by enumerating all Euler paths and converting them into the corresponding sequences.

With an appropriate evaluation function or set of constraints, the sequence design problem can be formulated as a search for sequences that maximize (minimize) the evaluation function or satisfy the constraints.

The simplest strategy is to generate sequences randomly, and then modify them until they satisfy the constraints. Faulhammer et al. developed a program called PERMUTE that designs sequences on the basis of this strategy (Faulhammer et al. 2000).

A similar strategy is to generate a sequence randomly and then add it to a sequence set if it satisfies all the constraints. This process is repeated until the sequence set contains a predetermined number of sequences. Suyama's group developed a procedure using this strategy for designing orthogonal DNA sequences (Yoshida and Suyama 2000). The sequences are designed to satisfy three constraints: (i) uniform melting temperature, (ii) no mishybridization, and (iii) no formation of stable intra-molecular structures. A disadvantage of this strategy is that it easily falls into a local optimum, resulting in the saturation of the number of sequences successfully designed. With the aim of overcoming this drawback, Kashiwamura et al. developed a modified algorithm called "two-step search" (Kashiwamura et al. 2004). They observed that critical sequences, which have higher scores of Hamming distance with sequences in a sequence set, prevent the design of more sequences. In line with this

analysis, the two-step search generates sequences with Hamming distances as short as possible. This is analogous to packing particles into a limited space, for which an effective strategy is to pack them as tightly as possible.

Ruben et al. developed a program called “PUNCH” that designs sequences using a local search algorithm (Ruben et al. 2001). The strategy is to find sequences based on uniqueness, mishybridization, base equality, and folding scores. The program searches neighbors obtained by mutating previous best sequences randomly. Therefore, this search procedure cannot escape from local optima.

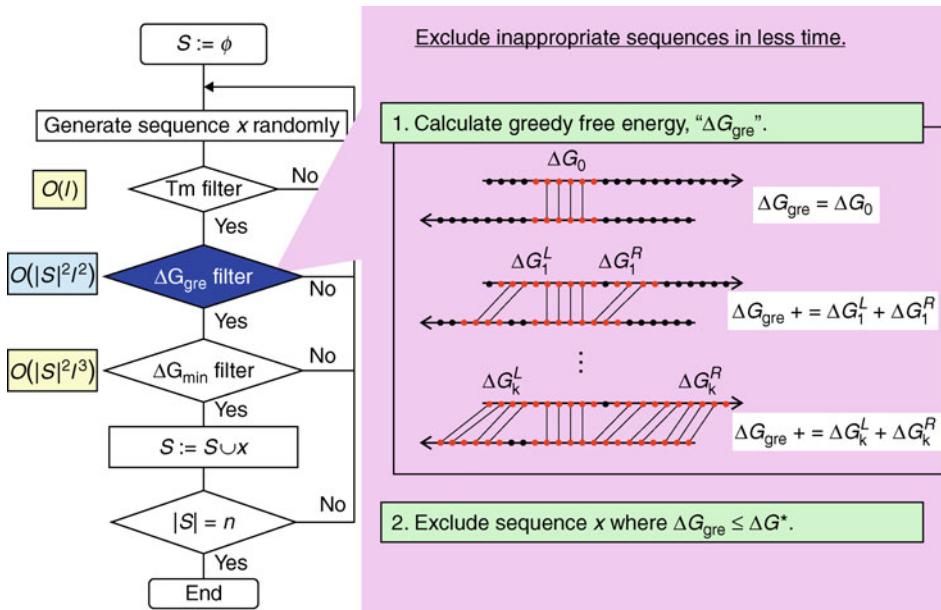

A more sophisticated algorithm is the stochastic local search (SLS) algorithm. The algorithm designs sequences by improving a given sequence set iteratively. First, it chooses a pair of sequences s_1 and s_2 that violate one of the given constraints. Then, it generates a set S_1 of sequences obtained by substituting some bases of s_1 and a set S_2 by substituting some bases of s_2 . With a probability of θ , it selects a sequence s' from $S_1 \cup S_2$ at random. Otherwise, it selects a sequence s' from $S_1 \cup S_2$ such that the number of conflict violations is maximally decreased. If $s' \in S_1$, it replaces s_1 by s' . Otherwise, it replaces s_2 by s' . This procedure is iterated for a predefined number of steps. Using the SLS algorithm, Tulpan et al. found sequence sets that matched or exceeded the best previously known constructions though they did not take into account a frameshift for the Hamming distance (Tulpan et al. 2003; Tulpan and Hoos 2003). They determined that it was effective to use “hybrid randomized neighborhoods” obtained by adding random sequences to neighborhoods by substituting one base (Tulpan and Hoos 2003).

Sequences can also be designed using metaheuristics such as the genetic algorithm (GA). Deaton et al. used GA to design sequences that satisfied various constraints such as the Hamming distances between them being a certain length (Deaton et al. 1996, 1998). Although they considered only Hamming distances without a frameshift, they showed that the Hamming distances for some sequences were identical to the upper bound, called the “Hamming bound.” Arita et al. proposed a design strategy in which an evaluation function calculated as the linear sum of multiple evaluation terms is optimized (Arita et al. 2000). The evaluation function considers restriction sites, GC content, Hamming distance, repetition of the same base, and complete hybridization at the 3'-end. They also utilized a GA for the optimization.

The sequence design methods described above approximate the stability of double strand on the basis of the number of base pairs. Some recently proposed design methods estimate the stability on the basis of the minimum free energy (ΔG_{\min}). This thermodynamic approach approximates the stability with greater accuracy because it takes into account the stability of some loops and the stacking between base pairs. However, it takes longer to calculate the minimum free energy. The time complexity of the minimum free energy calculation by dynamic programming is $O(l^3)$, where l is the sequence length (Lyngso et al. 1999). Therefore, efforts have been made to reduce the computational time. Tanaka et al. proposed approximating the calculation of the minimum free energy in a greedy manner to reduce the time (Tanaka et al. 2005). They defined the problem of designing a pool S containing n sequences of length l for which the minimum free energy is greater than the threshold (ΔG_{\min}^*) in any pairwise duplex of sequences in S and any concatenation of two sequences in S , plus their complements except for the complementary pairs. ➤ *Figure 6* shows a conceptual diagram of this greedy calculation. The approximated value for the minimum free energy, denoted by ΔG_{gre} , is calculated by searching for the most stable continuous base pairs and fixing them iteratively. The time complexity of ΔG_{gre} calculation is $O(l^2)$. Obviously, ΔG_{gre} is an upper bound of ΔG_{\min} (i.e., $\Delta G_{\min} \leq \Delta G_{\text{gre}}$). Thus, ΔG_{gre} can be used to check the sequence before calculating ΔG_{\min} .

Fig. 6

Schematic diagram for sequence design using greedy calculation of ΔG_{\min} . In this diagram, S and I denote a sequence set already designed and the sequence length, respectively. ΔG_{gre} denotes the approximate value of ΔG_{\min} calculated in a greedy manner.

Kawashimo et al. also developed a design procedure based on the thermodynamic approach (Kawashimo et al. 2008, 2009). They reduced the computation time by introducing a sophisticated search order and by limiting the loop size.

2.4 Future Direction of Sequence Design

We have discussed sequence design to date, but research on sequence design continues. What are the future directions?

One will be the development of sequence design that takes the kinetics of DNAs into consideration. Kitajima et al. proposed using a design criterion for rapid hybridization between two complementary sequences (Kitajima et al. 2008). They demonstrated that the rapidity of hybridization depended on the stability of the self-folded secondary structures and on the nucleation capability at the tails of their self-folded secondary structures. Although this finding cannot be directly used for sequence design, it can be used to exclude the sequences for which the hybridization rate is low.

Another direction will be sequence design that considers the dynamics of DNA machinery, in which DNA ruled by the machinery has multiple stable states. In this case, sequences must be designed that can transit from one state to another. To achieve this, we should estimate the energy landscape produced by the DNA sequences. However, it is difficult to predict the energy

landscape because the number of possible structures grows exponentially with the number of sequences. There have been several efforts to estimate the energy landscape efficiently (Uejima and Hagiya 2004; Kubota and Hagiya 2005).

Uejima and Hagiya developed a sequence design method for their multi-state molecular machine that is based on the minimum free energies, the structure transition paths, and the total frequency of the optimal and suboptimal structures (Uejima and Hagiya 2004). The transition paths were estimated using Morgan and Higgs' heuristics. This estimation was expanded by Kubota and Hagiya (2005). They proposed a technique for analyzing the energy landscapes given the minimax path, which is a path on the minimum spanning tree.

In short, sequence designs that consider the above constraints will be developed for more complex DNA machinery.

3 Memory Operations

As mentioned in the introduction of this chapter, one of the most crucial issues for constructing a molecular memory is how to access a specified word in its address space. This section summarizes various techniques that have been developed to implement memory operations on a molecular memory.

To compare various implementations, an associative molecular memory consisting of words that are divided into two portions is considered: the address part and the data part. The address part can be further divided into multiple address digits, comprising a hierarchical address space. For each memory operation, it is first assumed that the address part consists of a single address digit, and then it touches on the possibility of extending the memory operation to a hierarchical memory.

The data part of a memory word can be designed in various ways. It can represent a single bit, that is, 0 or 1. In some molecular memories, the base sequence of a data part is not relevant. For example, a long data part represents bit 1, and a short data part represents bit 0. Data parts can also be empty. In such a molecular memory, existence of a word having a specified address means bit 1 of the address and nonexistence of a word means bit 0. Each address (digit) can have its complementary address (digit). This is typical when variable assignments are represented by a DNA molecule. Each variable and its negation correspond to complementary address digits and they comprise a hierarchical molecular memory.

The data part can represent richer information. For example, if an artificial tag sequence is attached to a gene extracted from a chromosome or cDNA in a library of genes, then the tag sequence is regarded as the address part and the gene sequence as the data part.

This section is organized as follows. In the first subsection, various implementations of the access operation as mentioned above are summarized. In the next sections, the read and write operations are briefly explained. The final section touches on some other operations on a molecular memory.

3.1 Access Operation

This section explains how to access a memory word having a specified address in a molecular memory. If there is no data part in a memory word, success in accessing the word amounts to reading bit 1 of the address, and failure amounts to reading bit 0.

3.1.1 Extraction by Magnetic Beads

As in the seminal work of Adleman, extraction using magnetic beads is a typical access operation on a molecular memory. More generally, any kind of affinity separation based on the address part of a word can be used as an access operation. Affinity separation by magnetic beads is performed as follows.

The address part of a memory word should be represented by a single-stranded segment of a DNA molecule. Typically, a whole word takes the form of a single strand of DNA as in [Fig. 7](#). As Baum pointed out (Baum 1995), in order to avoid unexpected interaction, the data part of a memory word can be double-stranded. Such words comprising a molecular memory are mixed and diluted in an aqueous solution.

DNA molecules containing the sequence complementary to the address part, called probes, are also single-stranded and attached on the surface of magnetic beads as in [Fig. 8](#). The protein called biotin is covalently bonded to the probes. Such modified DNA can be ordered to a DNA synthesizing company as ordinary plain DNA with some additional cost. The surface of the magnetic beads is coated with another kind of protein called streptavidin. Strong interaction between streptavidin and biotin attaches the probes to the surface of the magnetic beads.

The magnetic beads are then put into the aqueous solution of the molecular memory in a test tube. The resulting test tube looks like muddy water, in which the molecular words and the probes attached on the surface of magnetic beads interact, and those words having the address part complementary to the probes are trapped by DNA hybridization. Those with different address parts are still in the solution.

A strong magnet is then placed at the side of the test tube. Not surprisingly, all the magnet beads are pulled together near the magnet ([Fig. 9](#)), and the solution quickly becomes transparent, in which memory words not trapped in the beads are still diluted. The solution is then extracted by a pipet while the beads are fixed to the magnet. Pure water is then poured into the test tube and the magnet is removed. The water is then turned into mud. This process is repeated to separate all memory words that are not trapped in the beads.

Fig. 7

A simple memory word. A single strand of DNA consists of the address part and the data part.

Fig. 8

A strand trapped by a magnetic bead. Probes containing the sequence complementary to the target are attached on the surface of a magnetic bead. A single strand containing the target sequence is trapped by the bead.

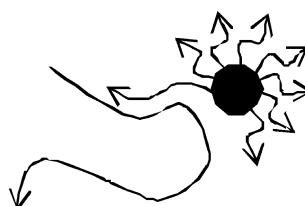

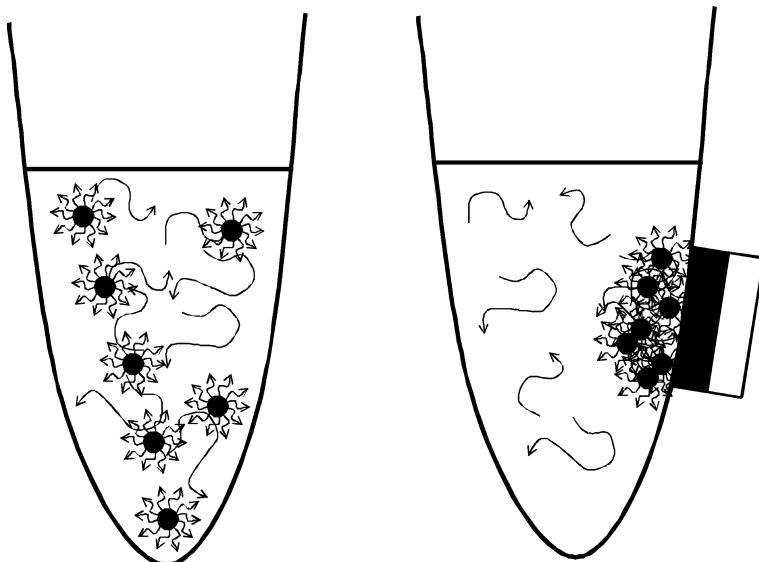

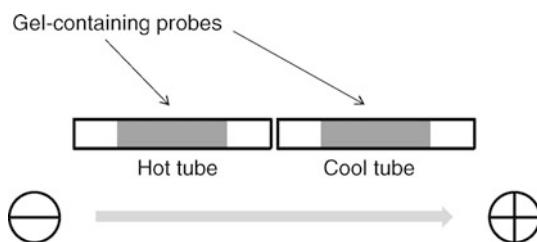

Fig. 9

Magnetic beads. In the left panel, magnetic beads are diluted in the tube to trap the target DNA. In the right panel, magnetic beads with the trapped DNA are collected by a magnet.

**Fig. 10**

A hot tube connected to a cool tube. DNA molecules released from the hot tube are moved and trapped in the cool tube.

Finally, hot water is poured into the test tube. At this time, since hydrogen bonds in DNA hybridization are broken at high temperatures, the memory words trapped in the beads become free and diluted in the hot water. In this way, memory words having the specified address are separated from those having different addresses.

In the experiment conducted by Adleman et al., in which they solved a 20-variable SAT problem, probes are fixed in a gel filled inside a thin tube (Braich et al. 2002). Probes are chemically modified so that they are fixed in a gel and cannot move.

As in Fig. 10, two such tubes are connected and placed in a specially designed electrophoresis box, in which one tube is heated while the other is cooled down. In the hot tube, trapped DNA molecules are released and moved toward the cool tube according to the voltage

Fig. 11

A word in a molecular memory with a hierarchical address space. Each word consists of multiple address digits (three digits in this figure) and a data part.

of electrophoresis, and trapped in the cool tube if they are complementary to the probes fixed in the cool tube.

A hierarchical molecular memory consists of memory words whose address is comprised of multiple address digits as in [Fig. 11](#). If a single digit has r different values and each address consists of n digits, the whole address space contains r^n different addresses.

It is easy to implement a hierarchical molecular memory whose access operation is implemented by affinity separation as explained so far. The access operation is iterated for each digit, that is, affinity separation by the i th digit is applied to the result for $(i-1)$ th digit. A serious problem of this iterative approach is that at each round of affinity separation, some memory words are lost due to the limitation of the employed experimental technique. The yield of extraction thus exponentially decreases as n increases. This problem is solved by the approach using PCR, since copies of the extracted memory word are made.

3.1.2 Extraction by PCR

As is well known, PCR (polymerase chain reaction) is a method to amplify specified DNA molecules, that is, make their copies. Copied DNA molecules should have the specified sequences at their ends, with which short DNA molecules, called primers, hybridize.

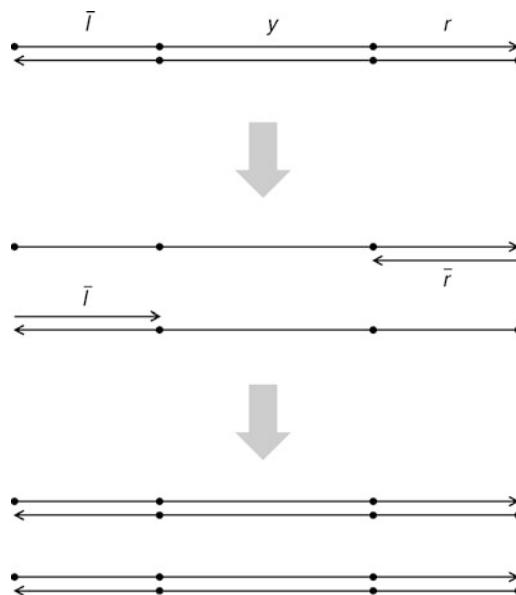

To be more precise, copied DNA molecules are double-stranded, formed by a sequence x and its complement \bar{x} . The sequence x should end with a short sequence r , while the sequence \bar{x} should also end with a short sequence l . Consequently, x should be of the form $\bar{l}yr$ ([Fig. 12](#)). Primers are single-stranded DNA molecules whose sequence is \bar{r} and \bar{l} .

PCR is conducted as follows ([Fig. 12](#)). Double strands consisting of x and \bar{x} are mixed with the pair of primers \bar{r} and \bar{l} in an appropriate buffer, containing polymerase, nucleotides, and adenosine triphosphate (ATP), which is called the polymerization buffer. The concentration of primers is much larger than that of double strands. The solution is then heated up to over 90°C, denaturing double strands into single strands x and \bar{x} . When the solution is cooled down, single strands hybridize with primers rather than their counterparts because they have more chances to contact the primers. During an appropriate duration for incubation, the 3'-end of \bar{r} in the hybrid of x and \bar{r} is extended by polymerase and the hybrid turns into a complete double strand consisting of x and \bar{x} . This process is called polymerization. The hybrid of \bar{x} and \bar{l} similarly turns into the same double strand. In this way, in a cycle of heating up, cooling down, and incubation, the concentration of x and \bar{x} is doubled, and repeating the cycle amplifies the concentration of the double strands.

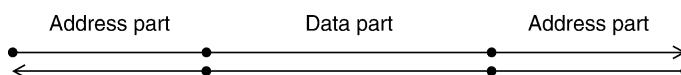

In order to use PCR for accessing memory words in a DNA memory, each word should have its data part surrounded by two primer sequences at its ends as in [Fig. 13](#). These primer sequences comprise the address part, since a memory word can be amplified only if it has both

Fig. 12

PCR (polymerase chain reaction). A double strand is first denatured to single strands at high temperature. If cooled down, they hybridize with short DNA molecules, called primers. Polymerase then extends the primers and two copies of the original double strand are made.

**Fig. 13**

A memory word extractable by PCR. Each word is a double strand having primer sequences as its address.

primer sequences. Therefore, in order to extract a memory word, the solution of the DNA memory is diluted and mixed with the primers in the polymerization buffer. Since PCR only amplifies the target memory word, if the resulting buffer is diluted, the concentration of memory words other than the target becomes less than detectable. This means that the target word is extracted by PCR.

A hierarchical address space can be obtained by introducing multiple primer pairs into a memory word. These primer pairs are nested as in [Fig. 14](#). In order to extract a memory word, PCR is conducted with the outermost primer pair first. The obtained memory words are then processed by the second iteration of PCR with the next outer primer pair. Note that after PCR is conducted with an inner primer pair, the outer primer sequences are lost.

In [Sect. 4.2](#), an actual PCR-based molecular memory is described in detail.

3.1.3 Hybridization and Conformational Change

Instead of extracting a memory word with a specified address, separating it from other words, it is also possible to access a memory word by changing its state, while words with different addresses are unchanged. In this kind of molecular memory, since memory words are not separated or mixed again, they can be fixed on a surface or in a space. In particular, it is possible to make a two-dimensional molecular memory by fixing DNA molecules on a surface of gold or other appropriate material.

If memory words are represented as single strands, simply adding a single-stranded probe whose sequence is complementary to the address of the target changes it into a double strand (☞ Fig. 15). In a simple setting, where a memory word does not have a data part, this process is considered as a write operation. The single-stranded form represents bit 0 and the double-stranded form represents bit 1.

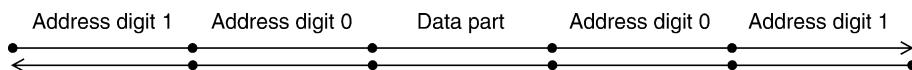

As explained in detail in ☞ Sect. 5, Suyama's group employs hairpin molecules as memory words. The use of hairpins can introduce an additional condition for the access operation. Since hairpin formation is an intra-molecular reaction, it is more efficient than hybridization between a hairpin and its complement, which is an inter-molecular reaction. Therefore, it is necessary to denature a hairpin structure by raising temperature in order for its complement to hybridize with the hairpin (☞ Fig. 16).

They attach hairpins with different addresses to a gold surface, and employ a laser beam to locally raise temperature on the surface. Those hairpins on the laser spot are denatured and if their sequence is complementary to that of single strands in the surrounding solution, they can hybridize with the single strands.

