We start with only one object in the system, the catalyst c . If we want to compute the square of a number n , then we have to input n copies of the object a in the skin region of the system. In that moment, the system starts working by using the rule $a \rightarrow b_1 b_2$, which has to be applied in parallel to all copies of a ; hence, in one step, all objects a are replaced by n copies of b_1 and n copies of b_2 . From now on, the other two rules from region 1 can be used. The catalytic rule $cb_1 \rightarrow cb'_1$ can be used only once in each step, because the catalyst is present in only one copy. This means that in each step one copy of b_1 gets primed. Simultaneously (because of the

Fig. 2

A P system with catalysts and promoters.

maximal parallelism), the rule $b_2 \rightarrow b_2(e, in)|_{b_1}$ should be applied as many times as possible — n times, because we have n copies of b_2 . Note the important difference between the promoter b_1 , which allows us to use the rule $b_2 \rightarrow b_2(e, in)|_{b_1}$, and the catalyst c : the catalyst is involved in the rule and is counted when applying the rule, while the promoter makes possible the use of the rule but it is not counted; the same (copy of an) object can promote any number of rules. Moreover, the promoter can evolve at the same time by means of another rule (the catalyst is never changed).

In this way, in each step we change one b_1 to b'_1 and we produce n copies of e (one for each copy of b_2); the copies of e are sent to membrane 2 (the indication in from the rule $b_2 \rightarrow b_2(e, in)|_{b_1}$). The computation should continue as long as there are applicable rules. This means exactly n steps: in n steps, the rule $cb_1 \rightarrow cb'_1$ will exhaust the objects b_1 and in this way neither this rule can be applied, nor $b_2 \rightarrow b_2(e, in)|_{b_1}$, because its promoter no longer exists. Consequently, in membrane 2, considered as the output membrane, we get n^2 copies of object e .

Note that the computation is deterministic, always the next configuration of the system is unique, and that, changing the rule $b_2 \rightarrow b_2(e, in)|_{b_1}$ with $b_2 \rightarrow b_2(e, out)|_{b_1}$, the n^2 copies of e will be sent to the environment; hence we can read the result of the computation outside the system, and in this case membrane 2 is useless.

2.7 Symport and Antiport Rules

An important part of the cell activity is related to the passage of substances through membranes, and one of the most interesting ways to handle this transmembrane communication is by coupling molecules as suggested by cell biology. The process by which two molecules pass together across a membrane (through a specific protein channel) is called *symport*; when the two molecules pass simultaneously through a protein channel in opposite directions the process is called *antiport*.

These operations can be formalized by considering symport rules of the form (x, in) and (x, out) , and antiport rules of the form $(z, out; w, in)$, where x, z , and w are multisets of arbitrary size; one says that the length of x , denoted by $|x|$, is the *weight* of the symport rule, and $\max(|z|, |w|)$ is the *weight* of the antiport rule. Thus, we obtain the following important class of P systems.

A P system with symport/antiport rules is a construct of the form

$$\Pi = (O, \mu, w_1, \dots, w_m, E, R_1, \dots, R_m, i_{in}, i_{out})$$

where all components $O, \mu, w_1, \dots, w_m, i_{in}, i_{out}$ are as in a P system with multiset rewriting rules, $E \subseteq O$, and R_1, \dots, R_m are finite sets of symport/antiport rules associated with the m membranes of μ . The objects of E are supposed to be present in the environment of the system with an arbitrary multiplicity. (Note that the symport/antiport rules do not change the number of objects, but only their place, which is why we need a supply of objects in the environment; this supply is inexhaustible, that is, it does not matter how many objects are introduced in the system because arbitrarily many still remain in the environment.)

As above, the rules can be used in various ways, but here we consider again the nondeterministic maximally parallel manner. Transitions, computations, and halting computations will be defined in the usual way. The number of objects present in region i_{out} in the halting configuration is said to be computed by the system by means of that computation; the set of all numbers computed in this way by Π is denoted by $N(\Pi)$. The family of sets $N(\Pi)$ computed

by systems Π of degree at most $m \geq 1$, using symport rules of degree at most $p \geq 0$ and antiport rules of degree at most $q \geq 0$ (the cases $p = 0$ or $q = 0$ correspond to not having symport or antiport rules, respectively), is denoted by $NOP_m(\text{sym}_p, \text{anti}_q)$.

The definition of P systems is illustrated with symport/antiport with an example of more general interest: a construction for simulating a *register machine* is given. In this way, one of the widely used proof techniques for the universality results in this area is also introduced.

A (nondeterministic) *register machine* is a device $M = (m, B, l_0, l_h, R)$, where $m \geq 1$ is the number of registers, B is the (finite) set of instruction labels, l_0 is the initial label, l_h is the halting label, and R is the finite set of instructions labeled (and hence uniquely identified) by elements from B . The labeled instructions are of the following forms:

- $l_1 : (\text{add}(r), l_2, l_3)$, $1 \leq r \leq m$ (add 1 to register r and go nondeterministically to one of the instructions with labels l_2, l_3),
- $l_1 : (\text{sub}(r), l_2, l_3)$, $1 \leq r \leq m$ (if register r is not empty, then subtract 1 from it and go to the instruction with label l_2 , otherwise go to the instruction with label l_3).

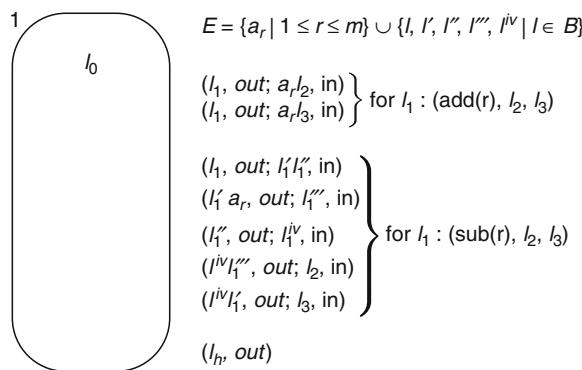

A register machine generates a set of natural numbers in the following manner: we start computing with all m registers empty, with the instruction labeled l_0 ; if the label l_h is reached, then the computation *halts* and the value of register 1 is the number generated by the computation (all other registers can be assumed to be empty at that time). The set of all natural numbers generated in this way by M is denoted by $N(M)$. It is known that nondeterministic register machines (with three registers) can compute any set of Turing computable sets of natural numbers.

A register machine can be easily simulated by a P system with symport/antiport rules. The idea is illustrated in Fig. 3, where we have represented the initial configuration of the system, the rules associated with the unique membrane, and the set E of objects present in the environment.

The value of each register r is represented by the multiplicity of object $a_r, 1 \leq r \leq m$, in the unique membrane of the system. The labels from B , as well as their primed versions, are also objects of our system. We start with the unique object l_0 present in the system. In the presence of a label object l_1 we can simulate the corresponding instruction $l_1 : (\text{add}(r), l_2, l_3)$ or $l_1 : (\text{sub}(r), l_2, l_3)$.

Fig. 3

An example of symport/antiport P system.

The simulation of an `add` instruction is clear, so we discuss only a `sub` instruction. The object l_1 exits the system in exchange for the two objects $l'_1 l''_1$ (rule $(l_1, out; l'_1 l''_1, in)$). In the next step, if any copy of a_r is present in the system, then l'_1 has to exit (rule $(l'_1 a_r, out; l'''_1, in)$), thus diminishing the number of copies of a_r by one, and bringing inside the object l'''_1 ; if no copy of a_r is present, which corresponds to the case when the register r is empty, then the object l'_1 remains inside. Simultaneously, rule $(l''_1, out; l''_1, in)$ is used, bringing inside the “checker” l''_1 . Depending on what this object finds in the system, either l'''_1 or l'_1 , it introduces the label l_2 or l_3 , respectively, which corresponds to the correct continuation of the computation of the register machine.

When the object l_h is introduced, it is expelled into the environment and the computation stops. Clearly, the (halting) computations in Π directly correspond to (halting) computations in M ; hence $N(M) = N(\Pi)$.

2.8 P Systems with Active Membranes

In the systems discussed above, the membrane structure is static, the membranes can be at most dissolved, which is not quite similar to what happens in biology, where membranes can be created or divided, and operations of exocytosis, endocytosis, phagocytosis change the membrane structure. In this section only the operation of membrane division is considered – actually, a case when the membranes play a direct part in the rules is considered.

This leads to a very important class of P systems, the main one used in devising polynomial solutions to computationally hard problems, namely the class of *P systems with active membranes*, which are constructs of the form

$$\Pi = (O, H, \mu, w_1, \dots, w_m, R)$$

where O, w_1, \dots, w_m are as in a P system with multiset rewriting rules or with symport/antiport rules, H is a finite set of *labels* for membranes, μ is a membrane structure of degree $m \geq 1$, with polarizations associated with membranes, that is “electrical charges” $\{+, -, 0\}$, and R is a finite set of rules, of the following forms:

- (a) $[_h a \rightarrow v]_h^e$, for $h \in H, e \in \{+, -, 0\}, a \in O, v \in O^*$ (object evolution rules);
- (b) $a[_h]_h^{e_1} \rightarrow [_h b]_h^{e_2}$, for $h \in H, e_1, e_2 \in \{+, -, 0\}, a, b \in O$ (in communication rules);
- (c) $[_h a]_h^{e_1} \rightarrow [h]_h^{e_2} b$, for $h \in H, e_1, e_2 \in \{+, -, 0\}, a, b \in O$ (out communication rules);
- (d) $[_h a]_h^e \rightarrow b$, for $h \in H, e \in \{+, -, 0\}, a, b \in O$ (dissolving rules);
- (e) $[_h a]_h^{e_1} \rightarrow [_h b]_h^{e_2} [_h c]_h^{e_3}$, for $h \in H, e_1, e_2, e_3 \in \{+, -, 0\}, a, b, c \in O$

(division rules for elementary membranes; in reaction with an object, the membrane is divided into two membranes with the same label, and possibly of different polarizations; the object specified in the rule is replaced in the two new membranes possibly by new objects; the remaining objects are duplicated and may evolve in the same step by rules of type (a)).