It is not obvious to construct a hierarchical molecular memory based on hybridization, in which a memory word contains multiple address digits. For accessing a target memory word of the form in ☞ Fig. 11, single strands whose sequences are complementary to the address digits of the target are mixed with the whole molecular memory. Then the address part of the target

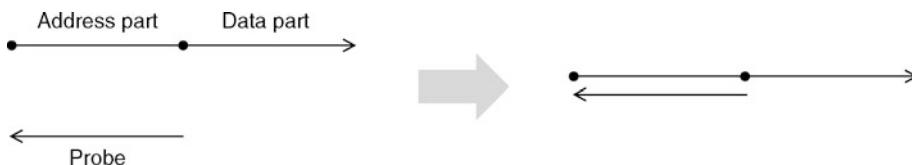

■ Fig. 14

A memory word in a hierarchical molecular memory extractable by PCR. Each word contains nested primer pairs.

■ Fig. 15

Hybridization of a memory word and a probe that is complementary to the address part of the word. The address part is changed from a single strand to a double strand.

word becomes fully double-stranded. It is therefore necessary to distinguish the target word from other words whose address part is not double-stranded or partially double-stranded.

Hagiya's group employed hairpins to construct a hierachal molecular memory based on hybridization (Kameda et al. 2008b). A memory word consists of concatenated hairpins and a single-stranded end as in **Fig. 17**.

A memory word has a single-stranded part to the left of the first hairpin. Single strands called openers are used to open the hairpins successively. The first opener is complementary to the single-stranded part of a word and the stem of the first (leftmost) hairpin. It first hybridizes with the single-stranded part, and then invades into the stem of the first hairpin by branch migration. Eventually, it completely hybridizes with the single-stranded part and the adjacent part of the stem. Consequently the first hairpin is opened, and the other part of the stem is exposed as single-stranded. Therefore, if the second opener, which is complementary to the exposed stem and the adjacent part of the second hairpin, is present, it first

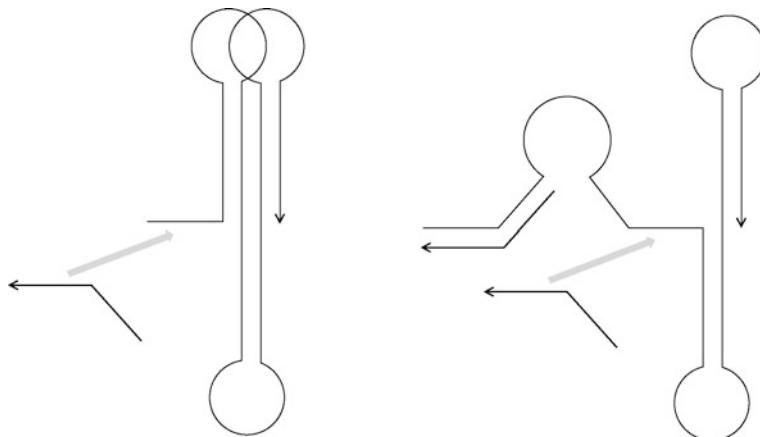

Fig. 16

A hairpin molecule as a memory word. If the temperature is raised, the hairpin is denatured and it can hybridize with a probe that is complementary to the hairpin loop and one side of the stem.

Fig. 17

A memory word consisting of three consecutive hairpins. A single strand called an opener hybridizes with the single-stranded part of the memory word and opens the adjacent (first) hairpin. As a result, the next opener that opens the second hairpin can hybridize with the exposed stem of the first hairpin.

hybridizes with the exposed stem and then invades the stem of the second hairpin by branch migration. Note that without the first opener, the second cannot hybridize with the memory word and open the second hairpin. Therefore, only if all the openers are present, are all the hairpins opened. In particular, the final hairpin is opened only if all the openers are present. This means that a memory word is accessed if and only if the final hairpin is opened.

Hagiya's group actually constructed a memory word consisting of four hairpins and verified that the proposed scheme actually worked (Kameda et al. 2008b). They also constructed a molecular memory consisting of 3^3 addresses by employing the scheme. In this molecular memory, a memory word consists of three hairpins, and there are three variations for each opener that opens one of the hairpins. Consequently, there are 3^3 combinations of three openers. They verified that the final hairpin of each memory word can only be opened by the corresponding combination of three openers.

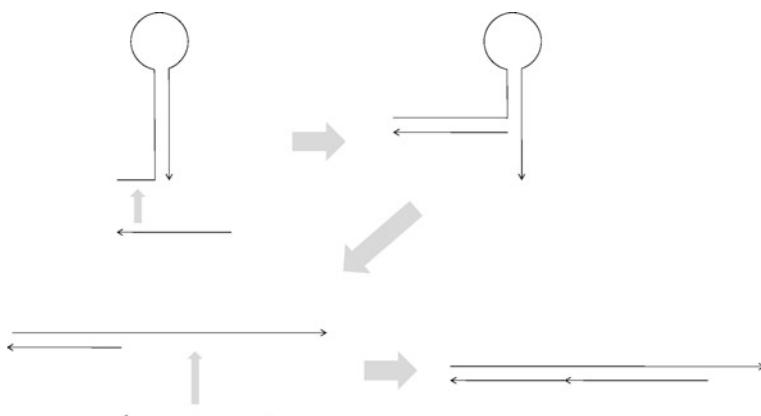

It is also possible to combine schemes described in this section. For example, in the scheme by Suyama's group a hairpin molecule can hybridize with its complement only if the local temperature is raised (Takinoue and Suyama 2004, 2006). If the stem of the hairpin is longer, raising the temperature is not sufficient to denature the hairpin. In this case, a single strand can be used to partially open the stem as in Fig. 18. This is a combination of the scheme of Hagiya's group (Kameda et al. 2008b) and that of Suyama's group (Takinoue and Suyama 2004, 2006).

3.2 Read Operation

In an extraction-based molecular memory, if a memory word consists of only the address part, and if existence and nonexistence of a word means bit 1 and bit 0, respectively, then extracting a memory word, whether by affinity separation or by PCR, amounts to reading the bit of the address of the word.

Fig. 18

A hairpin memory word accessible by the combination of an opener and temperature. If an opener is present, it partially opens the hairpin. If the temperature is raised (from the upper right diagram to the lower left one), then the hairpin is completely opened and it can hybridize with the complementary strand.

If a memory word contains a data part that encodes some additional information, then it is necessary to read the data part by a separate read operation. In an extraction-based molecular memory, the extracted word is given to a read operation such as gel electrophoresis, sequencing, or DNA chip detection. If the length of the data part encodes the information stored in the memory word, gel electrophoresis is the most efficient way to read the data. If the sequence of the data part encodes information, then sequencing is required to determine the bases in the data part.

As sequencing technology is progressing rapidly, it is becoming more and more efficient to read the base sequence of a given DNA molecule. However, it is still time consuming to read out individual bases in DNA. Moreover, sequencing requires a certain number of copies of the given DNA molecule, and additional amplification by PCR is usually necessary. Therefore, PCR-based memories are more suitable for sequencing.

DNA chips are also used if the target memory word is amplified with a fluorescent label. Single strands whose sequences are complementary to possible data parts are attached on a DNA chip. Single-stranded copies of the target word with a fluorescent label are then put on the DNA chip. The fluorescent label is observed at the spot having the sequence complementary to the data part.

Fluorescence resonance energy transfer (FRET) is more useful because the target need not be amplified. It can be used if the extracted target word (or its data part) is single-stranded. A molecular beacon is a hairpin structure having a fluorescent group at its end and a quencher group at the other end (Fig. 19). If the data part is complementary to the loop sequence of the beacon, the hairpin is opened and the beacon hybridizes with the data part. Consequently, the fluorescent group and the quencher group part and fluorescence is observed.

In a hybridization-based molecular memory, since the target memory word is not extracted but is still mixed with other memory words, the methods mentioned above (except that of FRET) cannot be used in general.

In the simplest hybridization-based scheme in which each memory word consists of only a nonhierarchical address part, a molecular beacon corresponding to the address part of a memory word can be used to detect the existence of the memory word.

If each memory word contains a data part in addition to a nonhierarchical address part, a single-stranded probe whose sequence is complementary to the address part can be used together with another probe for the data part. Both probes are labeled with different

Fig. 19

A molecular beacon. A fluorescent group and a quencher group are attached at the terminals of a small hairpin. Since the stem of the hairpin is short, it can hybridize with the strand whose sequence is complementary to the hairpin loop. After hybridization, the fluorescent group parts from the quencher and fluorescence is observed.

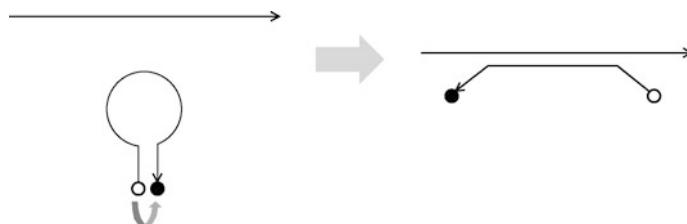

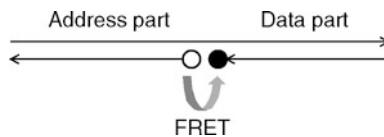

Fig. 20

FRET between an address probe and a data probe. The two probes are complementary to the address part and the data part of a memory word. If they hybridize with the memory word, they come in close proximity and FRET occurs.

fluorescent groups. If both probes hybridize with the memory word, these groups come in close proximity to each other and energy transfer occurs (☞ Fig. 20).

Note that this method cannot be applied to a naïve hierarchical memory in which address digits are simply concatenated. The address digit next to the data part is only significant for energy transfer, and other digits are irrelevant.

The hairpin-based scheme proposed by Hagiya's group solves this problem (Kameda et al. 2008b). In this scheme, the last hairpin is regarded as a data part. Remember that the last hairpin can be opened only after all the preceding hairpins have been opened by their openers. If the last hairpin is opened, since it becomes single-stranded, FRET as in a molecular beacon, can be used to detect this single-stranded part.

So far, we assumed that the sequence (or length) of the data part of a memory word represents the content of the word. In general, however, the read operation of a molecular memory depends on the write operation. For example, in some hybridization-based memory schemes, each memory word consists of only an address part and does not have a data part. The single-stranded and double-stranded states of a memory word are regarded as bit 0 and 1, respectively. If a memory word hybridizes with the corresponding probe and becomes double-stranded, the word is considered to have bit 1, while if it is single-stranded, it is considered to have bit 0. In this kind of scheme, it is not obvious how to read out the single- or double-stranded state of the memory word.

A molecular beacon can be used here because it does not hybridize with the memory word having bit 1, since it is already double-stranded. However, if a beacon hybridizes with the memory word having bit 0, it becomes double-stranded. So this method is destructive. It is also possible to raise the temperature of the whole molecular memory, and collect all the probes attached to memory words. Each probe denotes that the corresponding memory word has had bit 1. This read operation is also destructive. Undestructive read operations require more sophisticated schemes in this kind of hybridization-based memory.

There are some other operations related to the read operation. For example, extraction with respect to the data part is a kind of read operation. They are explained in ☞ Sect. 3.3.

3.3 Write Operation

If existence and nonexistence of a memory word mean bit 1 and bit 0, respectively, then writing bit 1 to an address amounts to simply inserting the memory word of that address into the molecular memory. This operation is always easy. On the other hand, writing bit 0 to an address amounts to deleting the memory word of that address from the molecular memory.

This is easy in a molecular memory based on extraction by affinity separation. It is difficult or impossible to implement the delete operation in a molecular memory based on extraction by PCR or hybridization.

If the data part of a memory word encodes some information, then the write operation should change the data part according to the specified data.

In a molecular memory based on extraction by affinity separation, changing the data part of a memory word having a specified address amounts to deleting the memory word and adding a new memory word having the same address and the specified data. If a molecular memory is based on extraction by PCR, it is also possible to add a new memory word with the specified data, while it is difficult to delete the old memory word with the original data.

In a (nonhierarchical) hybridization-based molecular memory, it is possible to add a new data part to the accessed memory word or delete the original data part. For example, if the new data part is put together with the probe complementary to the address part and the new data part, they form a double strand with the target memory word (without a data part) as in [Fig. 21](#). After ligation is performed, the target word is concatenated with the new data part. On the other hand, it is also possible to cut the target memory word with some restriction enzyme, if it hybridizes with a probe that is complementary to the address part and the adjacent portion of the data part. The double strand formed by the probe and the word is supposed to contain the recognition site of the restriction enzyme ([Fig. 22](#)).

The hairpin-based scheme proposed by Hagiya's group also allows the write operation in a hierarchical molecular memory (Kameda et al. [2008b](#)). After the last hairpin is opened, it is possible to add a specified data part with the help of an appropriate probe.

As explained in [Sect. 3.2](#), if a memory word does not have a data part, hybridization between a memory word and its probe is considered as writing bit 1 onto the word. Although writing bit 1 is easy, reading the bit is difficult. Writing bit 0 is also nontrivial. Using branch migration as in molecular tweezers (Yurke et al. [2000](#)), the strand complementary to the probe can remove it from the memory word ([Fig. 23](#)).

Fig. 21

Writing a new data part to a memory word. The new data part is put together with the probe complementary to the address part and the new data part. After ligation, the new data part is concatenated with the address part.

Deleting the data part of a memory word. The probe is complementary to the address part and the adjacent portion of the data part. The double strand formed by the word and the probe is cut by a restriction enzyme.

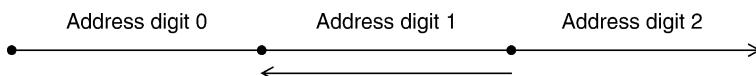

Fig. 23

Removing a probe from a memory word. The strand complementary to the probe hybridizes with the single-stranded portion of the probe and eventually removes it from the memory word.

**Fig. 24**

Writing on an address digit. A probe hybridizes with the address digit 1. This operation is regarded as writing bit 1 to the address digit.

3.4 Other Operations

Due to the features of molecular memories, there are some more operations that can be implemented efficiently.

In a nonhierarchical molecular memory, the address part and the data part are symmetric. Therefore, it is also possible to extract memory words with respect to their data part. This kind of operation is called content-based addressing, and memories that allow such an operation are called associative memories.

In a hierarchical molecular memory, it is also possible to extract memory words based on a specified address digit or on a combination of address digits. For example, when an NP-complete problem like SAT is solved, each candidate of a solution is regarded as a memory word consisting of multiple address digits. Iteration of extraction results in a solution of such a problem. For solving a SAT problem, extraction is performed for each clause of a given Boolean formula. Each extraction operation selects those memory words that contain at least one digit corresponding to a literal in the corresponding clause.

Like extraction, it is also possible to write data onto a specified address digit. For example, in a hybridization-based hierarchical memory, a probe for a particular address digit hybridizes with those memory words having the address digit ([Fig. 24](#)). In the simplest case of this scheme, each address digit has only one possible sequence, and whether or not a probe hybridizes with an address digit is based on whether the address digit is 1 or 0. In this case, the write operation is considered to change the address of a memory molecule from, for example, 000 to 010 ([Fig. 24](#)).

As a result of this operation, each memory word contains a certain number of probes that hybridize with one of its address digits. Another possible operation is separation by counting. Using gel electrophoresis, for example, it is possible to separate memory words according to the number of probes they contain.

The two operations mentioned above, writing bit 1 to an address digit and separation by counting, compose the molecular computing paradigm called aqueous computing (Head and Gal 2001). Note that this scheme is different from the scheme described in [Sect. 4.1](#), where each address digit has two possible sequences.

4 In Vitro DNA Memory

This section briefly touches on molecular memories in an aqueous solution, that is, in a test tube. They are manipulated using the operations mentioned in the previous section.

4.1 Solving NP-Complete Problems

Mainly for solving NP-complete problems, various memory schemes were proposed in the early days of DNA computing.

As mentioned in the previous section, Adleman's group solved a 20-variable SAT problem (Braich et al. 2002). For solving the problem, they constructed a pool consisting of 2^{20} different assignments to 20 Boolean variables. Each assignment can be regarded as a hierarchical memory word with 20 address digits, where each digit has two possible values, true or false. The size of this molecular memory is therefore 2^{20} .

The initial pool of assignments, that is, the whole address space, was constructed in two steps. In the first step, assignments to 10 variables were generated using a mix-and-split synthesis technique (Faulhammer et al. 2000). They used two tubes (or columns) beginning with synthesizing the two sequences for the tenth variable. The results were mixed and then separated into two again. The two sequences for the ninth variable were then attached. The assignments to the first 10 variables and those to the rest were combined using PCR (Stemmer et al. 1995).

The only memory operation employed for solving the problem is extraction with respect to a combination of address digits. For each clause in a given Boolean expression, those memory words that contain an address digit corresponding to a literal in the clause are extracted. If there remain memory words after all the extraction operations are performed, the formula is known to be satisfiable.

4.2 Nested Primer Molecular Memory (NPMM)

Yamamoto et al. constructed a molecular memory consisting of 16^6 addresses (Yamamoto et al. 2008). Their molecular memory is called NPMM, which stands for nested primer molecular memory. Each memory word consists of a data part and an address part. The data part is surrounded by the address part. Each address digit to the left of the data part is paired with a digit to the right, and they comprise a primer pair. In the 16^6 -version of NPMM, there are six address digits, denoted by AL, AR, BL, BR, CL, and CR. The digits AL, BL, and CL are paired with AR, BR, and CR, respectively. The sequence CL is put to the leftmost end of a word and CR is put to the rightmost end. They comprise the first primer pair to extract a memory word. The sequence BL is put to the right of CL, and BR is put to the left of CR. The sequences AL

and AR are put to the left and right of the data part. Therefore, each memory word having the data part, Data, is of the form

$$\text{CL} - \text{BL} - \text{AL} - \text{Data} - \text{AR} - \text{BR} - \text{CR}$$

These memory words are prepared as double strands of DNA. It suffices to repeat three PCR experiments to extract a single memory word.

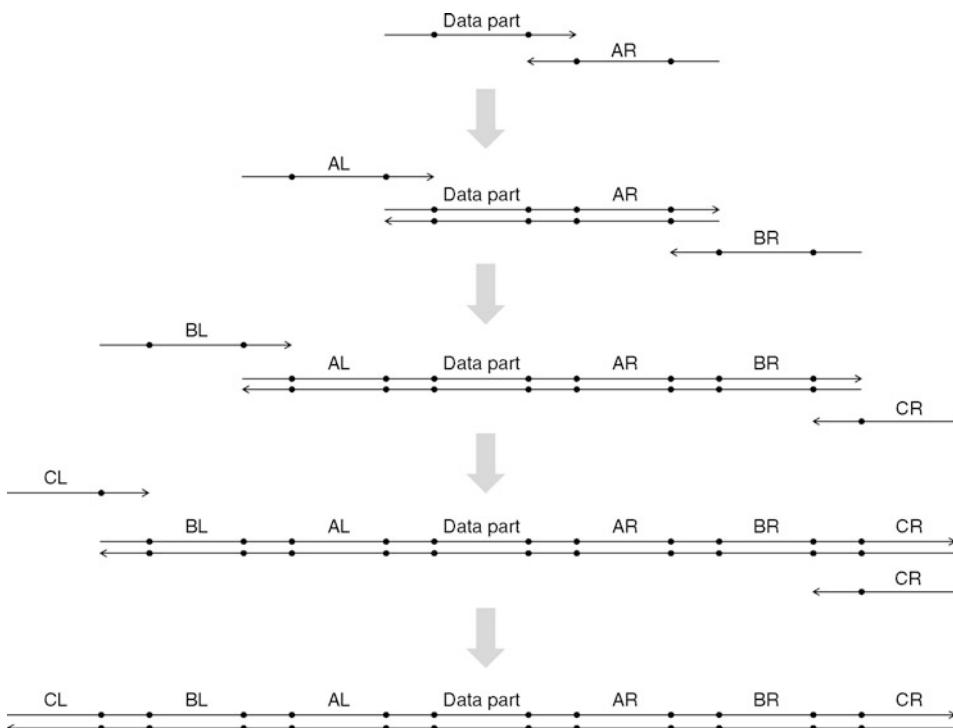

In the 16^6 -version of NPMM, 16 sequences were prepared for each address digit, denoted by AL_i , AR_i , BL_i , etc. Consequently, the entire address space consists of $16^6 = 16,777,216$ addresses. In addition to the 16×6 sequences for the address digits, six linker sequences were inserted between adjacent address digits and between the data part and the address part. As for the data part, three sequences of different lengths were prepared. In total, 105 different sequences were designed, using a two-step search method, which was developed for this molecular memory.

The entire memory was constructed in a style of parallel overlap assembly (Stemmer et al. 1995) as in Fig. 25. The common linker sequences were used as primers in PCR.

In order to verify that the access operation was correctly implemented, Yamamoto et al. picked up one address ($\text{CL}_0, \text{BL}_0, \text{AL}_0, \text{AR}_0, \text{BR}_0, \text{CR}_0$) and inserted a memory word with a longer data part (data40) with the address. The initial memory consists of memory words having a fixed data part (data20). Similarly, they inserted a memory word with the longest

Fig. 25

The construction of NPMM. PCR is iterated four times to construct a molecular memory with six digits.

data part (data60) at another address (CL8, BL8, AL8, AR8, BR8, CR8). Then they accessed 16 different addresses ($CL_i, BL_i, AL_i, AR_i, BR_i, CR_i$) and verified by gel electrophoresis that the access operation was always correct.

One of the most important factors for implementing this kind of molecular memory is to reduce variation of concentrations of memory words. Using real-time PCR, Yamamoto et al. measured the concentrations of the first products in the construction of NPMM, that is, memory words of the form $AL_i - \text{data}20 - AR_j$. They observed that, compared to the least concentration of a memory word, the largest concentration was 2.36 times larger and the average was 1.4. In the 16^6 -version of NPMM with six address digits, it is expected that compared to the least concentration of a memory word, the largest concentration is 173 and the average is 7.53. The molecular memory they actually constructed was supposed to contain 185 molecules for each memory address on average. Therefore, the least number of molecules for a word is expected to be 25.

Yamamoto et al. also estimated the limitation of their approach by analyzing a mathematical model based on the current experimental technologies including PCR. (The numbers in parentheses are their tentative estimations.)