Note that each rule has specified the membrane where it is applied; that is why a global set of rules R is considered. The rules are applied in a maximally parallel manner, with the following details: a membrane can be subject to only one rule of types (b)–(e) (the rules of type (a) are not considered to involve the membrane where they are applied); inside each membrane, the rules of type (a) are applied in parallel; each copy of an object is used by only one rule of any type. The rules are used in a bottom-up manner: we use first the rules of type (a), and then the rules of other types; in this way, in the case of dividing membranes, the

result of using first the rules of type (a) is duplicated in the newly obtained membranes). As usual, only halting computations give a result in the form of the number (or the vector) of objects expelled into the environment during the computation.

The set H of labels has been specified because it is possible to allow the change of membrane labels. For instance, a division rule can be of the more general form

$$(e') [_{h_1} a]^{e_1}_{h_1} \rightarrow [_{h_2} b]^{e_2}_{h_2} [_{h_3} c]^{e_3}_{h_3} \quad \text{for } h_1, h_2, h_3 \in H, e_1, e_2, e_3 \in \{+, -, 0\}, a, b, c \in O.$$

The change of labels can also be considered for rules of types (b) and (c). Also, we consider the possibility of dividing membranes into more than two copies, or even of dividing nonelementary membranes (in such a case, all inner membranes are duplicated in the new copies of the membrane).

P systems with active membranes can be used for computing numbers, but their main usefulness is in devising polynomial-time solutions to computationally hard problems, by a time–space trade-off. The space is created both by duplicating objects and by dividing membranes. This possibility is illustrated by the way of using membrane division for the generation of all 2^n truth assignments possible for n propositional variables; this is the basic step in solving SAT (satisfiability of propositional formulas in the conjunctive normal form) in polynomial time in this framework.

Assume that we have the variables x_1, x_2, \dots, x_n ; we construct the following system (of degree 2):

$$\begin{aligned} \Pi &= (O, \{1, 2\}, [1]_2^0[2]_1^0, \lambda, a_1 a_2 \dots a_n c_1, R) \\ O &= \{a_i, c_i, t_i, f_i \mid 1 \leq i \leq n\} \cup \{\text{check}\} \\ R &= \{[2]a_i[2]^0 \rightarrow [2]t_i[2]^0[2]f_i[2]^0 \mid 1 \leq i \leq n\} \\ &\quad \cup \{[2]c_i \rightarrow c_{i+1}[2]^0 \mid 1 \leq i \leq n-1\} \\ &\quad \cup \{[2]c_n \rightarrow \text{check}[2]^0, [2]\text{check}[2]^0 \rightarrow \text{check}[2]_2^+\} \end{aligned}$$

We start with the objects a_1, \dots, a_n in the inner membrane and we divide this membrane repeatedly by means of the rules $[2]a_i[2]^0 \rightarrow [2]t_i[2]^0[2]f_i[2]^0$; note that the object a_i used in each step is nondeterministically chosen, but each division replaces that object by t_i (for *true*) in one membrane and with f_i (for *false*) in the other membrane; hence after n steps the configuration obtained is the same regardless of the order of expanding the objects. Specifically, we get 2^n membranes with label 2, with each one containing a truth assignment for the n variables. Simultaneously with the division, we have to use the rules of type (a) that update the “counter” c ; hence at each step we increase by one the subscript of c . Therefore, when all variables have been expanded, we get the object *check* in all membranes (the rule of type (a) is used first, and after that the result is duplicated in the newly obtained membranes). In step $n+1$, this object exits each copy of membrane 2, changing its polarization to positive; this is meant to signal the fact that the generation of all truth assignments is completed, and we can start checking the truth values of (the clauses of) the propositional formula.

The previous example was also chosen to show that the polarizations of membranes are not used while generating the truth assignments, though they might be useful after that; until now, this has been the case in all polynomial-time solutions to NP-complete problems obtained in this framework. An important *open problem* in this area is whether or not the polarizations can be avoided. This can be done if other ingredients are considered, such as label changing or division of nonelementary membranes, but without adding such features the best result obtained so far is that the number of polarizations can be reduced to two.

2.9 Structuring the Objects

In the previous classes of P systems, the objects were considered atomic, identified only by their name, but in a cell many chemicals are complex molecules (e.g., proteins, DNA molecules, other large macromolecules), whose structures can be described by strings or more complex data, such as trees, arrays, etc. Also from a mathematical point of view, it is natural to consider P systems with string objects.

Such a system has the form

$$\Pi = (V, T, \mu, M_1, \dots, M_m, R_1, \dots, R_m)$$

where V is the alphabet of the system, $T \subseteq V$ is the terminal alphabet, μ is the membrane structure (of degree $m \geq 1$), M_1, \dots, M_m are finite sets of strings present in the m regions of the membrane structure, and R_1, \dots, R_m are finite sets of string-processing rules associated with the m regions of μ .

We have given the system in general form, with a specified terminal alphabet (we say that the system is *extended*; if $V = T$, then the system is said to be *non-extended*), and without specifying the type of rules. These rules can be of various forms, but we consider here only two cases: rewriting and splicing.