- The total number of molecules should not exceed the number of primers (50 pmol).
- The number of PCR iterations is limited (30 cycles).
- After amplification, the copy number of a target word should be significantly larger than the total number of molecules (1,000 times larger).
- The total number of sequences for address digits is limited (200 sequences).

Using the model, they estimated that it was not possible to construct a molecular memory having more than 170M addresses. In this sense, the molecular memory they constructed was comparable to this limit.

As a possible application of a molecular memory with a huge address space, Hagiya's group proposed to use a molecular memory for DNA ink (Kameda et al. 2008a). By simply diluting a molecular memory, the total number of molecules becomes less than the total number of addresses. Consequently, each memory address may or may not exist in the diluted solution. This amounts to tossing a coin for each address. The diluted solution can be amplified with common primers, and if the primers are removed after amplification, it is practically impossible to completely determine the contents of the memory. Therefore, it can be used for authentication or as a seed for key generation. For example, it can be mixed with ink and used for printing passports or signing secret documents. It is possible to obtain more and more information from the memory by sampling more and more addresses by PCR.

5 DNA Memory on Surfaces

5.1 Introduction

A DNA molecule is a molecular memory stably storing genetic information. The information is described in a DNA base sequence and is accurately read out when DNA is replicated or RNA is transcribed. The specificity of the Watson–Crick base pairing between complementary DNA strands realizes high fidelity in replication and transcription. The specificity of the DNA base pairing is also utilized to construct structures, devices, and computers working in a nanometer scale (Bath and Turberfield 2007; Seeman and Lukeman 2005; Simmel and Dittmer

2005), which are actively developed today: DNA nanostructures (He et al. 2008; Rinker et al. 2008; Rothemund 2006), DNA nanomachines (Goodman et al. 2008; Venkataraman et al. 2007), DNA computers (Benenson et al. 2004; Komiya et al. 2006; Seelig et al. 2006; Takinoue et al. 2008; Zhang et al. 2007), etc.

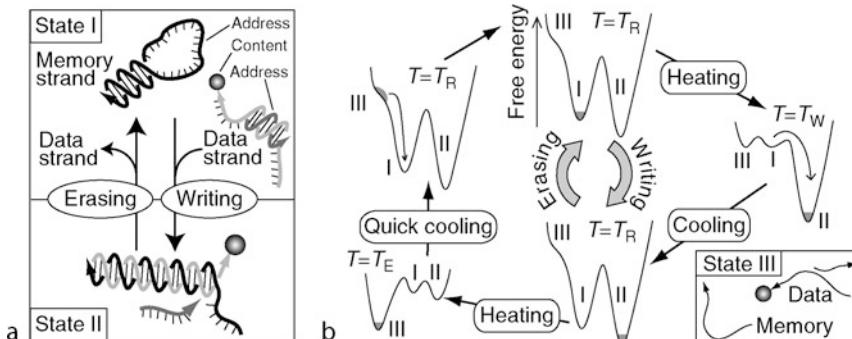

The specificity of the DNA base pairing can achieve even rewritable molecular memories (Shin and Pierce 2004; Takinoue and Suyama 2006). This section introduces one of the rewritable DNA molecular memories. This memory is based on physicochemical reactions of hairpin-shaped DNA molecules; that is, a temperature-controlled conformational transition and DNA hybridization of the hairpin DNA molecules achieve memory addressing and data storing (Takinoue and Suyama 2004, 2006). Although, in life systems, a DNA molecule is a read-only and non-rewritable molecular memory storing information as a base sequence, the physicochemical reactions of the hairpin DNA can realize not only the readout but also the rewriting of the DNA molecular memory. By cooperation between the base sequence information and the physicochemical reactions, the hairpin DNA memory achieves massively parallel and highly selective addressing in a very large memory space.

5.2 Hairpin DNA Memory Dissolved in a Solution

First, the hairpin DNA memory dissolved in a solution is explained. A hairpin DNA memory has two states: a single-stranded hairpin structure (unwritten state, state I of Fig. 26a) and a double-stranded linear structure (written state, state II of Fig. 26a). A memory strand has a hairpin DNA sequence with a memory address in its loop region. A data strand is composed of an address part and a content part. The address part is a linear DNA sequence, whereas the data part can be composed of various substances, such as DNA/RNA sequences, proteins, metal nanoparticles, or quantum dots. The DNA sequence of the address part of the data strand is complementary to that of the hairpin loop of the memory strand, so that the memory and the corresponding data strands can hybridize with each other by base pairing between the

Fig. 26

A hairpin DNA memory dissolved in a solution. (a) Structures of memory and data. State I: unwritten state (hairpin structure). State II: written state (linear structure). (b) Writing and erasing by temperature control. T_R , T_W , and T_E : temperatures of readout, writing, and erasing ($T_R < T_W < T_E$). State III: dissociated state.

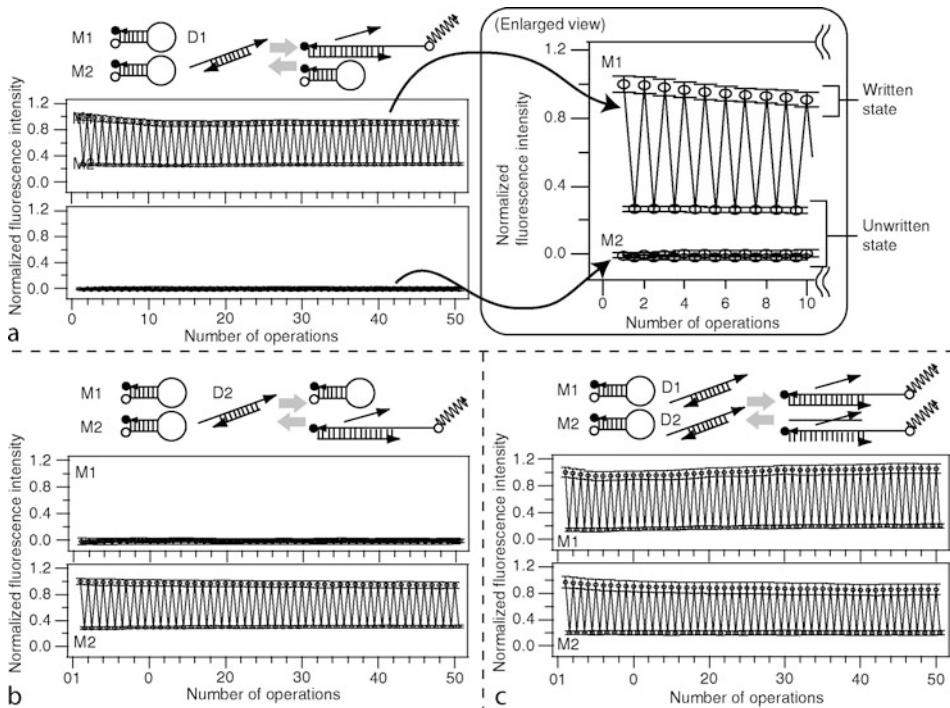

complementary sequences. The address part of the data strand partly forms a double helix with an auxiliary DNA strand to prevent the data strand from spontaneously hybridizing with the memory strand.

The writing and erasing of the hairpin-DNA memory are performed by temperature control of a solution containing memory and data strands. [Figure 26b](#) illustrates the mechanism of memory writing and erasing. Data is written to the memory through a state transition from state I to state II. When a solution containing the memory and the data strands is exposed to a writing temperature (T_W), the hairpin structure of the memory strand opens and the data strand is released from the auxiliary strand, and therefore the data strand hybridizes with the memory strand. Conversely, data is erased through a state transition from state II to state I. When the solution is quickly cooled down to a readout temperature (T_R) after being exposed to an erasing temperature (T_E), the hairpin structure of the memory strand closes before the data strand hybridizes with it again. The intramolecular hairpin formation of the memory strand is faster than the intermolecular hybridization between the memory and the data strands. Once the memory and the data strands are separated, they can hardly hybridize with each other until the solution temperature is raised to T_W .

The writing and erasing of the hairpin DNA memory can be performed even when multiple memory addresses coexist in a memory solution. [Figure 27](#) shows the experimental results of

Fig. 27

Alternate repetition of writing and erasing of hairpin DNA memory. M1, M2: Memory 1, 2. D1, D2: Data 1, 2. (a) Selective writing and erasing of M1-D1, and the enlarged view. (b) Selective writing and erasing of M2-D2. (c) Parallel writing and erasing of M1-D1 and M2-D2. $T_R=25^\circ\text{C}$, $T_W = 50^\circ\text{C}$, $T_E = 90^\circ\text{C}$. Experimental detail: reference Takinoue and Suyama (2006).

selective and parallel writing and erasing of the hairpin DNA memory in the case of the coexistence of two memory addresses. In **Fig. 27a** and **b**, Data 1 (D1) and Data 2 (D2) are selectively written to the memories with the corresponding address. **Figure 27c** shows that D1 and D2 are written to the memories with the corresponding address in parallel. The hairpin DNA memory works very stably as shown in the 50-times repeated writing and erasing operations in **Fig. 27**.

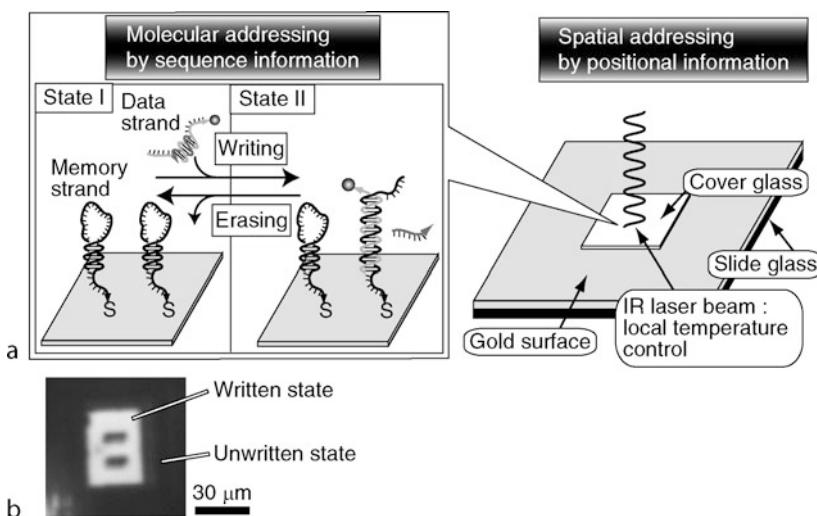

5.3 Hairpin DNA Memory Immobilized on a Surface

The functionality of the hairpin DNA memory can be extended by immobilizing hairpin DNA memory strands onto a solid surface. The immobilization allows spatial addressing of the memory by physically positioning memory locations on the surface, as well as molecular addressing of the memory by hybridization between memory and data strands (**Fig. 28**). In the memory substrate of **Fig. 28a**, the memory strand is uniformly immobilized on the surface of a thin gold layer via a thiol-Au bond. The spatial addressing is achieved through local heating of the memory substrate by IR laser beam irradiation. No irradiation, weak irradiation, and strong irradiation of the IR laser beam correspond to the temperature controls T_R , T_W and T_E in **Fig. 26b**. On the other hand, molecular addressing is performed through hybridization of a data strand with the immobilized memory strand. The reaction is the same as the reaction shown in **Fig. 26a**.

Fig. 28b shows a fluorescence microscope image of a hairpin DNA memory immobilized on a surface. The white and black areas indicate the written and unwritten states,

Fig. 28

respectively. Local irradiation with the IR laser beam allows data storing with microscale spatial patterning. The memory addressing is not limited only to a single memory address. Selective and parallel writing and erasing for multiple memory addresses can also be realized. In addition, this system is stable for many repetitions of the writing and erasing.

5.4 Conclusion

This section explained the hairpin DNA memory and its immobilization on a solid surface. Hybridization of data strands with memory strands and the structural transition of hairpin-shaped memory strands realize molecular addressing and data storing to the memory. Immobilization makes possible spatial addressing to the memory using locations on the surface.

Hairpin DNA memory immobilized on a solid surface has a lot of possibilities for applications in micro and nanotechnology. In information technology, it will provide a large amount of memory space and massively parallel addressing to store plenty of information, especially molecular information such as molecular computing outputs. It will also provide a universal plate for assembling DNA nanostructures, nanoparticles, and other functional molecules by both molecular addressing and spatial addressing. The memory substrate can be extended to a fundamental technique for a molecular imaging plate to directly store the spatial distribution of mRNAs and proteins in tissues and cells. No silicon-based memory devices can succeed in these applications.

6 In Vivo DNA Memory

6.1 Introduction

The perfect design of in vivo memory requires substantial knowledge of cellular and molecular mechanisms. Ideally, the memory function should be isolated from the native physiological functions to avoid unexpected interactions among sequences. However, it is difficult to meet this requirement, especially if memory mechanisms are implemented with standard nucleic acids. Knowledge of the mechanisms of DNA transcription or translation remains elementary; previous attempts to computationally estimate transcribed regions (or gene structures) never matched the findings of tiling arrays, that as much as 70% of the human genome is transcribed (Kapranov et al. 2002). It is also unknown why bacterial genomes can detect and excise foreign DNA sequences with significantly biased GC contents. Due to these difficulties, in vivo memories have not been as widely investigated as in vitro approaches.

6.2 Encryption into Non-coding Regions

The simplest way to encode information into DNA is to apply a code table translating alphabet letters and digits to DNA triplets.  [Table 2](#) was used by Clelland et al. to encode the message “June 6 Invasion: Normandy” (all in capitals) into a short DNA fragment in vitro (Clelland et al. 1999). A similar translation table was used in other approaches, such as encoding a song phrase of “It’s a small world” into the genomes of *Escherichia coli* and *Deinococcus radiodurans* (Leier et al. 2000; Wong et al. 2003). This straightforward method has a fatal flaw; DNA

An example of comma-free words of DNA triplets that also consider reverse strands. The maximum number of words is 10

ACA	AGA	AAU	ACC	CGA	ACU	GCA	AGG	AGU	CGG
-----	-----	-----	-----	-----	-----	-----	-----	-----	-----

sequences are retrieved by polymerase chain reaction (PCR) using short primer sequences, but such sequences may appear in the encoded message. It is an absolute requirement for primer sequences and their reverse complements to never occur in any combination of encrypted sequences irrespective of frame shifts. This condition is met by the design of comma-free codes.

A code is said to be comma-free if separator symbols are unnecessary to parse its words unambiguously. The concept of comma-freeness was first introduced by Francis Crick, as an elegant (but mistaken) association between codons and 20 amino acids (Crick et al. 1957). Indeed, the maximum number of comma-free DNA triplets is exactly 20 out of $4^3 = 64$. (It is easy to say that in this association there is no room for the “stop” sign. It is probably because we now know the correct codon table.)

How many comma-free words can be designed with DNA quadruplets or pentuplets? Obviously, any circular permutation of a comma-free word cannot be another word in the same code. Soon after Crick offered his beautiful hypothesis, Solomon Golomb proved that the maximum number of comma-free words of length k using n letters is $(n^k - n)/k$ (k : prime) (Golomb et al. 1958). When the comma-free condition for reverse complements is also considered, the number is halved (Table 3). Since encryption of alphabet letters, digits, and primer sequences requires at least 40 letters, the necessary comma-free words can be no shorter than DNA pentuplets.

DNA pentuplets may raise different types of complication. The first is a larger bias for GC content, resulting in a broader range of melting temperatures. Since the melting temperature should be the same for all primer sequences, words for primers must be carefully chosen from comma-free DNAs. The second complication is vulnerability to mutations or sequencing errors. Enhancement of the error-correcting ability further lengthens the DNA words, and practical codes may become as long as 12 base-pairs (Arita and Kobayashi 2002). The third and the most serious complication is the possible interaction with native genome sequences. Especially in eukaryotic cells, any noncoding or intergenic region may be functional and it is impossible to guarantee the safety of inserting a long sequence into their genome.

6.3 Encryption into Coding Regions

A better way to achieve *in vivo* memories is to override artificial information on sequences whose biological information is well known. If we can superimpose a message in protein coding regions in a way that the message does not affect amino acid sequences to be translated, then the message can be used as a secret signature, or *DNA watermark*. This idea can be realized easily.

The translation table of amino acids specifies only 21 patterns (20 amino acids and the stop sign) using the 64 codons; the third position of the codons for frequently used amino acids may change without changing the translation result. This is called a *wobbled* codon (❷ [Table 4](#)).

Arita and Ohashi proposed association of a single bit for each codon where a value of 0 indicates the presence of the normal (wild-type) bases at the third position, and a value of one indicates altered bases at this position (wobbled codon by mutation) (Arita and Ohashi 2004).

In this scheme, the normal sequence of an organism is considered to carry information 000...0, and once some of its codons are wobbled, those positions are interpreted as one. The decoding of information requires the sequencing of the protein coding regions, for example, using PCR. Its obvious disadvantage is therefore little storage capacity; the sequence length that can be PCR-amplified is limited.

When wobbling between base U↔C and base A↔G is utilized in the standard codon table (❷ [Table 4](#)), a single bit can be overridden for 60 codons out of 64. Exceptions are UGA, UGG, AUA, and AUG, whose wobbling counterparts code different amino acids or a stop codon. Such codons are skipped in the encoding. For example, if alphabet letters and digits are encoded using the ASCII code (7 bits), one character can be watermarked in approximately

❸ **Table 4**

Codon usage chart of a standard eukaryotic genome. “Stop” indicates stop codons. Bold letters are codons that cannot be used for encoding artificial information (see main text)

UUU Phe	UUA Leu	UAU Tyr	UAA Stop	GAA Glu	GAU Asp	GUG Val	GUU Val
UUC Phe	UUG Leu	UAC Tyr	UAG Stop	GAG Glu	GAC Asp	GUA Val	GUC Val
UCU Ser	UCA Ser	UGU Cys	UGA Stop	GGA Gly	GGU Gly	GCA Ala	GCU Ala
UCC Ser	UCG Ser	UGC Cys	UGG Trp	GGG Gly	GGC Gly	GCG Ala	GCC Ala
CCC Pro	CCG Pro	CGC Arg	CGG Arg	AGG Arg	AGC Ser	ACG Thr	ACC Thr
CCU Pro	CCA Pro	CGU Arg	CGA Arg	AGA Arg	AGU Ser	ACA Thr	ACU Thr
CUC Leu	CUA Leu	CAC His	CAG Gln	AAG Lys	AAC Asn	AUA Ile	AUC Ile
CUU Leu	CUG Leu	CAU His	CAA Gln	AAA Lys	AAU Asn	AUG Met	AUU Ile

Table 5

Translation from binaries to DNA bases

00 → T	01 → G	10 → C	11 → A
--------	--------	--------	--------

every $7 \times 3 = 21$ base-pairs (this is an approximation because we may need to skip some codons). Using 6 bits for each letter, Arita and Ohashi demonstrated the encoding of “KEIO,” the name of their university, into an essential gene of *Bacillus subtilis* (*ftzZ*). The watermarked bacterium did not exhibit any superficial anomaly with respect to colony morphology, growth rate, and the level of protein expression.

Their idea was later extended by Heider and Barnekow (2007). Instead of associating a single bit for all codons, they first translate binary information into DNA bases according to [Table 5](#), and the DNA bases are embedded at the third position of codons one by one. If the substitution produces a wobbled codon, the embedding takes place. If it does not (i.e., if it alters the amino acid in [Table 4](#) or if it is identical to the native sequence), the codon is skipped and the next codon is tested. This method can assign 2 bits for each embedded letter as in [Table 5](#), although the total length of the embedded sequence is information- and genome-dependent: every time a base to be embedded is identical to the third position of the target codon, or if the substitution does not produce a wobbled codon, then the encryption span becomes one codon longer. The actual encoding length is therefore unpredictable.

They also proposed the use of several cryptographic algorithms and error-correcting codes in the translation of the original information into the binary bits. Although they did not demonstrate this error-correcting mechanism, they tested the encoding method in the *Vam7* gene of *Saccharomyces cerevisiae*, a diploidal eukaryote (Heider and Barnekow 2008). The watermarked yeast again exhibited no superficial anomalies including sporulation. The issue of sexual reproduction with recombination, a notable characteristic of eukaryotic cells, was not addressed. These authors subsequently proposed the use of Y-chromosomal or mitochondrial sequences in future trials (Heider and Kessler 2008).

6.4 Conclusion

The use of error-correcting codes or cryptographic algorithms such as RSA is essentially irrelevant to the implementation of DNA memories because the technology under focus is to address how and where to encode information in genomic DNA. We must remember a simple way of implementing the error-correcting ability, that is, the encoding of any of the above code multiple times at different locations in a genome. In fact, using *Bacillus subtilis*, Yachie et al. demonstrated an application of a multiple sequence alignment for embedded memory fragments, each of which was retrieved by PCR experimentally (Yachie et al. 2007). They also proposed whole genome sequencing for retrieving memory sequences. Having seen the recent advances in high-speed genome sequencing, we no longer dismiss such a proposal as unrealistic.

Research on synthetic biology may lead to another type of information storage in vivo. Gardner et al. used two DNA-binding regulatory genes, each of which represses the other, to implement a bistable, genetic toggle switch (Gardner et al. 2000). This switch can be regarded as a single-bit memory although the reliability of keeping the memory bit under cell replication is not clear. In their system, toggling was performed by externally adding

a chemical agent that blocks the DNA-binding ability of a protein used. Although their approach is obviously not scalable, it exemplifies the advantage of read-write, visual memory. Since it is not difficult to visualize the cellular state by using several different fluorescent proteins, one interesting application area would be scalable, multi-bit, visual *in vivo* memory.

7 Conclusion

We hope the reader now realizes that there exist a variety of models and methods to store information in terms of molecules. In particular, types of DNA memories range from those in solution or on surfaces to those stored *in vivo*. However, they all require careful design of base sequences of DNA. In particular, DNA memories in solution and on surfaces rely on selective hybridization between complementary sequences of DNA, and efforts to construct a reasonably large memory space in those types have led to the theory and practice of sequence design explained in Sect. 2. Such theory and practice can also be applied to molecular machines or nanostructures constructed from DNA.