In a *rewriting P system*, the string objects are processed by rules of the form $a \rightarrow u(\text{tar})$, where $a \rightarrow u$ is a context-free rule over the alphabet V and tar is one of the target indications here, in, and out. When such a rule is applied to a string x_1ax_2 in a region i , we obtain the string x_1ux_2 , which is placed in region i , in any inner region, or in the surrounding region, depending on whether tar is here, in, or out, respectively. The strings that leave the system do not come back; if they are composed only of symbols from T , then they are considered as generated by the system. The language of all strings generated in this way is denoted by $L(\Pi)$.

In a *splicing P system*, we use splicing rules like those in DNA computing, that is, of the form $u_1\#u_2\$u_3\#u_4$, where u_1, u_2, u_3 , and u_4 are strings over V . For four strings $x, y, z, w \in V^*$ and a rule $r : u_1\#u_2\$u_3\#u_4$, we write

$$(x, y) \vdash_r (z, w) \text{ if and only if } \begin{aligned} x &= x_1u_1u_2x_2, & y &= y_1u_3u_4y_2, \\ z &= x_1u_1u_4y_2, & w &= y_1u_3u_2x_2, \\ &\text{for some } x_1, x_2, y_1, y_2 \in V^* \end{aligned}$$

We say that x and y are spliced at the sites u_1u_2 and u_3u_4 , respectively, and the result of the splicing (obtained by recombining the fragments obtained by cutting the strings as indicated by the sites) is the strings z and w .

In our case, we add target indications to the two resulting strings, that is, we consider rules of the form $r : u_1\#u_2\$u_3\#u_4(\text{tar}_1, \text{tar}_2)$, with tar_1 and tar_2 one of here, in, and out. The meaning is as standard: After splicing the strings x, y from a given region, the resulting strings z, w are moved to the regions indicated by $\text{tar}_1, \text{tar}_2$, respectively. The language generated by such a system consists again of all strings over T sent into the environment during the computation, without considering only halting computations.

An example of a rewriting or a splicing P system is not given here, but an important extension of rewriting rules — namely, *rewriting with replication* — is introduced. In such systems, the rules are of the form $a \rightarrow (u_1, \text{tar}_1) \parallel (u_2, \text{tar}_2) \parallel \dots \parallel (u_n, \text{tar}_n)$, with the meaning that by rewriting a string x_1ax_2 we get n strings, $x_1u_1x_2, x_1u_2x_2, \dots, x_1u_nx_2$, which have to be moved in the regions indicated by targets $\text{tar}_1, \text{tar}_2, \dots, \text{tar}_n$, respectively.

The replicated rewriting is important because it provides the possibility to replicate strings, thus enlarging the workspace. Indeed, this is one of the frequently used ways to generate an exponential workspace in linear time, used then for solving computationally hard problems in polynomial time.

2.10 P Systems with Objects on Membranes

Consider that objects placed only in membranes cover only part of the biological reality, where most of the reactions taking place in a cell are controlled by proteins bound on membranes. Thus, it is a natural challenge for membrane computing to take care of this situation and, indeed, several types of P systems were investigated where membranes carry objects.

Three main approaches are considered in the literature. The first one is inspired from Cardelli (2005), where six basic operations were introduced. Counterparts of biological operations with membranes and two calculi were defined on this basis: pino/exo/phago calculus and mate/drip/bud calculus. Part of these operations were rephrased in terms of membrane computing and used in defining classes of P systems where objects are placed only on membranes. We call *membrane systems* the obtained P systems. A few ideas from Cardelli and Păun (2006) will be recalled below.

In the above-mentioned systems, we do not have objects also in compartments, as in usual P systems. Two models taking care of this aspect are what we call *the Ruston model* and *the Trento model*. In both cases, objects are placed both on the membranes and in their compartments, with the difference that in the former case the objects do not change their places, those bound on membranes remain there, while in the latter model the objects can move from compartments to membranes and back. The first type of systems were introduced in Păun and Popa (2006) and the second one in Brijder (2007). Several further papers were devoted to these systems, but the reader can refer to Păun et al. (2009) and www.ppage.psystems.eu for details.

Just to have an idea about this direction of research, here the P systems based on mate/drip operations are introduced.

One can consider an alphabet A of special objects called “proteins.” A membrane that has associated a multiset $u \in A^*$ is represented by $[]_u$; we also say that u marks the membrane. When necessary, we can also use labels for identifying membranes, but in most cases the objects marking them are sufficient. The operations considered here are the following:

$$\begin{aligned} \text{mate: } & []_{ua} []_v \rightarrow []_{uxv} \\ \text{drip: } & []_{uav} \rightarrow []_{ux} []_v \end{aligned}$$

where $a \in V$ and $u, v, x \in A^*$. The length of the string uxv (i.e., the total multiplicity of the multiset represented by this string) from each rule is called the *weight* of the rule.

In each case, multisets of objects are transferred from membranes appearing in the left-hand side of rules to membranes appearing in the right-hand side of rules, with protein a evolved into the multiset x . It is important to note that in *drip* rules the multiset uxv is precisely split into ux and v , with these two multisets assigned to the two new membranes.