Many of the achievements reported in this chapter, including NPMM and hairpin-based memories, were supported by the JST-CREST project on molecular memory.

Abstract

This chapter overviews the past and current state of a selected part of the emerging research area of DNA-based biomolecular devices. We particularly emphasize molecular devices that are: *autonomous*, executing steps with no exterior mediation after starting; and *programmable*, the tasks executed can be modified without entirely redesigning the nanostructure.

We discuss work in this area that makes use of synthetic DNA to self-assemble into DNA nanostructure devices. Recently, there has been a series of impressive experimental results that have taken the technology from a state of intriguing possibilities into demonstrated capabilities of quickly increasing scale. We discuss various such programmable molecular-scale devices that achieve: computation, 2D patterning, amplified sensing, and molecular or nanoscale transport.

This article is written for a general audience, and particularly emphasizes the interdisciplinary aspects of this quickly evolving and exciting field.

1 Introduction

1.1 Autonomous Programmable Molecular Devices

This chapter introduces the reader to a rapidly evolving and very exciting topic of nanoscience, namely, self-assembled DNA nanostructures, and their use in molecular computation and molecular transport. To tighten the focus, and to emphasize techniques that seem most promising, the discussion will be limited to processes that are *autonomous* (executing steps with no exterior mediation after starting), and *programmable* (the tasks executed can be modified without entirely redesigning the nanostructure).

1.2 Questions About Biomolecular Devices

We will see that DNA self-assembly processes can be made computational-based and programmable, and it seems likely that computer science techniques will be essential to the further development of this emerging field of biomolecular computation. This chapter particularly illustrates the way in which computer science techniques and methods impact on this emerging field. Some of the key questions one might ask are given below.

- What is the theoretical basis for these devices?
- How will such devices be designed and implemented?
- How can we simulate them prior to manufacture?
- How can we optimize their performance?
- How will such devices be manufactured?
- How much do the devices cost?
- How scalable is the device design?
- How will efficient I/O be accomplished?
- How will they be programmed?

- What efficient algorithms can be programmed?
- What will be their applications? What can they control?
- How can we correct errors or repair them?

Note that these questions are exactly the sort of questions that computer scientists routinely ask about conventional computing devices. The discipline of computer science has developed a wide variety of techniques to address such basic questions, and we will later point out some which have an important impact on molecular-scale devices.

1.3 Why Bottom-Up Self-assembly?

Construction of molecular-scale structures and devices is one of the key challenges facing science and technology in the twenty-first century. This challenge is at the core of the emerging discipline of nanoscience. A key deficiency is the need for robust, error-free methods for self-assembly of complex devices out of large numbers of molecular components. This key challenge requires novel approaches.

For example, the macroelectronics industry is now reaching the limit of miniaturization possible by top-down lithographic fabrication techniques. New bottom-up methods are needed for self-assembling complex, aperiodic structures for nanofabrication of molecular electronic circuits that are significantly smaller than conventional electronics.

1.4 Why Use DNA for Assembly of Biomolecular Devices?

The particular molecular-scale devices that are the topic of this chapter are known as DNA nanostructures. As will be explained, DNA nanostructures have some unique advantages among nanostructures: they are relatively easy to design, fairly predictable in their geometric structures, and have been experimentally implemented in a growing number of labs around the world. They are primarily made up of synthetic DNA. A key principle in the study of DNA nanostructures is the use of self-assembly processes to actuate the molecular assembly. Conventional electronics fabrication is reaching the limit of miniaturization possible by top-down techniques. Since self-assembly operates naturally at the molecular scale, it does not suffer from the limitation in scale reduction that so restricts lithography or other more conventional top-down manufacturing techniques.

In attempting to understand the modern development of DNA self-assembly, it is interesting to recall that mechanical methods for computation date back to the very onset of computer science, for example, to the cog-based mechanical computing machine of Babbage. Lovelace stated in 1843 that Babbage's "Analytical Engine weaves algebraic patterns just as the Jacquard-loom weaves flowers and leaves." In some of the recently demonstrated methods for biomolecular computation described here, computational patterns were essentially woven into molecular fabric (DNA lattices) via carefully controlled and designed self-assembly processes.

1.5 The Dual Role of Theory and Experimental Practice

In many cases, self-assembly processes are programmable in ways analogous to more conventional computational processes. We will overview theoretical principles and techniques

(such as tiling assemblies and molecular transducers) developed for a number of DNA self-assembly processes that have their roots in computer science theory (e.g., abstract tiling models and finite state transducers).

However, the area of DNA self-assembled nanostructures and molecular robotics is by no means simply a theoretical topic – many dramatic experimental demonstrations have already been made and a number of these will be discussed. The complexity of these demonstrations has increased at an impressive rate (even in comparison to the rate of improvement of silicon-based technologies).

1.6 Applications of Autonomous Programmable Molecular Devices

This chapter discusses the accelerating scale of complexity of DNA nanostructures (such as the number of addressable pixels of 2D patterned DNA nanostructures) and provides some predictions for the future. Molecular-scale devices using DNA nanostructures have been engineered to have various capabilities, ranging from (1) execution of molecular-scale computation, (2) use as scaffolds or templates for the further assembly of other materials (such as scaffolds for various hybrid molecular electronic architectures or perhaps high-efficiency solar cells), (3) robotic movement and molecular transport (akin to artificial, programmable versions of cellular transport mechanisms), (4) exquisitely sensitive molecular detection and amplification of single molecular events, and (5) transduction of molecular sensing to provide drug delivery. Error-correction techniques for correct assembly and repair of DNA self-assemblies have also been recently developed. Computer-based design and simulation are also essential to the development of many complex DNA self-assembled nanostructures and systems.

1.7 The Operation of Programmable Molecular Devices

While we will describe a wide variety of methods for executing molecular computation, these methods can be partitioned into two basic classes:

- *Distributed parallel molecular computations* execute a computation for which they require multiple distinct molecules that interact to execute steps of each computation. An example is the tiling assembly computations described in [Sect. 5](#).
- *Local molecular computations* execute computations within a single molecule, possibly in parallel with other molecular computing devices. An example is Whiplash polymerase chain reaction (PCR) described in [Sect. 9.1](#).

2 Introducing DNA, Its Structure and Its Manipulation

2.1 Introducing DNA

In general, nanoscience research is highly interdisciplinary. In particular, DNA self-assembly uses techniques from multiple disciplines such as biochemistry, physics, chemistry, and material science, as well as computer science and mathematics. While this makes the topic

quite intellectually exciting, it also makes it challenging for a typical computer science reader. Having no training in biochemistry, one must obtain a coherent understanding of the topic from a short article. For this reason, this chapter was written with the expectation that the reader is a computer scientist with little background knowledge of chemistry or biochemistry. On the other hand, a reader with a basic knowledge of DNA, its structure and its enzymes can skip this section and proceed to the next.

2.2 DNA and Its Structure

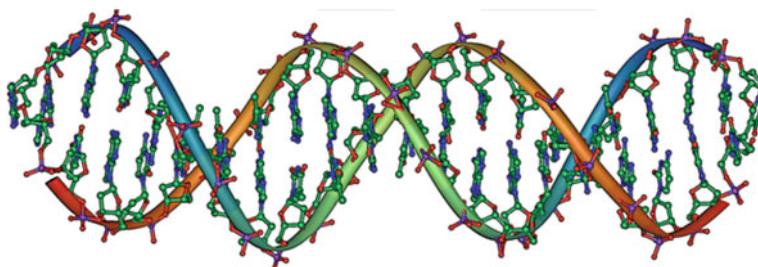

A brief introduction to DNA is given here. *Single stranded DNA* (denoted ssDNA) is a linear polymer consisting of a sequence of nucleotide bases spaced along a backbone with chemical directionality (i.e., the 5-prime and 3-prime ends of the backbone are chemically distinct). By convention, the base sequence is listed starting from the 5-prime end of the polymer and ending at the 3-prime end (these names refer to particular carbon atoms in the deoxyribose sugar units of the sugar-phosphate backbone, the details of which are not critical to the present discussion). The consecutive monomer units (base + sugar + phosphate) of an ssDNA molecule are connected via covalent bonds. There are four types of DNA bases: adenine, thymine, guanine, and cytosine typically denoted by the symbols A, T, G, and C, respectively. These bases form the alphabet of DNA; the specific sequence comprises DNA's information content. The bases are grouped into *complementary pairs* (G, C) and (A, T).

The most basic DNA operation is *hybridization* where two ssDNA oriented in opposite directions can bind to form a double-stranded *DNA helix* (dsDNA) by pairing between complementary bases. DNA hybridization occurs in a physiologic-like buffer solution with appropriate temperature, pH, and salinity (● Fig. 1).

Since the binding energy of the pair (G, C) is approximately half-again the binding energy of the pair (A, T), the association strength of hybridization depends on the sequence of complementary bases, and can be approximated by known software packages. The *melting temperature* of a DNA helix is the temperature at which half of all the molecules are fully hybridized as double helix, while the other half are single-stranded. The kinetics of the DNA hybridization process is quite well understood; it often occurs in a (random) zipper-like manner, similar to a biased one-dimensional random walk.

■ Fig. 1

Structure of a DNA double helix. (Image by Michael Ströck and released under the GNU Free Documentation License (GFDL).)

Whereas ssDNA is a relatively floppy molecule, dsDNA is quite stiff (over lengths of less than 150 or so bases) and has the well characterized double helix structure. The exact geometry (angles and positions) of each segment of a double helix depends slightly on the component bases of its strands and can be determined from known tables. There are about 10.5 bases per full rotation on this helical axis. A *DNA nanostructure* is a multimolecular complex consisting of a number of ssDNA that have partially hybridized along their subsegments.

2.3 Manipulation of DNA

Some techniques and known enzymes used for manipulation of DNA nanostructures are listed here.

Strand displacement, which is the displacement of a DNA strand from a prior hybridization with another complementary strand, is a key process in many of the DNA protocols for running DNA autonomous devices. (Figure 2a) illustrates the displacement of DNA strand via branch migration.

In addition to the hybridization reaction described above, there is a wide variety of known enzymes and other proteins used for manipulation of DNA nanostructures that have predictable effects. (Interestingly, these proteins were discovered in natural bacterial cells and tailored for laboratory use.) These include:

- *Restriction enzymes*, some of which can cut (or nick, which is to cut only one strand) strands of a DNA helix at locations determined by short specific DNA base sequences (Fig. 3).
- *Ligase enzymes* that can heal nicks in a DNA helix (i.e., form covalent bonds to join two backbones).
- *Polymerase enzymes*, which, given an initial “primer” DNA strand hybridized onto a segment of a template DNA strand, can extend the primer strand in the 5' to 3' direction by appending free DNA nucleotides complementary to the template's nucleotides (see Fig. 2b). Certain polymerase enzymes (e.g., phi-29) can, as a side effect of their polymerization reaction, efficiently displace previously hybridized strands.
- In addition, *Deoxyribozymes (DNAzymes)* is a class of nucleic acid molecules that possess enzymatic activity – they can, for example, cleave specific target nucleic acids. Typically, they are discovered by in vivo evolution search. They have had some use in DNA computations (e.g., see Stojanovic and Stefanovic 2003).

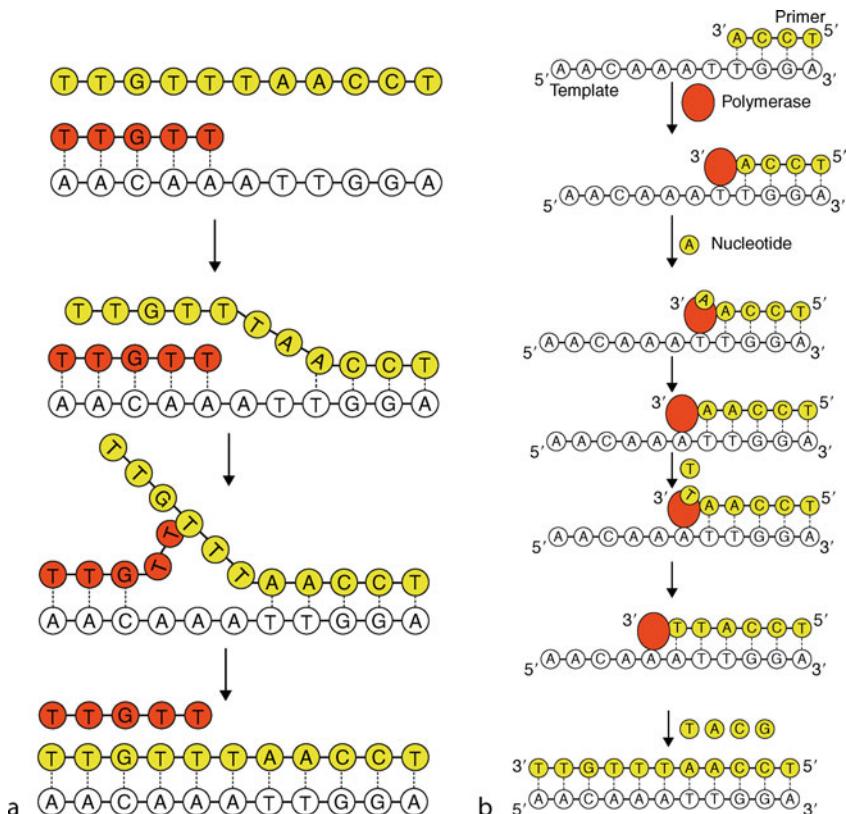

Besides their extensive use in other biotechnology, the above reactions, together with hybridization, are often used to execute and control DNA computations and DNA robotic operations. The restriction enzyme reactions are programmable in the sense that they are site specific, only executed as determined by the appropriate DNA base sequence. The latter two reactions, using ligase and polymerase, require the expenditure of energy via consumption of adenosine triphosphate (ATP) molecules, and thus can be controlled by ATP concentration.

2.4 Why Use DNA to Assemble Molecular-Scale Devices?

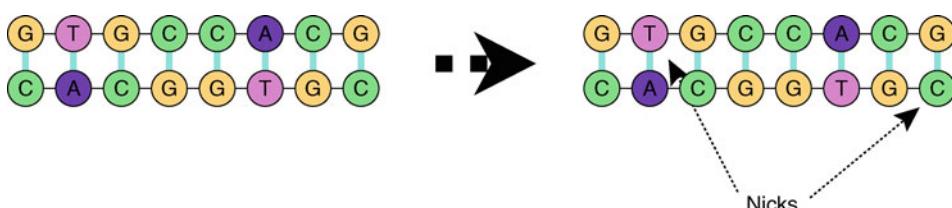

Listed below are some reasons why DNA is uniquely suited for the assembly of molecular-scale devices.

Fig. 2

(a) (Left) Strand displacement of dsDNA via a branch migration hybridization reaction: Figure illustrates DNA strand displacement of a DNA strand (indicated in red) induced by the hybridization of a longer strand (indicated in yellow), allowing the structure to reach a lower energy state. (b) (Right) Extension of primer strand bound to the template by DNA polymerase.

**Fig. 3**

Example of restriction enzyme cuts of a doubly stranded DNA subsequence.

There are many advantages of DNA as a material for building things at the molecular scale.

(a) From the perspective of design, the advantages are:

- The structure of most complex DNA nanostructures can be reduced to determining the structure of short segments of dsDNA. The basic geometric and thermodynamic properties of dsDNA are well understood and can be predicted by available software systems from key relevant parameters like sequence composition, temperature, and buffer conditions.
- The design of DNA nanostructures can be assisted by software. To design a DNA nanostructure or device, one needs to design a library of ssDNA strands with specific segments that hybridize to (and only to) specific complementary segments on other ssDNA. There are a number of software systems (developed at NYU, Caltech, Arizona State, and Duke University) for the design of the DNA sequences composing DNA tiles and for optimizing their stability, which employ heuristic optimization procedures for this combinatorial sequence design task (see [Sect. 4.4](#) for more details).

(b) From the perspective of experiments, the advantages are:

- The solid-phase chemical synthesis of custom ssDNA is now routine and inexpensive; a test tube of ssDNA consisting of any specified short sequence of bases (<150) can be obtained from commercial sources for modest cost (about half a US dollar per base at this time); it will contain a very large number (typically at least 10^{12}) identical ssDNA molecules. The synthesized ssDNA can have errors (premature termination of the synthesis is the most frequent error), but can be easily purified by well-known techniques (e.g., electrophoresis as mentioned below).
- The assembly of DNA nanostructures is a very simple experimental process: in many cases, one simply combines the various component ssDNA into a single test tube with an appropriate buffer solution at an initial temperature above the melting temperature, and then slowly cools the test tube below the melting temperature.
- The assembled DNA nanostructures can be characterized by a variety of techniques. One such technique is electrophoresis. It can provide information about the relative molecular mass of DNA molecules, as well as some information regarding their assembled structures. Other techniques like atomic force microscopy (AFM) and transmission electron microscopy (TEM) provide images of the actual assembled DNA nanostructures on 2D surfaces.

3 Adleman's Initial Demonstration of a DNA-Based Computation

3.1 Adleman's Experiment

The field of DNA computing began in 1994 with a laboratory experiment (Adleman 1994, 1998). The goal of the experiment was to find a Hamiltonian path in a graph, which is a path that visits each node exactly once. To solve this problem, a set of ssDNA was designed based on the set of edges of the graph. When combined in a test tube and cooled, they self-assembled into dsDNA. Each of these DNA nanostructures was a linear DNA helix that corresponded to a path in the graph. If the graph had a Hamiltonian path, then one (or a subset) of these DNA nanostructures encoded the Hamiltonian path. By conventional biochemical extraction

methods, Adleman was able to isolate only DNA nanostructures encoding Hamiltonian paths, and by determining their sequence, the explicit Hamiltonian path. It should be mentioned that this landmark experiment was designed and experimentally demonstrated by Adleman alone, a computer scientist with limited training in biochemistry.

3.2 The Non-scalability of Adleman's Experiment

While this experiment founded the field of DNA computing, it was not scalable in practice, since the number of different DNA strands needed increased exponentially with the number of nodes of the graph. Although there can be an enormous number of DNA strands in a test tube (10^{15} or more, depending on solution concentration), the size of the largest graph that could be solved by his method was limited to at most a few dozen nodes. This is not surprising, since finding the Hamiltonian path is an NP-complete problem, whose solution is likely to be intractable using conventional computers. Even though DNA computers operate at the molecular-scale, they are still equivalent to conventional computers (e.g., deterministic Turing machines) in computational power. This experiment taught a healthy lesson to the DNA computing community (which is now well recognized): to carefully examine scalability issues and to judge any proposed experimental methodology by its scalability.

3.3 Autonomous Biomolecular Computation

Shortly following Adleman's experiment, there was a burst of further experiments in DNA computing, many of which were quite ingenious. However, almost none of these DNA computing methods were autonomous, and instead required many tedious laboratory steps to execute. In retrospect, one of the most notable aspects of Adleman's experiment was that the self-assembly phase of the experiment was completely autonomous – it required no exterior mediation. This autonomous property makes an experimental laboratory demonstration much more feasible as the scale increases. The remaining article mostly discusses autonomous devices for biomolecular computation based on self-assembly.

4 Self-assembled DNA Tiles and Lattices

4.1 DNA Nanostructures

Recall that a DNA nanostructure is a multimolecular complex consisting of a number of ssDNA that have partially hybridized along their subsegments. The field of DNA nanostructures was pioneered by Seeman (Robinson and Seeman 1987; Sherman and Seeman 2004).

Particularly useful types of motifs often found in DNA nanostructures include:

A *stem-loop* (a), where ssDNA loops back to hybridize on itself (that is, one segment of the ssDNA (near the 5' end) hybridizes with another segment further along (nearer the 3' end) on the same ssDNA strand). The shown stem consists of the dsDNA region with sequence CACGGTGC on the bottom strand. The shown loop consists of the ssDNA region with sequence TTTT. Stem-loops are often used to form patterns on DNA nanostructures: a *sticky end* (b), where unhybridized ssDNA protrudes from the end of a double helix. The sticky end

shown (ATCG) protrudes from dsDNA (CACG on the bottom strand). Sticky ends are often used to combine two DNA nanostructures together via hybridization of their complementary ssDNA. **Figure 4** shows the antiparallel nature of dsDNA with the 5' end of each strand pointing toward the 3' end of its partner strand.

A *Holliday junction*, as illustrated in **Fig. 5**, where two parallel DNA helices form a junction with one strand of each DNA helix (blue and red) crossing over to the other DNA helix. Holliday junctions are often used to tie together various parts of a DNA nanostructure.

Fig. 4

DNA stem-loop and a DNA sticky end.

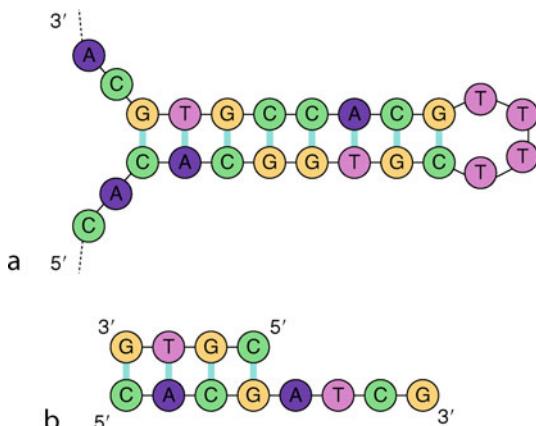

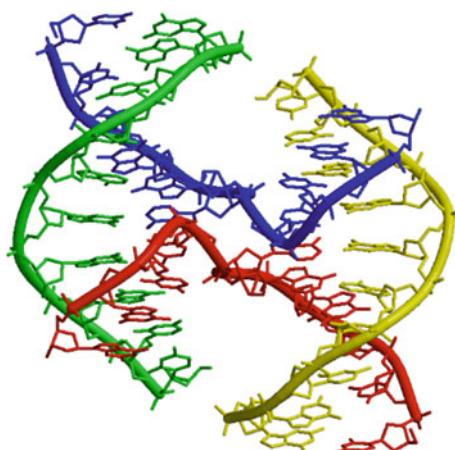

Fig. 5

DNA Holliday junction. (Created by Miguel Ortiz-Lombardía, CNIO, Madrid, Spain.)

4.2 Computation By Self-assembly

The most basic way that computer science ideas have impacted DNA nanostructure design is via the pioneering work by theoretical computer scientists on a formal model of 2D tiling due to Wang in 1961, which culminated in a proof by Berger in 1966 that universal computation could be done via tiling assemblies. Winfree et al. (1998) was the first to propose applying the concepts of computational tiling assemblies to DNA molecular constructs. His core idea was to use tiles composed of DNA to perform computations during their self-assembly process. To understand this idea, we will need an overview of DNA nanostructures, as presented in [Sect. 4.3](#).

4.3 DNA Tiles and Lattices

A *DNA tile* is a DNA nanostructure that has a number of sticky ends on its sides, which are termed *pads*. A DNA lattice is a DNA nanostructure composed of a group of DNA tiles that are assembled together via hybridization of their pads. Generally, the strands composing the DNA tiles are designed to have a melting temperature above those of the pads, ensuring that when the component DNA molecules are combined together in solution, first the DNA tiles assemble, and only then, as the solution is further cooled, do the tiles bind together via hybridization of their pads.

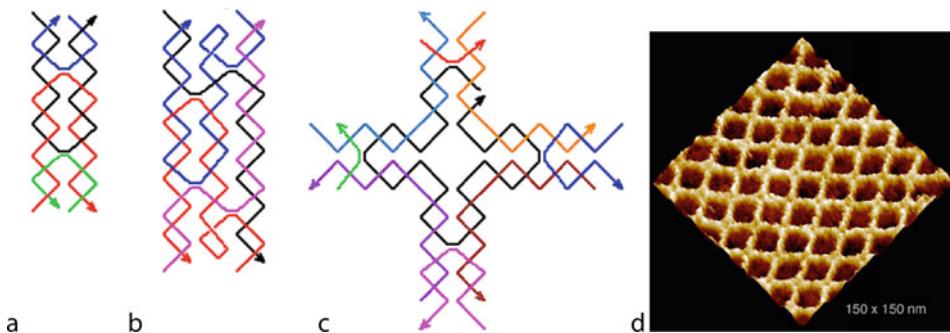

[Figure 6](#) describes some principal DNA tiles (also see LaBean et al. 2006).

Seeman and Winfree, in 1998, developed a family of DNA tiles known collectively as DX tiles (see [Fig. 6a](#)) that consisted of two parallel DNA helices linked by immobile Holliday junctions. They demonstrated that these tiles formed large 2D lattices, as viewed by AFM.

Subsequently, other DNA tiles were developed to provide more complex strand topology and interconnections, including a family of DNA tiles known as TX tiles (see [Fig. 6b](#)) composed of three DNA helices. Both the DX tiles and the TX tiles are rectangular in shape, where two opposing edges of the tile have pads consisting of ssDNA sticky ends of the component strands. In addition, TX tiles have topological properties that allow for strands to propagate in useful ways through tile lattices (this property is often used for aid in patterning DNA lattices as described below).

Fig. 6

DNA tiles. (a) DX tile. (b) TX tile. (c) Cross tile. (d) AFM image of 2D DNA lattice of cross tiles.

Other DNA tiles known as *Cross tiles* (see [Fig. 6c](#)) (Yan et al. 2003b) are shaped roughly square (or more accurately, square cruciform), and have pads on all four sides, allowing for binding of the tile directly with neighbors in all four directions in the lattice plane. [Figure 6d](#) shows an AFM image of a 2D DNA lattice using Cross tiles.

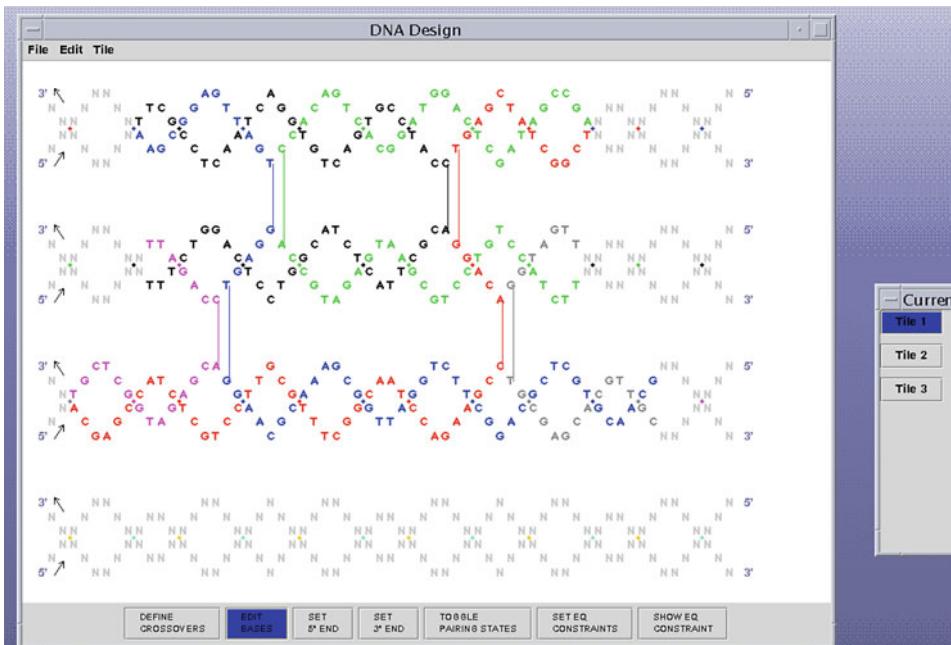

To program a tiling assembly, the pads of tiles are designed so that tiles assemble together as intended. Proper designs ensure that only the adjacent pads (two pairs of sticky ends in the case of Cross tiles) of neighboring tiles are complementary, so only those pads hybridize together.

4.4 Software for the Design of DNA Tiles

A number of prototype computer software systems have been developed for the design of the DNA sequences composing DNA tiles, and for optimizing their stability. [Figure 7](#) gives a screen shot of a software system known as TileSoft (Yin et al. 2004a, b), developed jointly by Duke and Caltech, which provides a graphically interfaced sequence optimization system for designing DNA secondary structures. A more recent commercial product, NanoEngineer, with enhanced capabilities for DNA design and a more sophisticated graphic interface, was developed by Nanorex, Inc.

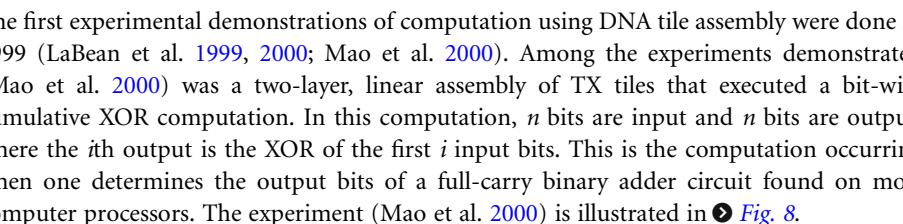

Fig. 7

TileSoft: sequence optimization software for designing DNA secondary structures.

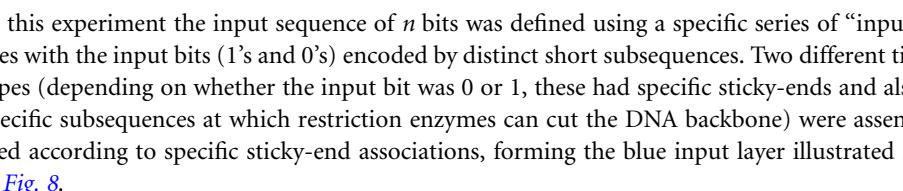

5 Autonomous Finite State Computation Using Linear DNA Nanostructures

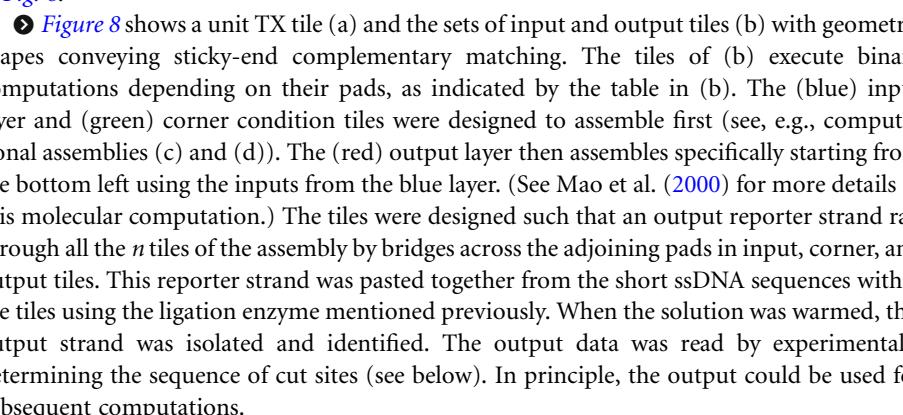

5.1 The First Experimental Demonstration of Autonomous Computations Using Self-assembly of DNA Nanostructures

The first experimental demonstrations of computation using DNA tile assembly were done in 1999 (LaBean et al. 1999, 2000; Mao et al. 2000). Among the experiments demonstrated (Mao et al. 2000) was a two-layer, linear assembly of TX tiles that executed a bit-wise cumulative XOR computation. In this computation, n bits are input and n bits are output, where the i th output is the XOR of the first i input bits. This is the computation occurring when one determines the output bits of a full-carry binary adder circuit found on most computer processors. The experiment (Mao et al. 2000) is illustrated in  Fig. 8.

These experiments (LaBean et al. 1999, 2000; Mao et al. 2000) provided initial answers to some of the most basic questions of how autonomous molecular computation might be done:

- *How can one provide data input to a molecular computation using DNA tiles?*

In this experiment the input sequence of n bits was defined using a specific series of “input” tiles with the input bits (1’s and 0’s) encoded by distinct short subsequences. Two different tile types (depending on whether the input bit was 0 or 1, these had specific sticky-ends and also specific subsequences at which restriction enzymes can cut the DNA backbone) were assembled according to specific sticky-end associations, forming the blue input layer illustrated in  Fig. 8.

 Figure 8 shows a unit TX tile (a) and the sets of input and output tiles (b) with geometric shapes conveying sticky-end complementary matching. The tiles of (b) execute binary computations depending on their pads, as indicated by the table in (b). The (blue) input layer and (green) corner condition tiles were designed to assemble first (see, e.g., computational assemblies (c) and (d)). The (red) output layer then assembles specifically starting from the bottom left using the inputs from the blue layer. (See Mao et al. (2000) for more details of this molecular computation.) The tiles were designed such that an output reporter strand ran through all the n tiles of the assembly by bridges across the adjoining pads in input, corner, and output tiles. This reporter strand was pasted together from the short ssDNA sequences within the tiles using the ligation enzyme mentioned previously. When the solution was warmed, this output strand was isolated and identified. The output data was read by experimentally determining the sequence of cut sites (see below). In principle, the output could be used for subsequent computations.

The next question of concern is:

- *How can one execute a step of computation using DNA tiles?*

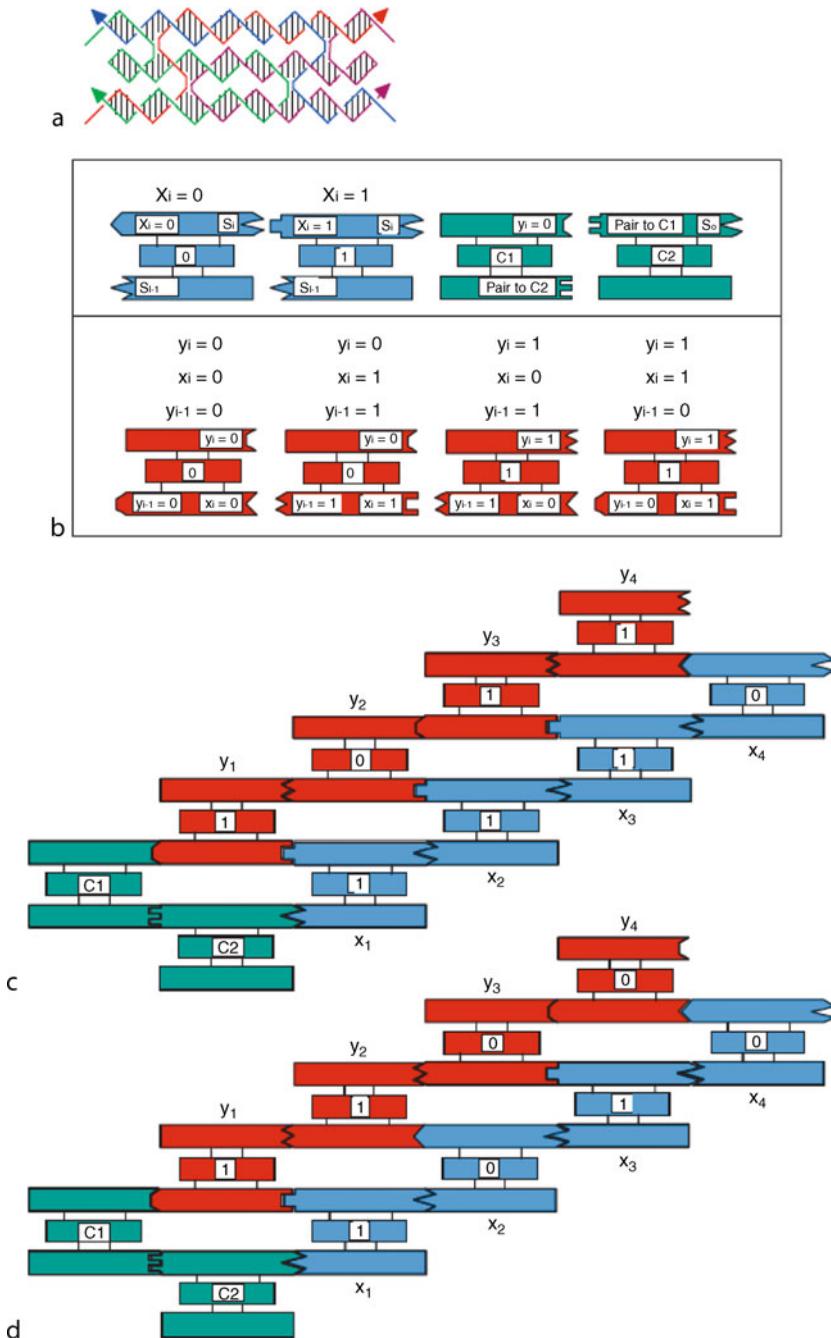

To execute steps of computation, the TX tiles were designed to have pads at one end that encoded the cumulative XOR value. Also, since the reporter strand segments ran through each such tile, the appropriate input bit was also provided within its structure. These two values implied the opposing pad on the other side of the tile to be the XOR of these two bits.

A final question of concern is:

- *How can one determine and/or display the output values of a DNA tiling computation?*

Fig. 8

Sequential Boolean computation via a linear DNA tiling assembly. (Adapted with permission from Mao et al. (2000).) (a) TX tile used in assembly. (b) Set of TX tiles providing logical programming for computation. (c) and (d) Example resulting computational tilings.

The output in this case was read by determining which of the two possible cut sites (endonuclease cleavage sites) were present at each position in the tile assembly. This was executed by first isolating the reporter strand, then digesting separate aliquots with each endonuclease separately and the two together, and finally these samples were examined by gel electrophoresis and the output values were displayed as banding patterns on the gel.

Another method for output (presented below) is the use of AFM observable patterning. The patterning was made by designing the tiles computing a bit 1 to have a stem loop protruding from the top of the tile. The sequence of this molecular patterning was clearly observable under appropriate AFM imaging conditions.

Although only very simple computations, the experiments of LaBean et al. 1999, 2000; Mao et al. 2000; and Yan et al. 2003b did demonstrate for the first time methods for autonomous execution of a sequence of finite-state operations via algorithmic self-assembly, as well as for providing inputs and for outputting the results. Further DNA tile assembly computations will be presented below.

5.2 Autonomous Finite-State Computations via Disassembly of DNA Nanostructures

An alternative method for autonomous execution of a sequence of finite-state transitions was subsequently developed by Shapiro and Benenson (2006). Their technique essentially operated in the reverse of the assembly methods described above, and instead can be thought of as disassembly. They began with a linear double-stranded DNA nanostructure whose sequence encoded the inputs, and then they executed a series of steps that digested the DNA nanostructure from one end. On each step, a sticky end at one end of the nanostructure encoded the current state, and the finite transition was determined by hybridization of the current sticky end with a small “rule” nanostructure encoding the finite-state transition rule. Then a restriction enzyme, which recognized the sequence encoding the current input as well as the current state, cut the appended end of the linear DNA nanostructure, to expose a new sticky end encoding the next state (► Fig. 9).

The hardware–software complex for this molecular device is composed of dsDNA with an ssDNA overhang (shown at the top left ready to bind with the input molecule) and a protein restriction enzyme (shown as gray pinchers).

This ingenious design is an excellent demonstration that there is often more than one way to do any task at the molecular scale. Adar et al. (2004) (see the conclusion, ► Sect. 11 for further discussion) demonstrated in the test tube a potential application of such a finite-state computing device to medical diagnosis and therapeutics.

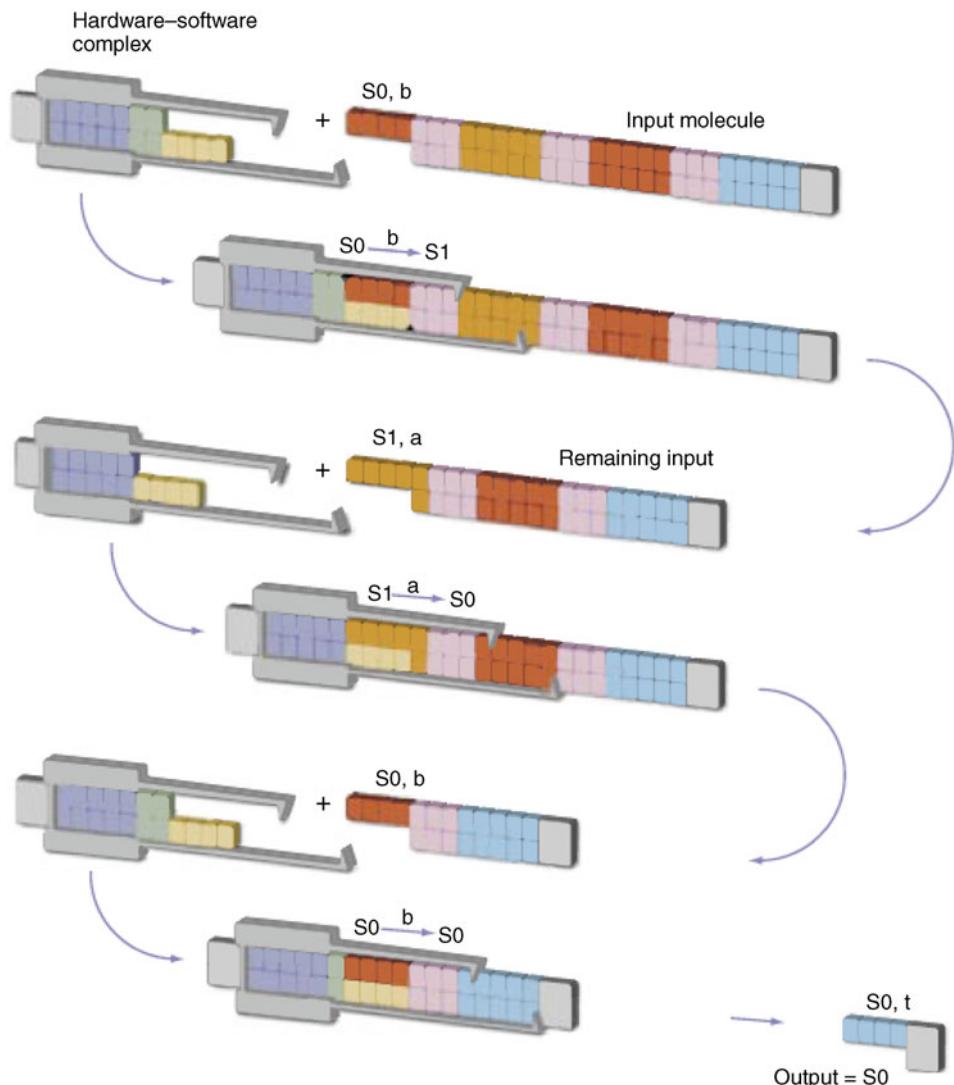

6 Assembling Patterned and Addressable 2D DNA Lattices

One of the most appealing applications of tiling computations is their use to form patterned nanostructures to which other materials can be selectively bound.

An *addressable* 2D DNA lattice is one that has a number of sites with distinct ssDNA. This provides a superstructure for selectively attaching other molecules at addressable locations. Examples of addressable 2D DNA lattices will be given in ► Sect. 6.2.

Fig. 9

Autonomous finite-state computations via disassembly of a double-stranded DNA nanostructure. (Figure adapted with permission from Shapiro and Benenson (2006).)

As discussed below, there are many types of molecules to which one can attach DNA. Known attachment chemistry allows them to be tagged with a given sequence of ssDNA. Each of these DNA-tagged molecules can then be assembled by hybridization of their DNA tags to a complementary sequence of ssDNA located within an addressable 2D DNA lattice. In this way, we can program the assembly of each DNA-tagged molecule onto a particular site of the addressable 2D DNA lattice.