The rules are applied to given membranes if they are marked with multisets of objects, which include the multisets mentioned in the left-hand side of rules. All objects placed on membranes but not involved in the rules are not affected by the use of rules; in the case of *drip*,

these objects are randomly distributed to the two resulting membranes. In the case of *mate*, the result is uniquely determined.

The contents of membranes involved in these operations (i.e., the membranes possibly placed inside) is transferred from the input membranes to the output membranes in the same way as in brane calculi. Denoting these contents (empty or consisting of other membranes) by \mathbf{P}, \mathbf{Q} , we can indicate the effect of the two operations as follows:

$$\begin{aligned} \text{mate: } & [\mathbf{P}]_{ua}[\mathbf{Q}]_v \rightarrow [\mathbf{P} \ \mathbf{Q}]_{uxv} \\ \text{drip: } & [\mathbf{P}]_{uav} \rightarrow [\]_{ux}[\mathbf{P}]_v \end{aligned}$$

Now, a P system of the following form can be defined

$$\Pi = (A, \mu, u_0, u_1, \dots, u_m, R)$$

where A is an alphabet (its elements are called *objects* or *proteins*), μ is a membrane structure with at least two membranes (hence $m \geq 1$), labeled with $0, 1, \dots, m$, where 0 is the skin membrane, $u_0, u_1, \dots, u_m \in A^*$ are multisets of objects bound to the membranes of μ at the beginning of the computation, with $u_0 = \lambda$, R is a finite set of mate, drip rules, of the forms specified above, using objects from the set A .

As usual in membrane computing, the evolution of the system proceeds through transitions among configurations, based on the nondeterministic maximally parallel use of rules. In each step, each membrane and each object can be involved in only one rule. A membrane remains unchanged if no rule is applied to it. The skin membrane never evolves.

A computation that starts from the initial configuration (the one described by μ and multisets u_0, u_1, \dots, u_m) is successful only if (1) it halts, that is, it reaches a configuration where no rule can be applied, and (2) in the halting configuration there are only two membranes, the skin (marked with the empty multiset) and an inner one. The result of a successful computation is the number of proteins that mark the inner membrane in the halting configuration.

The set of all numbers computed in this way by Π is denoted by $N(\Pi)$. The family of all sets $N(\Pi)$ computed by P systems Π using at any moment during a halting computation at most m membranes, and mate, drip rules of weight at most p, q , respectively, is denoted by $NOP_m(\text{mate}_p, \text{drip}_q)$.

3 Tissue-Like P Systems

We pass now to consider a very important generalization of the membrane structure, passing from the cell-like structure, described by a tree, to a tissue-like structure, with the membranes placed in the nodes of an arbitrary graph (which corresponds to the complex communication networks established among adjacent cells by making their protein channels cooperate, moving molecules directly from one cell to another). Actually, in the basic variant of tissue-like P systems, this graph is virtually a total one; what matters is the communication graph, dynamically defined during computations. In short, several (elementary) membranes – also called cells – are freely placed in a common environment; they can communicate either with each other or with the environment by symport/antiport rules. Specifically, antiport rules of the form $(i, x/y; j)$ are considered, where i, j are labels of cells or at most one is zero, identifying the environment, and x, y are multisets of objects. This means that the multiset x is moved from i to j at the same time as the multiset y is moved from j to i . If one of the multisets x, y is empty, then we have, in fact, a symport rule. Therefore, the communication among cells is done either directly, in one

step, or indirectly, through the environment: One cell throws some objects out and other cells can take these objects in the next step or later. As in symport/antiport P systems, the environment contains a specified set of objects in arbitrarily many copies. A computation develops as standard, starting from the initial configuration and using the rules in the nondeterministic maximally parallel manner. When halting, we count the objects from a specified cell, and this is the result of the computation.

The graph plays a more important role in so-called *tissue-like P systems with channel-states*, whose rules are associated with synapses and are of the form $(s, x/y, s')$, where s, s' are states from a given finite set and x, y are multisets of objects. Such a rule of the form $(s, x/y, s') \in R_{(i,j)}$ is interpreted as an antiport rule $(i, x/y, j)$ as above, acting only if the synapse (i, j) has the state s ; the application of the rule means (1) moving the objects specified by x from cell i (from the environment, if $i = 0$) to cell j , at the same time with the move of the objects specified by y in the opposite direction, and (2) changing the state of the synapse from s to s' . The use of states provides a powerful way to control the application of rules.

A still more elaborated class of systems, called *population P systems*, was introduced in Bernardini and Gheorghe (2004) with motivations related to the dynamics of cells in skin-like tissues, populations of bacteria, and colonies of ants. These systems are highly dynamical: not only the links between cells, corresponding to the channels from the previous model with states assigned to the channels, can change during the evolution of the system, but also the cells can change their names, can disappear (get dissolved), and can divide, thus producing new cells; these new cells inherit, in a well-specified sense, links with the neighboring cells of the parent cell. The generality of this model makes it rather attractive for applications in areas such as those mentioned above, related to tissues, populations of bacteria, etc.

A further interesting version of tissue-like P systems is that of *neural-like P systems*, where we again use a population of cells (each one identified by its label) linked by a specified set of synapses. This time, each cell has at every moment a state from a given finite set of states, its contents in the form of a multiset of objects from a given alphabet of objects, and a set of rules for processing these objects.