6.1 Attaching Materials to DNA

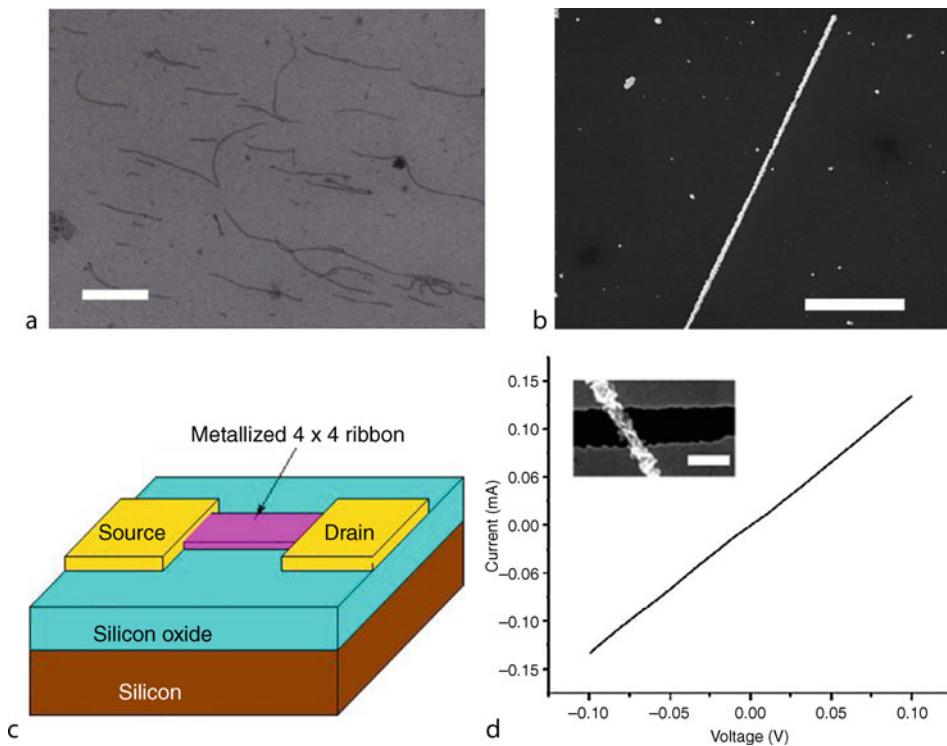

There are many materials that can be made to directly or indirectly bind to specific segments of DNA using a variety of known attachment chemistries. Materials that can directly bind to specific segments of DNA include other (complementary) DNA, RNA, proteins, peptides, and various other materials. Materials that can be made to indirectly bind to DNA include a variety of metals (e.g., gold) that bind to sulfur compounds, carbon nanotubes (via various attachment chemistries), etc. These attachment technologies provide for a molecular-scale method of attaching heterogeneous materials to DNA nanostructures. For example, it can potentially be used for attaching molecular electronic devices to a 2D or 3D DNA nanostructure. Yan et al. (2003c) and Park et al. (2006b) describes conductive wires fabricated from self-assembled DNA tubes plated with gold or silver, as illustrated in [Fig. 10](#).

6.2 Methods for Programmable Assembly of Patterned 2D DNA Lattices

The first experimental demonstration of 2D DNA lattices by Winfree and Seeman provided very simple patterning by repeated stripes determined by a stem loop projecting from every

Fig. 10

Conductive wires fabricated from self-assembled DNA tubes plated with silver. (a) DNA tubes prior to plating. (b) DNA tubes after silver plating. (c) Illustration of conductivity test on silicon oxide substrate. (d) TEM image of conductivity test on silicon oxide substrate.

DNA tile on an odd column. This limited sort of patterning needed to be extended to large classes of patterns.

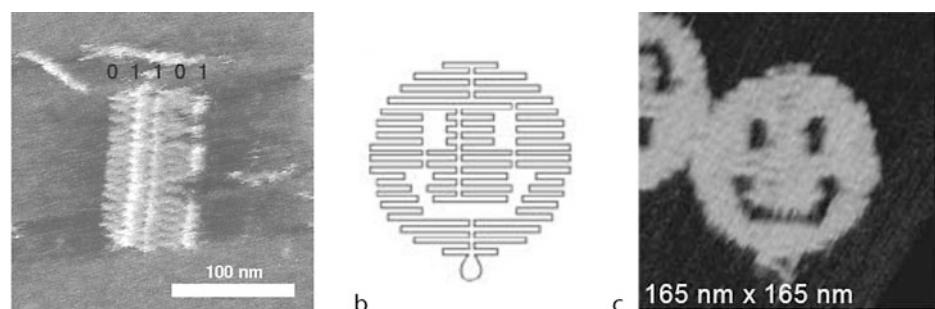

In particular, the key capability needed is a programmable method for forming distinct patterns on 2D DNA lattices, without having to completely redesign the lattice to achieve any given pattern. There are at least three methods for assembling patterned 2D DNA lattices that now have been experimentally demonstrated, as described in the next few sections.

6.2.1 Methods for Programmable Assembly of Patterned 2D DNA Lattices by Use of Scaffold Strands

A *scaffold strand* is a long ssDNA around which shorter ssDNA assemble to form structures larger than individual tiles. Scaffold strands were used to demonstrate programmable patterning of 2D DNA lattices in Yan et al. (2003a) by propagating 1D information from the scaffold into a second dimension to create AFM observable patterns. The scaffold strand weaves through the resulting DNA lattice to form the desired distinct sequence of 2D barcode patterns (left panel of ▶ Fig. 11). In this demonstration, identical scaffold strands ran through each row of the 2D lattices, using short stem loops extending above the lattice to form pixels. This determined a bar code sequence of stripes over the 2D lattice that was viewed by AFM. In principle, this method may be extended to allow for each row's patterning, to be determined by a distinct scaffold strand, defining an arbitrary 2D pixel image. A spectacular experimental demonstration of patterning via scaffold strand is also known as *DNA origami* (Rothenmund 2006). This approach makes use of a long strand of “scaffold” ssDNA (such as from the sequence of a viral phage) that has only weak secondary structure and few long repeated or complementary subsequences. To this is added a large number of relatively short “staple” ssDNA sequences, with subsequences complementary to certain subsequences of the scaffold ssDNA. These staple sequences are chosen so that they bind to the scaffold ssDNA by hybridization and induce the scaffold ssDNA to fold together into a DNA nanostructure. A schematic trace of the scaffold strand is shown in the middle panel of ▶ Fig. 11, and an AFM image of the resulting assembled origami is shown in the right panel of ▶ Fig. 11. This landmark work of Rothenmund (2006)

■ Fig. 11

Methods for programmable assembly of patterned 2D DNA lattices by use of scaffold strands. (a) Barcode patterning. (b) DNA origami design. (c) AFM imaging of DNA origami.

very substantially increases the scale of 2D patterned assemblies to hundreds of molecular pixels (that is, stem loops viewable via AFM) within a square area less than 100 nm on a side. In principle, this “molecular origami” method with staple strands can be used to form arbitrary complex 2D patterned nanostructures as defined. DNA origami has now been extended to simple 3D filaments that were used to partially orient membrane proteins in structural studies employing solution NMR (Douglas et al. 2007).

6.2.2 Programmable Assembly of Patterned 2D DNA Lattices by Computational Assembly

Another very promising method is to use the DNA tile’s pads to program a 2D computational assembly. Recall that computer scientists in the 1970s showed that any computable 2D pattern can be so assembled. Winfree’s group has experimentally demonstrated various 2D computational assemblies, and furthermore provided AFM images of the resulting nanostructures.

☞ *Figure 12* gives a modulo-2 version of Pascal’s Triangle (known as the Sierpinski Triangle) (Rothenmund et al. 2004), where each tile determines and outputs to neighborhood pads the XOR of two of the tile pads. Example AFM images (scale bars = 100 nm) of the assembled structures are shown in the three panels of ☞ *Fig. 12*.

☞ *Figure 13* gives Rothenmund’s and Winfree’s design for a self-assembled binary counter, starting with 0 at the first row, and on each further row being the increment by 1 of the row below. The pads of the tiles of each row of this computational lattice were designed in a similar way to that of the linear XOR lattice assemblies described in the prior section. The resulting 2D counting lattice is found in MUX designs for address memory, and so this patterning may have major applications to patterning molecular electronic circuits (Barish et al. 2005).

■ **Fig. 12**

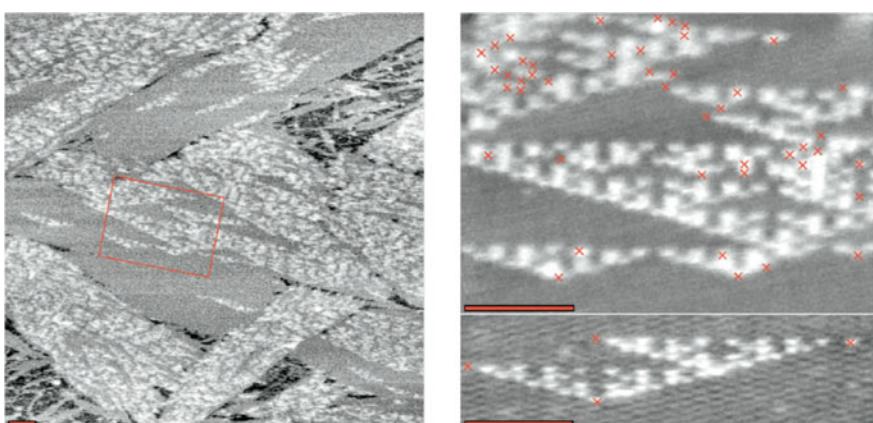

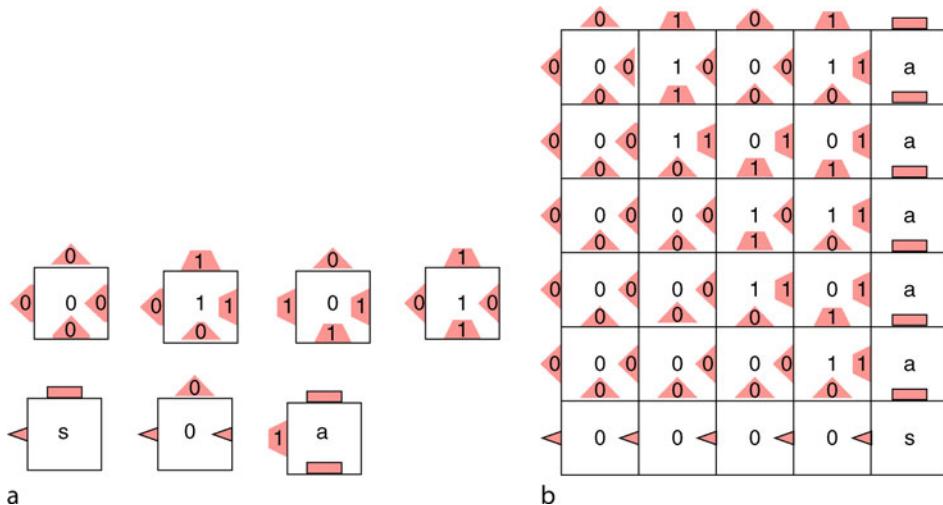

Fig. 13

Rothenmund's and Winfree's design for a self-assembled binary counter using tilings. (a) Tiles used and (b) binary counter assembly.

6.2.3 Programmable Assembly of Patterned 2D DNA Lattices by Hierarchical Assembly

A further approach, known as hierarchical assembly (Park et al. 2006a), is to assemble DNA lattices in multiple stages. **Figure 14** gives three examples of preprogrammed patterns displayed on addressable DNA tile lattices. Tiles are assembled prior to mixing with other preformed tiles. Unique ssDNA pads direct tiles to designed locations. White pixels are “turned on” by binding a protein (avidin) at programmed sites as determined in the tile assembly step by the presence or absence of a small molecule (biotin) appended to a DNA strand within the tile. Addressable, hierarchical assembly has been demonstrated for only modest size lattices to date, but has considerable potential particularly in conjunction with the above methods for patterned assembly.

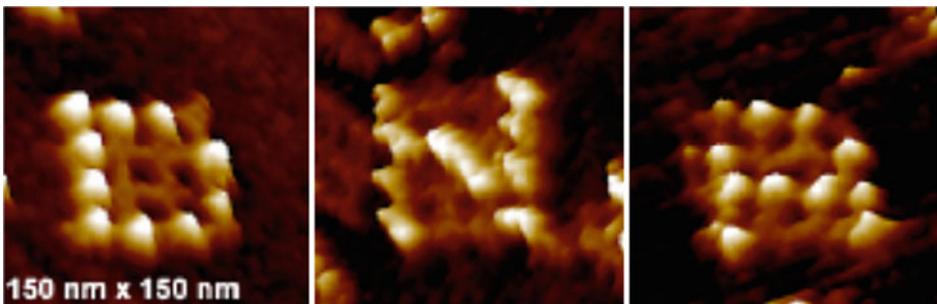

7 Error Correction and Self-repair at the Molecular-Scale

7.1 The Need for Error Correction at the Molecular-Scale

In many of the self-assembled devices described here, there can be significant levels of error. These errors occur both in the synthesis of the component DNA, and in the basic molecular processes that are used to assemble and modify the DNA nanostructures, such as hybridization and the application of enzymes. There are various purification and optimization procedures developed in biochemistry for minimization of many of these types of errors. However, there remains a need for the development of methods for decreasing the errors of assembly and for self-repair of DNA tiling lattices comprising a large number of tiles. A number of

Fig. 14

2D patterns by hierarchical assembly. (Figure adapted with permission from Park et al. (2006a).) AFM images of characters D, N, and A.

techniques have been proposed for decreasing the errors of a DNA tiling assembly, by providing increased redundancy, as described below.

7.2 Winfree's Proofreading Scheme for Error-Resilient Tilings

Winfree and Bekbolatov (2004) developed a “proofreading” method of replacing each tile with a subarray of tiles that provide sufficient redundancy to quadratically reduce errors, as illustrated in [Fig. 15](#). This method, however, increased the area of the assembly by a factor of 4.

7.3 Reif's Compact Scheme for Error-Resilient Tilings

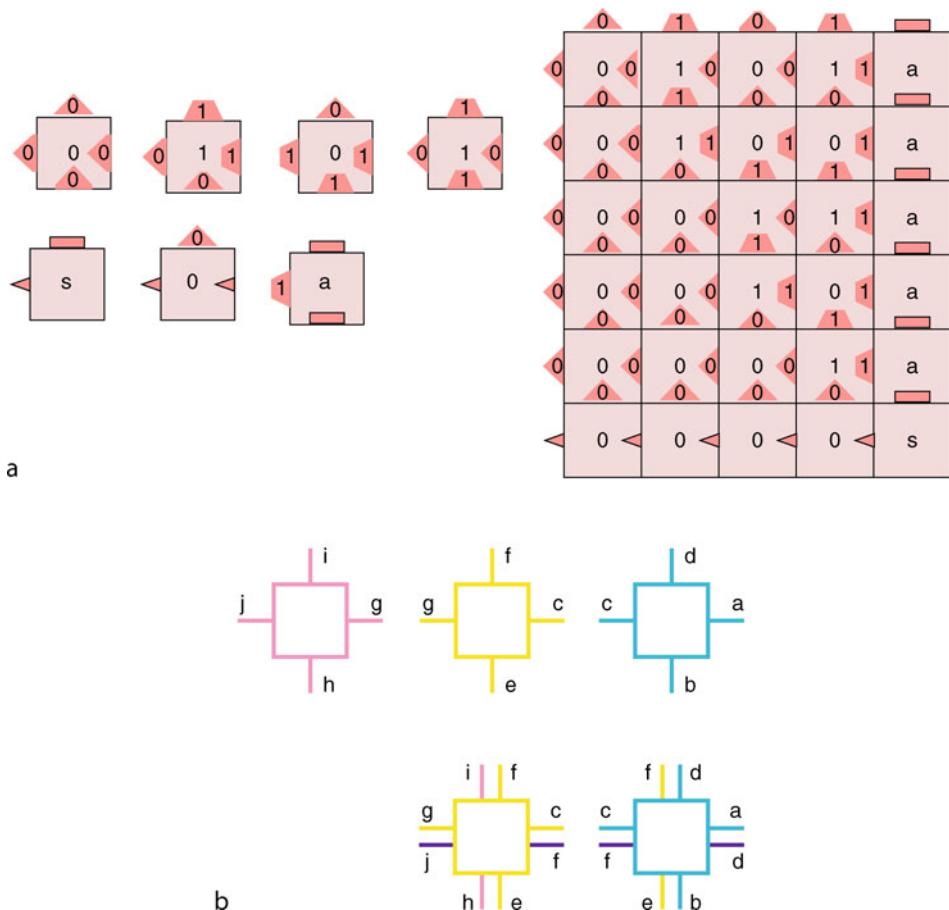

Reif et al. (2006) proposed a more compact method for decreasing assembly errors, as illustrated in [Fig. 16](#). This method modifies the pads of each tile, so that essentially each tile executes both the original computation required at that location, as well as the computation of a particular neighbor, providing a quadratic reduction of errors without increasing the assembly size. The experimental testing of these and related error-reduction methods is ongoing. It seems possible that other error-correction techniques (such as error-correcting codes) developed in computer science may also be utilized.

7.4 Activatable Tiles for Reducing Errors

The uncontrolled assembly of tiling assemblies in reverse directions is potentially a major source of errors in computational tiling assemblies, and a roadblock in the development of applications of large patterned computational DNA lattices. Methods for controlled directional assembly of tiling assemblies would eliminate these errors. Majumder et al. (2007) have recently developed novel designs for an enhanced class of error-resilient DNA tiles (known as *activatable tiles*) for controlled directional assembly of tiles. While conventional DNA tiles store no state, the activatable tiling systems make use of a powerful DNA polymerase enzyme that allows the tiles to make a transition between active (allowing assembly) and inactive states. A *protection-deprotection* process strictly enforces the direction of tiling assembly growth, so that the assembly process is robust against entire classes of growth errors.

Fig. 15

Winfree's proofreading scheme for error-resilient tilings. (a) Original tiles and (b) error-resilient tiles.

Initially, prior to binding with other tiles, the tile will be in an inactive state, where the tile is protected from binding with other tiles and thus prevents lattice growth in the (unwanted) reverse direction. After appropriate binding, other tiles bind to this tile, and then the tile makes a transition to an active state, allowing further growth.

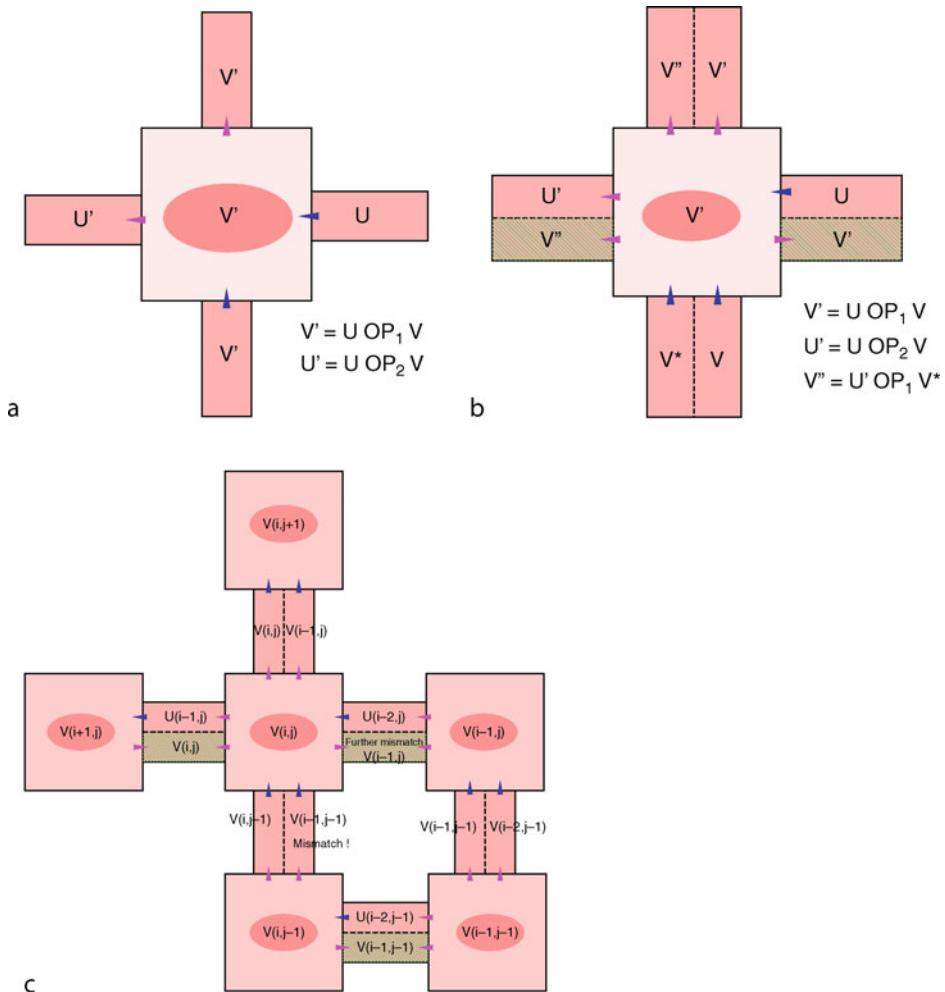

8 Three-Dimensional DNA Lattices

8.1 Potential Applications of Three-Dimensional DNA Lattices

Most of the DNA lattices described in this article have been limited to 2D sheets. It appears to be much more challenging to assemble 3D DNA lattices of high regularity. There are some very important applications to nanoelectronics and biology if this can be done, as described below.

Fig. 16

A compact scheme for error-resilient tilings. (a) Original tile. (b) Error-resilient tiling. (c) A single pad mismatch causes another pad mismatch so destabilizing the assembly.

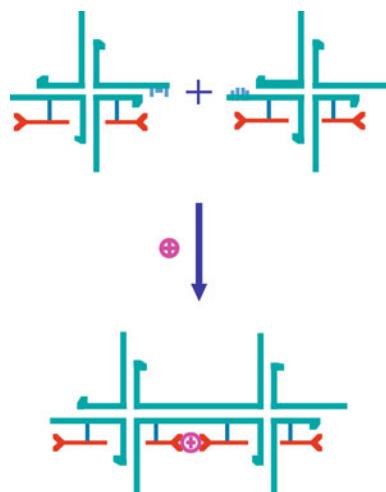

8.2 Scaffolding of 3D Nanoelectronic Architectures

The density of conventional nanoelectronics is limited by lithographic techniques to only a small number of layers. The assembly of even quite simple 3D nanoelectronic devices such as memory would provide much improvement in density. [Figure 17](#) shows DNA (cyan) and protein (red) organizing functional electronic structures.

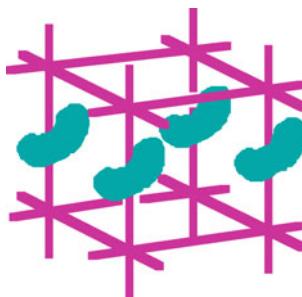

It has been estimated that at least one half of all natural proteins cannot be readily crystallized, and have unknown structure, and determining these structures would have a major impact in the biological sciences. Suppose a 3D DNA lattice can be assembled with sufficient regularity and with regular interstices (say within each DNA tile comprising the

Fig. 17

Scaffolding of 3D nanoelectronic architectures. (Adapted with permission from Robinson and Seeman (1987).)

**Fig. 18**

Scaffolding of proteins into regular 3D arrays. (Adapted with permission from Robinson and Seeman (1987).)

lattice). Then a given protein might be captured within each of the lattice's interstices, allowing it to be in a fixed orientation at each of its regularly spaced locations in 3D (see **Fig. 18**). This would allow the protein to be arranged in 3D in a regular way to allow for X-ray crystallography studies of its structure. This visionary idea is due to Seeman. So far, there has been only limited success in assembling 3D DNA lattices, and they do not yet have the degree of regularity (down to 2 or 3 Å) required for the envisioned X-ray crystallography studies. However, given the success up to now for 2D DNA lattices, this seems eventually achievable.

9 From Nucleic Detection Protocols to Autonomous Computation

9.1 The Detection Problem

A fundamental task of many biochemical protocols is to sense a particular molecule and then amplify the response. In particular, the detection of specific strands of RNA or DNA is an important problem for medicine. Typically, a protocol for nucleic detection is specialized to a subsequence of single-stranded nucleic acid (DNA or RNA oligonucleotide) to be detected. Given a sample containing a very small number of nucleic strand molecules to be detected, a detection protocol must amplify this to a much larger signal. Ideally, the detection protocol is exquisitely sensitive, providing a response from the presence of only a few of the target molecules.

There are a number of novel methods for doing DNA computation that can be viewed as being derived from protocols for detection of DNA. Therefore, understanding the variety of detection protocols can provide insight into these methods used for DNA computation.

9.2 Methods for Autonomous Molecular Computation Derived from PCR

9.2.1 The Polymerase Chain Reaction (PCR)

The original and still the most frequently used method for DNA detection is the *polymerase chain reaction (PCR)* (Saiki et al. 1985), which makes use of DNA polymerase to amplify a strand of DNA by repeated replication, using rounds of thermal cycling. (Recall that given an initial “primer” DNA strand hybridized onto a segment of a template DNA strand, polymerase enzyme can extend the primer strand by appending free DNA nucleotides complementary to the template’s nucleotides.) In addition to DNA polymerase, the protocol requires a pair of “primer” DNA strands, which are extended by the DNA polymerase, each followed by heating and cooling, to allow displacement of the product strands.

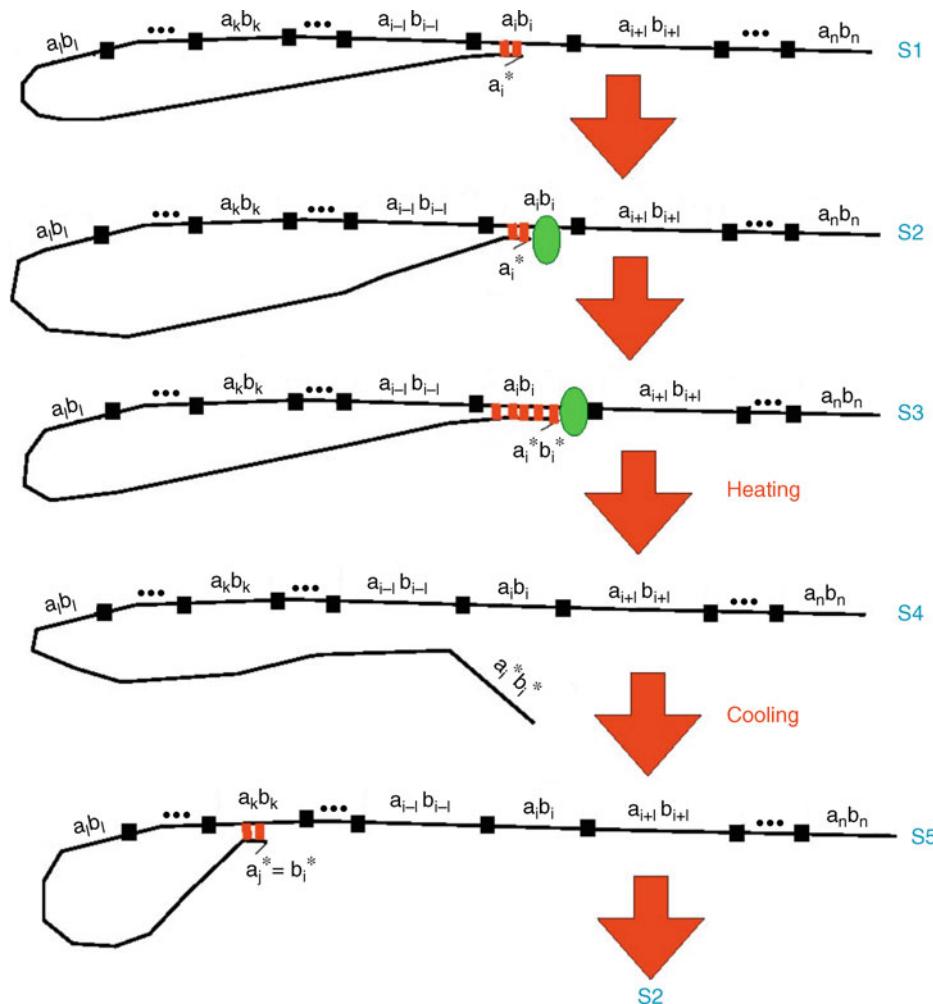

9.2.2 Whiplash PCR: A Method for Local Molecular Computation

A method for DNA computation, known as Whiplash PCR (Sakamoto et al. 1999) makes use of a strand of DNA that essentially encodes a “program” describing state transition rules of a finite state computing machine; the strand is comprised of a sequence of “rule” subsequences (each encoding a state transition rule), and each separated by stopper sequences (which can stop the action of DNA polymerase). On each step of the computation, the 3' end of the DNA strand has a final sequence encoding a state of the computation. A computation step is executed when this 3' end hybridizes to a portion of a “rule” subsequence, and the action of DNA polymerase extends the 3' end to a further subsequence encoding a new state (Fig. 19).

Whiplash PCR is interesting, since it executes a local molecular computation (recall that a molecular computation is local if the computation is within a single molecule, possibly in

Fig. 19

Whiplash PCR: Repeated rounds of heating and cooling allow for the execution of a finite state transition machine with state transitions $a_i \Rightarrow b_i$ encoded by the DNA strand sequence. Each of the state transitions is executed in the cool stages, where if the current state is a_i , the 3' end of the DNA strand has the complement at its 3' end, which hybridizes to a sequence a_i^* and the state transition via polymerization extension step at the 3' end, allowing a transition to a state b_i . The heating stage allows for displacement of the extended 3' end.

parallel with other molecular computing devices). In contrast, most methods for autonomous molecular computation (such as those based on the self-assembly of tiles) provide only a capability for distributed parallel molecular computation since to execute a computation they require multiple distinct molecules that interact to execute steps of each computation.

9.3 Isothermal and Autonomous PCR Detection and Whiplash PCR Computation Protocols

Neither the original PCR protocol nor the Whiplash PCR of Sakamoto et al. (1998) executes autonomously – they require thermal cycling for each step of their protocols. Walker et al. (1992a, b) developed isothermal (requiring no thermal cycling) methods for PCR known as strand displacement amplification (SDA) in which strands displaced from DNA polymerase are used for the further stages of the amplification reaction. Reif and Majumder recently developed (Reif and Majumder 2009) an autonomously executing version of Whiplash PCR (known as isothermal reactivating Whiplash PCR) that makes use of a strand-displacing polymerization enzyme (recall, however, that certain polymerase enzymes such as phi-29 can, as a side effect of their polymerization reaction, displace previously hybridized strands) with techniques to allow the reaction to process isothermally. In summary, an isothermal variant (strand-displacement PCR) of the basic PCR detection protocol provided insight on how to design an autonomous method for DNA computation. Like Whiplash PCR, this new isothermal reactivating Whiplash PCR provides for local molecular computation.

9.4 Autonomous Molecular Cascades and Related Hybridization Reactions for Autonomous DNA Computation

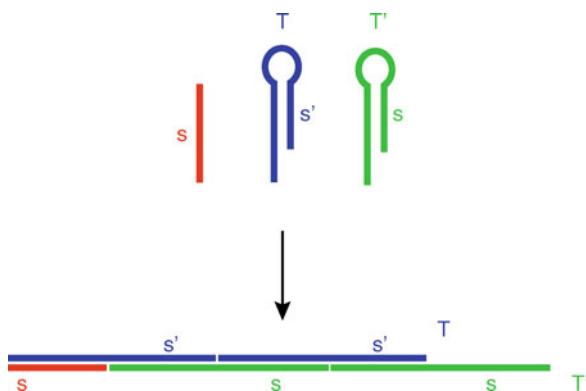

9.4.1 Autonomous Molecular Cascades for DNA Detection

Dirks and Pierce (2004) demonstrated an isothermal, enzyme-free (most known detection protocols require the use of protein enzymes) method for highly sensitive detection of a particular DNA strand. This protocol makes a triggered amplification by the hybridization chain reaction briefly illustrated in Fig. 20.

The protocol made use of multiple copies of two distinct DNA nanostructures T and T' that are initially added to a test tube. When ssDNA sequence S is added to the test tube, S initially has a hybridization reaction with a part of T, thus exposing a second ssDNA S' that had

Fig. 20

Autonomous molecular cascade for signal amplification.

been previously hidden within the nanostructure of T. Next, S' has a hybridization reaction with a part of T', thus exposing a second copy of S that had been previously hidden within the nanostructure of T'. The second copy of S then repeats the process of other similar (but so far unaltered) copies of T and T', allowing a cascade effect to occur completely autonomously such autonomous molecular cascade devices have applications to a variety of medical applications, where a larger response (e.g., a cascade response) is required in response to one of the multiple molecular detection events.

9.4.2 Hybridization Reactions for Autonomous DNA Computation

Winfree (Zhang et al. 2007) developed a general methodology for designing systems of DNA molecules by the use of catalytic reactions that are driven by entropy. In particular, Zhang et al. (2007) demonstrates a general, powerful scheme for executing any Boolean circuit computation via cascades of DNA hybridization reactions. The unique common property of the above detection protocol (Dirks and Pierce 2004) and the molecular computations of Zhang et al. (2007) are their use of only hybridization, making no use of restriction enzyme or any other protein enzymes.

Following on this work, Yin et al. (2008) developed an elegant and highly descriptive labeled diagram scheme (with nodes indicating inputs, products, etc.) for illustrating the programming of biomolecular self-assembly and reaction pathways.

9.5 Autonomous Detection Protocols and Molecular Computations Using DNAzyme

In addition, Chen et al. (2004) demonstrated a novel method for DNA detection, which made use of a dual set of DNAzyme (recall a DNAzyme is a DNA molecule that possesses enzymatic activity, in particular cutting particular single-stranded DNA) that provided for amplified DNA detection. This led to the DNAzyme-based autonomous DNA walker (Tian et al. 2005) described in  Sect. 10.4.2.

10 Autonomous Molecular Transport Devices Self-assembled from DNA

10.1 Molecular Transport

Many molecular-scale tasks may require the transport of molecules and there are a number of other tasks that can be done at the molecular scale that would be considerably aided by an ability to transport within and/or along nanostructures. For example, regarding the importance of molecular transport in nanoscale systems, consider the cell, which uses protein motors fueled by ATP to do this.

10.2 Nonautonomous DNA Motor Devices

In the early 2000s a number of researchers developed and demonstrated motors composed of DNA nanostructures; for example, Yurke et al. (2000) demonstrated a DNA actuator powered by DNA hybridization (complementary pairing between DNA strands). However, all of these

DNA motor devices required some sort of externally mediated changes (such as temperature-cycling, addition or elimination of a reagent, etc.) per work cycle of the device, and so did not operate autonomously.

10.3 The Need for Autonomous Molecular Transport

Almost all of the conventionally scaled motors used by mankind run without external mediation, and almost all natural systems for molecular motors are also autonomous (e.g., the cell's protein motors are all autonomous). The practical applications of molecular devices requiring externally mediated changes per work cycle are quite limited. So it is essential to develop autonomous DNA devices that do not require external mediation while executing movements.

10.4 Autonomous DNA Walkers

Reif (2003) first described the challenge of autonomous molecular transport devices which he called "DNA walkers" that traversed DNA nanostructures, and proposed two designs that gave bidirectional movement. In 2004, Sherman and Seeman demonstrated a DNA walker (Sherman and Seeman 2004), but it was nonautonomous since it required external mediation for every step it made.

10.4.1 Restriction Enzyme-Based Autonomous DNA Walkers

The first autonomous DNA walker was experimentally demonstrated in 2004 by Yin et al. (2004a, b). It employed restriction enzymes and ligase; see Yin et al. (2005) for its detailed general design (☞ Fig. 21).

The device is described in ☞ Fig. 19.

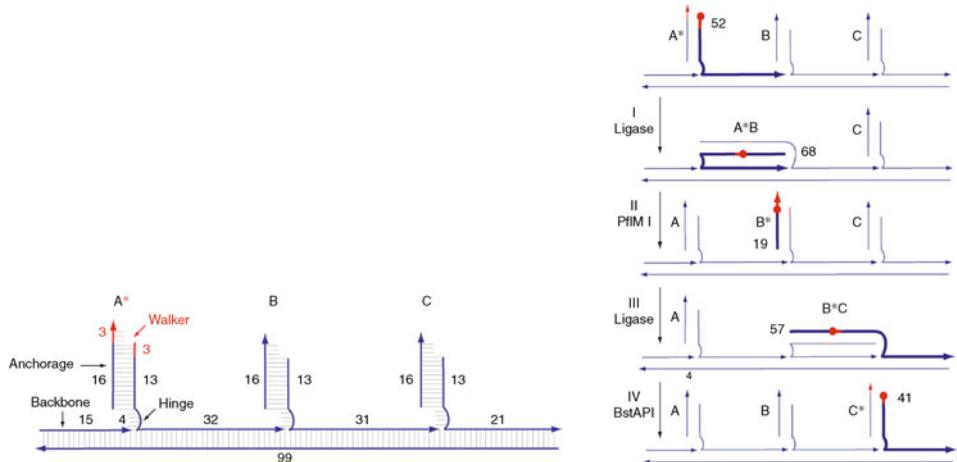

- Initially, a linear DNA nanostructure (the "road") with a series of attached ssDNA strands (the "steps") is self-assembled. Also, a fixed-length segment of DNA helix (the "walker") with short sticky ends (its "feet") are hybridized to the first two steps of the road.
- Then the walker proceeds to make a sequential movement along the road, where at the start of each step the feet of the walker are hybridized to two further consecutive steps of the road.
- Then a restriction enzyme cuts the DNA helix where the backward foot is attached, exposing a new sticky end forming a new replacement foot that can hybridize to the next step that is free, which can be the step just after the step where the other foot is currently attached. A somewhat complex combinatorial design for the sequences composing the steps and the walker ensures that there is unidirectional motion forward, along the road.

10.4.2 DNAzyme-Based Autonomous DNA Walkers

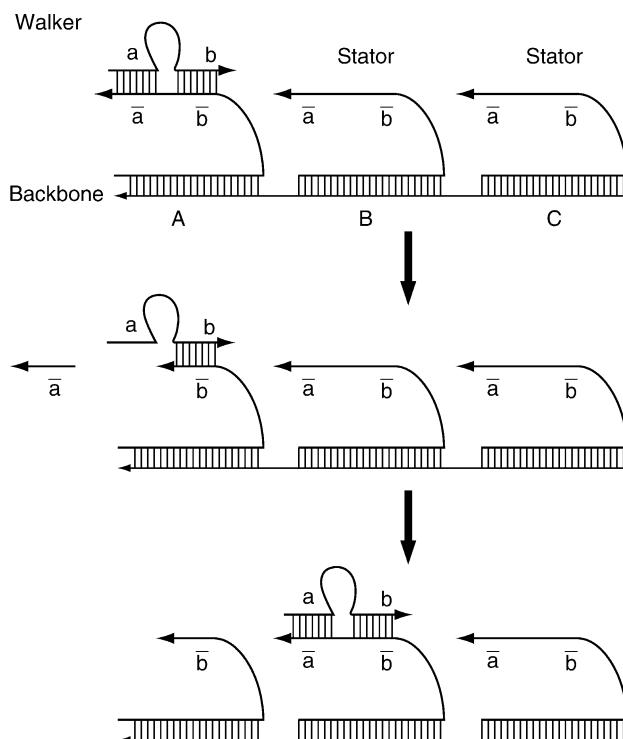

Subsequently in 2005 Mao's group (Tian et al. 2005) demonstrated an autonomous DNA walker that made use of a DNAzyme motor (Chen et al. 2004) that used the cuts provided by the enzymatic activity of DNAzyme to progress along a DNA nanostructure (☞ Fig. 22).

Fig. 21

Autonomous molecular transport devices self-assembled from DNA.

**Fig. 22**

Mao's DNAzyme walker.

Bath and Turberfield (2007) also give an extensive survey of these and further recent DNA motor and walker devices.

10.5 Programmable Autonomous DNA Devices: Nanobots

There are some important applications of these autonomous DNA walkers including transport of molecules within large self-assembled DNA nanostructures. However, the potential applications may be vastly increased if they can be made to execute computations while moving along a DNA nanostructure. This would allow them, for example, to make programmable changes to their state and to make movements programmable. Such programmable autonomous DNA walker devices will be called “programmable DNA nanobots.” Yin et al. (2006) describe an extension of the design of the restriction enzyme-based autonomous DNA walker (Yin et al. 2004a, b) described above in [Sect. 10.4.1](#), to allow programmed computation while moving along a DNA nanostructure.

Another DNA nanobot design (see [Fig. 23](#)) for programmed computation while moving along a DNA nanostructure was developed by Sahu and Reif (2008) using in this case an extension of the design of the DNAzyme-based autonomous DNA walker (Tian et al. 2005) also described below ([Fig. 24](#)).

It remains a challenge to experimentally demonstrate these.

11 Conclusions and Challenges

11.1 What Was Covered and What Was Missed: Further Reading

This chapter has covered most of the major known techniques and results for autonomous methods for DNA-based computation and transport.

However, there is a much larger literature of DNA-based computation that includes methods that are nonautonomous, but otherwise often ingenious and powerful. As just one notable example, Stojanovic demonstrated a deoxyribozyme-based molecular automaton (Stojanovic and Stefanovic 2003) and demonstrated its use to play the optimal strategy for a simple game.

Fig. 23

Reif and Sahu’s DNA nanobot: Figure illustrates the implementation of a state transition through DNAzymes. $D_{0,s1}$ in the transition machinery for state transition at 0 combines with input nanostructure when active input symbol encoded by the sticky end is 0. When the active input symbol encoded by the sticky end is 1, $D_{1,s1}$ in the transition machinery for state transition at 1 combines with the input nanostructure.

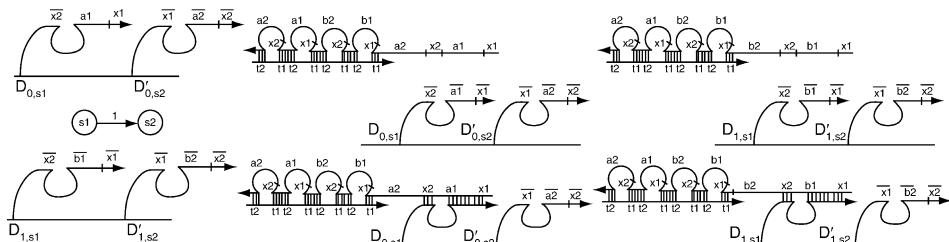

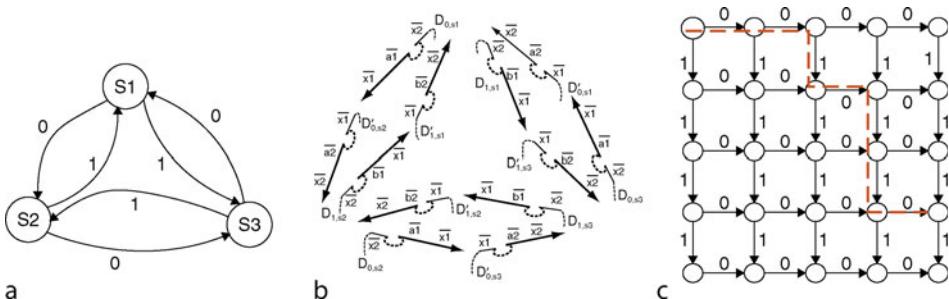

Fig. 24

(b) Illustration of programmable routing in two dimensions. (a) State transition diagram. (b) DNAzyme strands programming transitions. (c) Programmed traversal of DNA nanostructure grid.

Other excellent surveys of DNA nanostructures and devices have been given by Seeman (Sherman and Seeman 2004; Sha et al. 2005), Mao (Deng et al. 2006), de Castro (2006), LaBean and Li (2007), Yan and Liu (2006), and Bath and Turberfield (2007).