The rules are of the form $sw \rightarrow s'(x, here)(y, go)(z, out)$, where s, s' are states and w, x, y, z are multisets of objects; in state s , the cell consumes the multiset w and produces the multisets x, y, z ; the objects from multiset x remain in the cell, those of multiset y have to be communicated to the cells toward which there are synapses starting in the current cell; a multiset z , with the indication *out*, is allowed to appear only in a special cell, designated as the output cell, and for this cell the use of the previous rule entails sending the objects of z to the environment.

The computation starts with all cells in specified initial states, with initially given contents, and proceeds by processing the multisets from all cells, simultaneously, according to the local rules. Then the obtained objects are redistributed along synapses and send a result into the environment through the output cell; a result is accepted only when the computation halts.

Because of the use of states, there are several possibilities for processing the multisets of objects from each cell. In the *minimal* mode, a rule is chosen and applied once to the current pair (state, multiset). In the *parallel* mode, a rule is chosen, for example, $sw \rightarrow s'w'$, and used in the maximally parallel manner: The multiset w is identified in the cell contents in the maximal manner, and the rule is used for processing all these instances of w . Finally, in the *maximal* mode, we apply in the maximally parallel manner all rules of the form $sw \rightarrow s'w'$, that is, with the same states s and s' (note the difference with the parallel mode, where in each step a rule is chosen and only that rule is used as many times as possible).

There are also three ways to move the objects between cells (of course, we only move objects produced by rules in multisets with the indication *go*). Assume that a rule $sw \rightarrow s'(x, \text{here})(y, go)$ is applied in a given cell i . In the *spread* mode, the objects from y are nondeterministically distributed to all cells j such that (i, j) is a synapse of the system. In the *one* mode, all the objects from y are sent to one cell j , provided that the synapse (i, j) exists. Finally, we can also *replicate* the objects of y , and each object from y is sent to all cells j such that (i, j) is an available synapse.

We do not enter into more details; on the one hand, this class of P systems still waits for a systematic investigation; on the other hand, there is another class of P systems inspired from the brain's organization, whose study is much more developed, the *spiking neural P systems*.

4 Spiking Neural P Systems

Spiking neural P systems (SN P systems) were introduced in Ionescu et al. (2006) with the aim of defining P systems based on ideas specific to spiking neurons, recently much investigated in neural computing.

Very shortly, an SN P system consists of a set of *neurons* (cells consisting of only one membrane) placed in the nodes of a directed graph and sending signals (*spikes*, denoted in what follows by the symbol a) along *synapses* (arcs of the graph). Thus, the architecture is that of a tissue-like P system, with only one kind of object present in the cells. The objects evolve by means of *spiking rules*, which are of the form $E/a^c \rightarrow a;d$, where E is a regular expression over $\{a\}$ and c, d are natural numbers, $c \geq 1$, $d \geq 0$. The meaning is that a neuron containing k spikes such that $a^k \in L(E)$, $k \geq c$, can consume c spikes and produce one spike, after a delay of d steps. This spike is sent to all neurons to which a synapse exists outgoing from the neuron where the rule was applied. There also are *forgetting rules*, of the form $a^s \rightarrow \lambda$, with the meaning that $s \geq 1$ spikes are forgotten, provided that the neuron contains exactly s spikes. We say that the rules "cover" the neuron: all spikes are taken into consideration when using a rule. The system works in a synchronized manner; that is, in each time unit, each neuron that can use a rule should do it, but the work of the system is sequential in each neuron: Only (at most) one rule is used in each neuron. One of the neurons is considered to be the *output neuron*, and its spikes are also sent to the environment. The moments of time when a spike is emitted by the output neuron are marked with 1, the other moments are marked with 0. This binary sequence is called the *spike train* of the system – it might be infinite if the computation does not stop.

In the spirit of spiking neurons, the result of a computation is encoded in the distance between consecutive spikes sent into the environment by the (output neuron of the) system. For example, we can consider only the distance between the first two spikes of a spike train, or the distances between the first k spikes, the distances between all consecutive spikes, taking into account all intervals or only intervals that alternate, all computations or only halting computations, etc.

An SN P system can also be used in the accepting mode: A neuron is designated as the *input neuron* and two spikes are introduced in it, at an interval of n steps; the number n is accepted if the computation halts.

Another possibility is to consider the spike train itself as the result of a computation, and then we obtain a (binary) language generating device. We can also consider both input and

output neurons and then an SN P system can work as a transducer. Languages on arbitrary alphabets can be obtained by generalizing the form of rules: Take rules of the form $E/a^c \rightarrow a^p; d$, with the meaning, provided that the neuron is covered by E , c spikes are consumed and p spikes are produced, and sent to all connected neurons after d steps (such rules are called *extended*). Then, with a step when the system sends out i spikes, we associate a symbol b_i , and thus we get a language over an alphabet with as many symbols as the number of spikes simultaneously produced. Another natural extension is to consider several output neurons, thus producing vectors of numbers, not only single numbers.

The technical details are skipped, but a simple example is considered (if a rule $E/a^c \rightarrow a; d$ has $L(E) = \{a\}$, then it can be written in the simplified form $a^c \rightarrow a; d$):

$$\begin{aligned}\Pi_1 &= (O, \sigma_1, \sigma_2, \sigma_s, syn, out), \text{ with} \\ O &= \{a\} \text{ (alphabet, with only one object, the spike)} \\ \sigma_1 &= (2, \{a^2/a \rightarrow a; 0, \quad a \rightarrow \lambda\}) \\ &\quad (\text{first neuron: initial number of spikes, rules}) \\ \sigma_2 &= (1, \{a \rightarrow a; 0, \quad a \rightarrow a; 1\}) \\ &\quad (\text{second neuron: initial number of spikes, rules}) \\ \sigma_3 &= (3, \{a^3 \rightarrow a; 0, \quad a \rightarrow a; 1, \quad a^2 \rightarrow \lambda\}) \\ &\quad (\text{third neuron: initial number of spikes, rules}) \\ syn &= \{(1, 2), (2, 1), (1, 3), (2, 3)\} \text{ (synapses)} \\ out &= 3 \text{ (output neuron).}\end{aligned}$$

This system functions as follows. All neurons can fire in the first step, with neuron σ_2 choosing nondeterministically between its two rules. Note that neuron σ_1 can fire only if it contains two spikes; one spike is consumed, the other remains available for the next step.

Both neurons σ_1 and σ_2 send a spike to the output neuron, σ_3 ; these two spikes are forgotten in the next step. Neurons σ_1 and σ_2 also exchange their spikes; thus, as long as neuron σ_2 uses the rule $a \rightarrow a; 0$, the first neuron receives one spike, thus completing the needed two spikes for firing again.

However, at any moment, starting with the first step of the computation, neuron σ_2 can choose to use the rule $a \rightarrow a; 1$. On the one hand, this means that the spike of neuron σ_1 cannot enter neuron σ_2 and it only goes to neuron σ_3 ; in this way, neuron σ_2 will never work again because it remains empty. On the other hand, in the next step neuron σ_1 has to use its forgetting rule $a \rightarrow \lambda$, while neuron σ_3 fires, using the rule $a \rightarrow a; 1$. Simultaneously, neuron σ_2 emits its spike, but it cannot enter neuron σ_3 (it is closed at this moment); the spike enters neuron σ_1 , but it is forgotten in the next step. In this way, no spike remains in the system. The computation ends with the expelling of the spike from neuron σ_3 . Because of the waiting moment imposed by the rule $a \rightarrow a; 1$ from neuron σ_3 , the two spikes of this neuron cannot be consecutive, but at least two steps must exist in between.

Thus, it can be concluded that Π computes/generates all natural numbers greater than or equal to 2.

There are several classes of SN P systems, for instance, asynchronous SN P systems (no clock is considered, any neuron may use or not a rule), with exhaustive use of rules (when enabled, a rule is used as many times as made possible by the spikes present in a neuron), with certain further conditions imposed on the halting configuration, etc.

5 Computing Power

As previously mentioned, many classes of P systems that combine various ingredients (as described above or similar ones) are able to simulate Turing machines; hence they are *computationally complete*. Always, the proofs of results of this type are constructive, and this has an important consequence from the computability point of view: in this way we obtain *universal* (hence *programmable*) P systems. In short, starting from a universal Turing machine (or an equivalent universal device), we get an equivalent universal P system. Among others, this implies that in the case of Turing complete classes of P systems, the hierarchy on the number of membranes always collapses — at most at the level of the universal P systems. There are, however, classes of nonuniversal P systems for which “the number of membranes matters,” to cite the title of Ibarra (2005), where two classes of P systems were defined for which the hierarchies on the number of membranes are infinite. Actually, the number of membranes in a P system sufficient to characterize the power of Turing machines is always rather small.

Here only a few of the most interesting types of universality results for cell-like P systems are mentioned:

1. P systems with symbol-objects with catalytic rules, using only two catalysts and two membranes, are universal.
2. P systems with symport/antiport rules of a restricted size (e.g., three membranes, symport rules of weight 2, and no antiport rules, or three membranes and minimal symport and antiport rules) are universal.
3. P systems with symport/antiport rules (of arbitrary size), using only three membranes and only three objects, are universal.
4. P systems with active membranes, using rules of types (a), (b), (c) and two polarizations are universal.
5. P systems with string objects and rewriting rules usually generate only matrix languages, but adding priorities, ways to control the permeability of membranes, inhibitors, or using the rules in the leftmost way lead to universality.
6. P systems with *mate*, *drip* rules controlled by at most four objects and using at most five membranes are universal.

Universality can also be obtained for other types of P systems, such as tissue-like systems, SN P systems (provided that the number of spikes present in the neurons is not bounded, otherwise only semilinear sets of numbers can be computed), accepting P systems, etc. However, we do not recall here such results; one can refer to Păun et al. (2009) and www.ppage.psystems.eu for details. In general, around these results there are a series of open problems, mainly related to their optimality. Some of these results are continuously improved, so the interested reader is advised to consult the membrane computing current bibliography for the most recent results.