11.2 Future Challenges for Self-assembled DNA Nanostructures

There are a number of key challenges still confronting this emerging field:

Experimentally demonstrate:

1. *Complex, error-free DNA patterning to the scale of, say, at least 10,000 pixels – as required, say, for a functional molecular electronic circuit for a simple processor.*

Note: This would probably entail the use of a DNA tiling error correction method as well as a significant improvement over existing DNA patterning techniques.

2. *A programmable DNA nanobot autonomously executing a task critical to nano-assembly.*

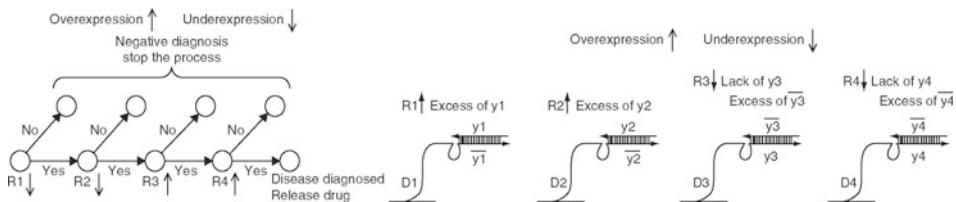

Note: The first stage might be a DNA walker that can be programmed to execute various distinct, complex traversals of a 2D DNA nanostructure, and to load and unload molecules at chosen sites on the nanostructure.

3. *An application of self-assembled DNA nanostructures to medical diagnosis.*

Adar et al. (2004) were the first to propose and to demonstrate in the test tube a finite-state computing DNA device for *medical diagnosis*: the device detects RNA levels (either over- or underexpression of particular RNA), computes a diagnosis based on a finite-state computation, and then provides an appropriate response (e.g., the controlled release of a single-stranded DNA that either promotes or interferes with expression). They demonstrated, in the test tube, a potential application of such a finite-state computing device to medical diagnosis and therapeutics. Sahu and Reif (2008) described a DNAzyme-based autonomous DNA nanobot (see **Sect. 10.4**) that can also function as a finite-state computing DNA device for medical diagnosis (**Fig. 25**).

Fig. 25

A finite-state computing DNA device for medical diagnosis based on Reif and Sahu's DNAzyme-based autonomous DNA nanobot. A state diagram for a DNAzyme doctor nanobot that controls the release of a "drug" RNA on the basis of the RNA expression tests for a disease. The figure shows the consequences of overexpression and underexpression of different RNAs on the concentrations of the respective characteristic sequences. The overexpression of $R1$ and $R2$ results in excess of y_1 and y_2 , respectively, and they block the path of the input nanostructure by hybridizing with $D1$ and $D2$. Similarly, underexpression of $R3$ and $R4$ results in excess of \bar{y}_3 and \bar{y}_4 , respectively, to block the path of input nanostructure.

It remains a challenge to apply such a finite-state computing DNA device for medical diagnosis within the cell, rather than in the test tube.

Abstract

This chapter introduces the basic ideas, results, and applications of membrane computing, a branch of natural computing inspired by the structure and the functioning of the living cell, as well as by the cooperation of cells in tissues, colonies of cells, and neural nets.

1 Introduction

Membrane computing is a branch of natural computing introduced by Păun (2000). Its main goal is to abstract computing models from the architecture and the functioning of living cells, as well as from the organization of cells in tissues, organs (brain included) or other higher-order structures such as colonies of cells (e.g., bacteria). The initial goal was to learn from cell biology something possibly useful to computer science, and the area quickly developed in this direction. Several classes of computing models, called P systems, were defined in this context and mainly investigated from mathematical and computer science points of view. Soon, other applications appeared, first in biology, then also in linguistics, computer science, economics, approximate optimization, etc. This chapter will introduce the main classes of P systems, with simple examples illustrating their structure and functioning, and then will briefly discuss some types of results and applications.

Consider that a cell is a hierarchical structure of compartments defined by membranes, with solutions of chemicals swimming in compartments and proteins bound on membranes, which also define selective channels among compartments. The computing model abstracted in this context is a distributed one, with (virtual) membranes defining its structure, with “reactions” taking place in compartments, and with a precise way of communicating among compartments. Thus, the main ingredients of a P system are (1) the membrane structure, (2) the multisets of objects placed in the compartments of the membrane structure, and (3) the rules for processing the objects and the membranes. The rules are used for changing the current configuration of the device and in this way we get computations, sequences of transitions among configurations starting with an initial configuration and, when halting, providing a result of the computation. Many classes of P systems have been defined, with biological, mathematical, or computer science motivation; these variants concern the arrangement of membranes, the form of rules, the way of using the rules, the way of defining the result of a computation, and so on. The main classes of P systems (cell-like, tissue-like, neural-like) will be discussed below.

Most of these classes of P systems are rather powerful from a computational point of view. They are Turing complete, even when using ingredients of a reduced complexity – a small number of membranes, rules of simple forms, ways of controlling the use of rules directly inspired from biology. Certain classes of P systems are also efficient. They can be used for solving computationally hard problems – typically NP-complete problems, in a feasible time, which are typically polynomial.

Membrane computing proved to be rather appealing as a modeling framework, especially for handling discrete (biological or biomedical, economic, etc.) processes. They have many attractive features: easy understandability, scalability and programmability, inherent compartmentalization, etc.

Membrane computing is a young research area, but already its bibliography is rather large. A comprehensive presentation can be found in the 2002 monograph (Păun 2002), with several

applications presented in Ciobanu et al. (2006), where a friendly introduction to membrane computing is given in the first chapter. An up-to-date coverage of membrane computing can be found in a recent handbook (Păun et al. 2009). The complete bibliography of the domain, which at the end of 2008 totaled around 1,250 titles, can be found on the P Systems website at www.ppage.psystems.eu. In general, the reader can refer to these bibliographical sources, as this chapter only specifies a few references.

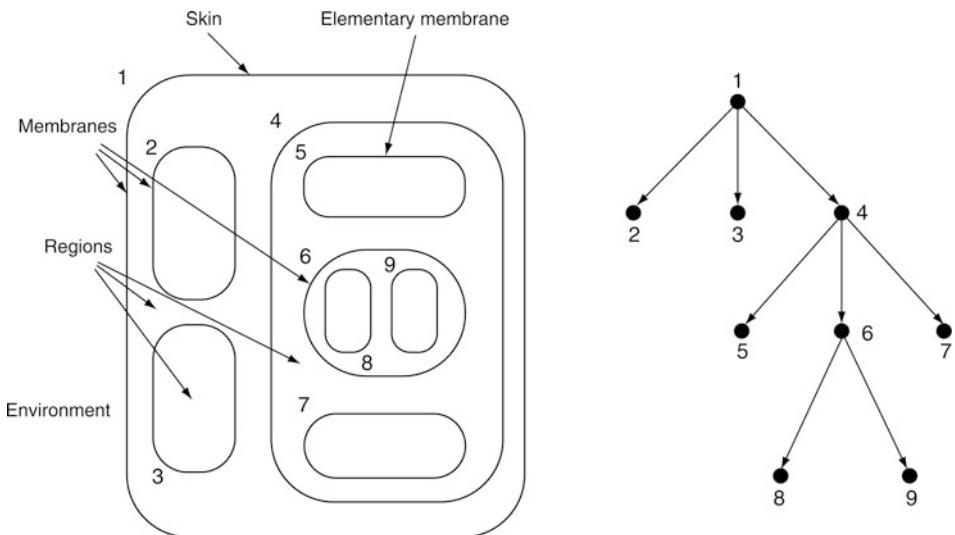

2 Cell-Like P Systems

In this section we discuss in some detail the first introduced and most investigated type of P system, inspired by the structure and functioning of the biological cell. Because the ingredients used in this model are also present, with variations, in other types of P systems, we discuss separately the main ingredients: membrane structure, types of rules, ways of using the rules and of defining the results.

2.1 Membrane Structure

One starts from the observation that the (eukaryotic) cell is compartmentalized by means of membranes, so that one considers hierarchical arrangements of membranes as suggested (in a 2D representation) in the left side of Fig. 1. Here we distinguish an external membrane (corresponding to the plasma membrane and usually called the *skin* membrane) as well as several membranes placed inside the skin membrane (corresponding to the membranes present in a cell, around the nucleus, in Golgi apparatus, vesicles, mitochondria, etc.). A membrane without any other membrane inside it is said to be *elementary*. Each membrane determines a compartment, called a *region*, which is the space delimited by it from above and

Fig. 1
A membrane structure and its tree representation.

from below by the membranes placed directly inside, if any exist. Clearly, the correspondence between the membrane and region is one-to-one; that is why the terms are sometimes used interchangeably.

Usually, the membranes are identified by *labels* from a given set. In [Fig. 1](#), we use numbers, starting with number 1 assigned to the skin membrane. (This is the standard labeling, but the labels can be more informative “names” associated with the membranes.) Also, in the figure the labels are assigned in a one-to-one manner to membranes, but this is possible only in the case of membrane structures that cannot grow (indefinitely); otherwise, several membranes would have the same label (such cases will be seen later). Due to the membrane–region correspondence, we identify by the same label a membrane and its associated region.

This hierarchical structure of membranes can be represented by a rooted unordered tree, with labeled nodes; the tree that describes the membrane structure in [Fig. 1](#) is given in the right-hand side of the same figure. The root of the tree is associated with the skin membrane and the leaves are associated with the elementary membranes.

Directly suggested by the tree representation is the symbolic representation of a membrane structure, by strings of labeled matching parentheses. For instance, a string corresponding to the structure from [Fig. 1](#) is the following:

$$[1 [2]_2 [3]_3 [4 [5]_5 [6 [8]_8 [9]_9]_6 [7]_7]_4]_1 \quad (*)$$

Because the tree is not ordered (and also corresponds to a biological reality), the membranes of the same level can float around. Therefore, by swapping two subexpressions placed at the same level, we get an expression that represents the same membrane structure. For instance, in the previous case, the expression

$$[1 [3]_3 [4 [6 [8]_8 [9]_9]_6 [7]_7 [5]_5]_4 [2]_2]_1$$

is a representation of the same membrane structure, equivalent to [\(*\)](#).

2.2 Multisets

In the compartments of a cell, there are various chemicals swimming in water (at this stage, we ignore the chemicals, mainly proteins, bound on membranes). Because in many cases for the biochemistry taking place in a cell “numbers matter”, the natural data structure to use in this framework is the *multiset*, the set with multiplicities associated with its elements. For this reason, some basic elements related to multisets and to their representation by strings, which is standard in membrane computing, are discussed here.

A *multiset* over a given set U is a mapping $M : U \rightarrow \mathbb{N}$, where \mathbb{N} is the set of nonnegative integers. For $a \in U$, $M(a)$ is the multiplicity of a in M . If the set U is finite, $U = \{a_1, \dots, a_n\}$, then the multiset M can be explicitly given in the form $\{(a_1, M(a_1)), \dots, (a_n, M(a_n))\}$, thus specifying for each element of U its multiplicity in M . In membrane computing, the usual way to represent a multiset $M = \{(a_1, M(a_1)), \dots, (a_n, M(a_n))\}$ over a finite set $U = \{a_1, \dots, a_n\}$ is by using strings: $w = a_1^{M(a_1)} a_2^{M(a_2)} \dots a_n^{M(a_n)}$ and all permutations of w represent M ; the empty multiset is represented by λ , the empty string. The total multiplicity of elements of a multiset (this is also called the *weight* of the multiset) clearly corresponds to the length of a string representing it. This compact representation is so frequent in membrane computing that we can usually say “the multiset w ” instead of “the multiset represented by string w .”

A few basic notions about multisets are useful in membrane computing, but they are not discussed here; the reader can refer to Calude et al. (2001) for details.

2.3 Evolution Rules

The main way the chemicals present in the compartments of a cell evolve is by means of reactions that consume certain chemicals and produce other chemicals. In what follows, the chemicals are considered to be unstructured and hence are described by symbols from a given alphabet; these symbols are called *objects*. Later, structured objects described by strings will also be considered.

Thus, in each compartment of a membrane structure, we consider a multiset of objects over a given alphabet. Corresponding to the biochemical reactions, the main type of rules for evolving these multisets are multiset rewriting rules (simply, evolution rules). Later, rules for moving objects across membranes, called communication rules, as well as rules for handling membranes will also be considered.

The multiset-rewriting rules are of the form $u \rightarrow v$, where u and v are multisets of objects. An example is $aab \rightarrow abcc$ (remember that the multisets are represented by strings). However, in order to make the compartments cooperate, objects have to be moved across membranes, and for this we add *target indications* to the objects produced by a rule as above (to the objects from multiset v). These indications are *here*, *in*, and *out*, with the meanings that an object associated with the indication *here* remains in the same region, one associated with the indication *in* goes immediately into an adjacent lower membrane that is nondeterministically chosen, and *out* indicates that the object has to exit the membrane, thus becoming an element of the region surrounding it. For instance, we can have $aab \rightarrow (a, \text{here})(b, \text{out})(c, \text{here})(c, \text{in})$. Using this rule in a given region of a membrane structure means to consume two copies of a and one of b (they are removed from the multiset of that region), and one copy of a , one of b , and two of c are produced; the resulting copy of a remains in the same region, and the same happens with one copy of c (indications *here*), while the new copy of b exits the membrane, going to the surrounding region (indication *out*), and one of the new copies of c enters one of the child membranes, nondeterministically chosen. If no such child membrane exists, that is, the membrane with which the rule is associated is elementary, then the indication *in* cannot be followed, and the rule cannot be applied. In turn, if the rule is applied in the skin region, then b will exit into the environment of the system (and it is “lost” there, since it can never come back). In general, the indication *here* is not specified when giving a rule.

The evolution rules are classified according to the complexity of their left-hand side. A rule with at least two objects in its left-hand side is said to be *cooperative*; a particular case is that of *catalytic* rules of the form $ca \rightarrow cv$, where c is an object (called catalyst), which assists the object a to evolve into the multiset v ; rules of the form $a \rightarrow v$, where a is an object, are called *noncooperative*.

The rules can also contain other ingredients or indications about their use. For instance, a rule of the form $u \rightarrow v\emptyset$ entails the dissolution of the membrane where it is used: if the rule is applied, then the corresponding membrane disappears and its contents, object and membranes alike, are left free in the surrounding membrane; the rules of the dissolved membrane disappear with the membrane. The skin membrane is never dissolved.

The rules can also be of the form $u \rightarrow v|_p$, where p is an object; it is said that p is a *promoter* and the rule can be applied only if p is present in the region where the rule is applied.

Similarly, we have rules with *inhibitors*: $u \rightarrow v|_{\neg p}$ can be applied only if the object p is not present in the region.

Very important are also the communication rules and the rules for evolving the membrane structure, but, before introducing them we discuss another central feature, the way of using the rules.

2.4 Ways of Using the Rules

The most investigated way of applying the rules in the regions of a P system is described by the phrase: *in the maximally parallel manner, nondeterministically choosing the rules and the objects*.

This means the following: we assign objects to rules, nondeterministically choosing the objects and the rules until no further assignment is possible. Mathematically stated, we look to the *set* of rules and try to find a *multiset* of rules by assigning multiplicities to rules with two properties: (1) the multiset of rules is *applicable* to the multiset of objects available in the respective region; that is, there are enough objects to apply the rules a number of times as indicated by their multiplicities; and (2) the multiset is *maximal*, that is, no further rule can be added to it (no multiplicity of a rule can be increased) such that the obtained multiset is still applicable.

Thus, an evolutionary step in a given region consists of finding a maximal applicable multiset of rules, removing from the region all objects specified in the left-hand sides of the chosen rules (with multiplicities as indicated by the rules and by the number of times each rule is used), producing the objects from the right-hand sides of the rules, and then distributing these objects as indicated by the targets associated with them. If at least one of the rules introduces the dissolving action δ , then the membrane is dissolved and its contents become part of the parent membrane, provided that this membrane was not dissolved at the same time; otherwise we stop at the first upper membrane that was not dissolved (the skin membrane at least remains intact).

The maximal parallelism both corresponds to the apparent simultaneity of reactions taking place in a cell and it is also very useful from a mathematical point of view, but there are several other possibilities, in general closer to the biological reality. *Partial parallelism* is one of them: in each step, one uses a specified number of rules, or at least/at most a specified number of rules. In the limit, we have the *sequential* use of rules: only one rule is used in each region, nondeterministically chosen.

An interesting case is that of *minimal parallelism*. The intuition is that each region that *can* evolve (using at least one rule) *must* evolve (by means of at least one rule). More specifically, we start by nondeterministically choosing one rule from each region where a rule can be used; this combination of rules or any applicable supermultiset of it can be used in evolving the system. Note that in comparison with the maximal parallelism, a considerable degree of nondeterminism is possible, as many choices of multisets of rules can be applied (in particular, any maximal multiset).

2.5 Computations and Results of Computations

A membrane structure and the multisets of objects from its regions identify a *configuration* of a P system. Note that both objects and rules are associated with regions; they are *localized*.

By using the rules in one of the ways suggested above, we pass to another configuration; such a step is called a *transition*. Note that in all cases considered in the previous section, the evolution of the system is synchronized; a global clock exists that marks the time uniformly for all regions and all regions evolve in each time unit. A sequence of transitions constitutes a *computation*. A computation is successful if it halts – it reaches a configuration where no rule can be applied to the existing objects. With a halting computation we can associate a *result* in various ways. One possibility is to count the objects present in the halting configuration in a specified elementary membrane; this is called the *internal output*. We can also count the objects that leave the system during the computation; this is called the *external output*. In both cases, the result is a number. If we distinguish among different objects, then we can have as the result a vector of natural numbers. The objects that leave the system can also be arranged in a sequence according to the moments when they exit the skin membrane, and in this case the result is a string.

Total halting as mentioned above is only one of the ways of defining successful computations and the most investigated in membrane computing (also because it is similar to the way Turing machines provide a result). Another possibility is *partial halting*: The computation stops when at least one region of the system halts; it cannot use any of its rules. Then, we can also use *signals* of various kinds for marking the step when a result is provided by a computation; for instance, if a specified object exits the system, then we count the number of objects in a given membrane in order to get a result.

An important issue is the way we use the system. In the previous discussion, it was assumed that one can start from an initial configuration and proceed through transitions (according to a given way of using the rules). Because of the nondeterminism of the application of rules, one can get several successful computations, and hence several results. This is the *generative* way of using a P system, and in this way a P system *computes* (or *generates*) a set of numbers, or a set of vectors of numbers, or a language. Another important possibility is the *accepting* case: we start from the initial configuration, where some objects codify an input, and that input is accepted if and only if the computation halts (or a specified object, say *yes*, is sent to the environment). A more general case is that of *computing* a function: We start with the argument introduced in the initial configuration and the value of the function is obtained at the end of the computation.

2.6 A Formal Definition and an Example

We now have all the prerequisites for formally defining a cell-like P system. Such a system is a construct

$$\Pi = (O, \mu, w_1, \dots, w_m, R_1, \dots, R_m, i_{in}, i_{out})$$

where O is the alphabet of objects, μ is the membrane structure (with m membranes), given as an expression of labeled parentheses, w_1, \dots, w_m are (strings over O representing) multisets of objects present in the m regions of μ at the beginning of a computation, R_1, \dots, R_m are finite sets of evolution rules associated with the regions of μ , and i_{in}, i_{out} are the labels of input and output membranes, respectively. If the system is used in the generative mode, then i_{in} is omitted; if the system is used in the accepting mode, then i_{out} is omitted. If the system is a catalytic one, then a subset C of O is specified, containing the catalysts. The number m of membranes in μ is called the *degree* of Π .

In the generative case, the set of numbers computed by Π when using the rules in mode *mode*, one of those mentioned in [Sect. 2.4](#), is denoted by $N_{\text{mode}}(\Pi)$; in what follows, the rules are always used in the maximally parallel way, hence the subscript is omitted. The family of all sets $N(\Pi)$ computed by systems Π of degree at most $m \geq 1$ and using rules of *types-of-rules* forms is denoted by $NOP_m(\text{types-of-rules})$; if there is no bound on the degree of systems, then the subscript m is replaced with $*$.

The architecture and the functioning of a cell-like P system is illustrated with a simple example of a computing P system. Formally, it is given as follows:

$$\Pi = (O, C, \mu, w_1, w_2, R_1, R_2, i_o)$$

where

$$O = \{a, b_1, b'_1, b_2, c, e\} \text{ (the set of objects)}$$

$$C = \{c\} \text{ (the set of catalysts)}$$

$$\mu = [\begin{smallmatrix} 1 & [\begin{smallmatrix} 2 & 2 \end{smallmatrix}]_2 \end{smallmatrix}]_1 \text{ (membrane structure)}$$

$$w_1 = c \text{ (initial objects in region 1)}$$

$$w_2 = \lambda \text{ (initial objects in region 2)}$$

$$R_1 = \{a \rightarrow b_1 b_2, cb_1 \rightarrow cb'_1, b_2 \rightarrow b_2 e_{\text{in}}|_{b_1}\} \text{ (rules in region 1)}$$

$$R_2 = \emptyset \text{ (rules in region 2)}$$

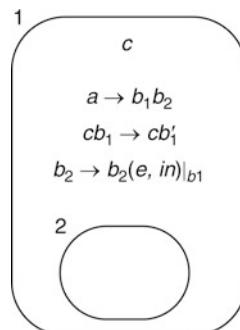

$$i_o = 2 \text{ (the output region)}$$

[Fig. 2](#) indicates the initial configuration (the rules included) of the system Π . It computes a function, namely $n \rightarrow n^2$, for any natural number $n \geq 1$. Besides catalytic and non-cooperating rules, the system also contains a rule with promoters, $b_2 \rightarrow b_2(e, in)|_{b_1}$: the object b_2 evolves to b_2e only if at least one copy of object b_1 is present in the same region.