In the accepting mode, an interesting issue appears, that of using deterministic systems. Most universality results were obtained in the deterministic case, but there also are situations where the deterministic systems are strictly less powerful than the nondeterministic ones. This is proven in Ibarra and Yen (2006) for the accepting catalytic P systems.

It is worth noting that the proofs of computational completeness are based on simulating various types of grammars with restricted derivation (mainly matrix grammars with

appearance checking) or on simulating register machines. In the case of SN P systems, this has an interesting consequence: Starting the proofs from small universal register machines, one can find small universal SN P systems. For instance, as shown in Păun and Păun (2007), there are universal computing SN P systems with 84 neurons using standard rules and with only 49 neurons using extended rules. In the generative case, the best results are 79 and 50 neurons, respectively.

6 Computational Efficiency

The computational power (the “competence”) is only one of the important questions to be dealt with when defining a new (bio-inspired) computing model. The other fundamental question concerns the computing *efficiency*. Because P systems are parallel computing devices, it is expected that they can solve hard problems in an efficient manner – and this expectation is confirmed for systems provided with ways for producing an exponential workspace in a linear time. Mainly, three such biologically inspired possibilities have been considered so far in the literature, and all of them were proven to lead to polynomial solutions to NP-complete problems, by a time–space trade-off.

These three ideas are membrane division, membrane creation, and string replication. The standard problems addressed in this framework were decidability problems, starting with SAT, the Hamiltonian path problem, and the node covering problem. Other types of problems were considered, such as the problem of inverting one-way functions, or the subset-sum and the knapsack problems (note that the last two are numerical problems, where the answer is not of the yes/no type, as in decidability problems). In general, the approach is of a brute force type: All candidate solutions are generated, making use of the massive parallelism (e.g., all truth assignments of the variables appearing in a SAT problem); then they are checked, again in parallel, in search of a solution. The computation may proceed nondeterministically provided that it is *confluent*: Either eventually we reach the same configuration and then we continue deterministically (strong confluence), or all computations halt and each of them provides the same result (weak confluence).

The formal framework for dealing with complexity matters in terms of P systems is provided by the *accepting P systems with input*: A family of P systems of a given type is constructed starting from a given problem, and an instance of the problem is introduced as an input in one such systems; working in a deterministic (or a confluent) mode, the system sends to the environment the answer to the respective instance. The family of systems should be constructed in a uniform mode by a Turing machine, working a polynomial time.

This direction of research has been much investigated. A large number of problems were considered, the membrane computing complexity classes were refined, characterizations of the $P \neq NP$ conjecture were obtained in this framework, several characterizations of the class P, even problems that are PSPACE-complete, were proven to be solvable in polynomial time by means of membrane systems provided with membrane division or membrane creation. An important (and difficult) problem is that of finding the border between efficiency and non-efficiency: which ingredients should be used in order to be able to solve hard problems in a polynomial time? The reader is referred to the complexity chapter from Păun et al. (2006) and to the literature available at www.ppage.psystems.eu for details – including many problems that are still open in this area.

7 Applications

There are many features of membrane computing that make it attractive for applications in several disciplines, especially for biology and biomedicine: *distribution* (with the important system–part interaction, emergent behavior, nonlinearly resulting from the composition of local behaviors), easy programmability, scalability/extensibility, transparency (multiset rewriting rules are nothing other than reaction equations such as those customarily used in chemistry and biochemistry), parallelism, nondeterminism, communication, and so on and so forth.

As expected, most of the applications have been carried out in biology. These applications are usually based on experiments using programs for simulating/implementing P systems on usual computers, and there are already several such programs, more and more elaborated (e.g., with better and better interfaces, which allow for the friendly interaction with the program). An overview of membrane computing software reported in the literature (some programs are available at the webpage www.ppage.psystems.eu together with sample applications) can be found in the volume Ciobanu et al. (2006).

Of course, when using a P system for simulating a biological process, we are no longer interested in its computing behavior (power, efficiency, etc.), but in its evolution in time; the P system is then interpreted as a dynamical system, and its trajectories are of interest, its “life.” Moreover, the ingredients we use are different from those considered in theoretical investigations. For instance, in mathematical terms, we are interested in results obtained with a minimum of premises and with weak prerequisites, while the rules are used in ways inspired from automata and language theory (e.g., in a maximally or minimally parallel way), but when dealing with applications the systems are constructed in such a way that they capture the features of reality (for instance, the rules are of a general form, they are applied according to probabilistic strategies, based on stoichiometric calculations, the systems are not necessarily synchronized, and so on).

The typical applications run as follows. One starts from a biological process described in general in graphical terms (chemicals are related by reactions represented in a graph-like manner, with special conventions for capturing the context-sensitivity of reactions, the existence of promoters or inhibitors, etc.) or already available in data bases in SBML (system biology mark-up language) form; these data are converted into a P system that is introduced in a simulator. The way the evolution rules (reactions) are applied is the key point in constructing this simulator (often, the classical Gillespie algorithm is used in compartments, or multi-compartmental variants of it are considered). As a result, the evolution in time of the multiplicity of certain chemicals is displayed, thus obtaining a graphical representation of the interplay in time of certain chemicals, their growth and decay, and so on. Many illustrations of this scenario can be found in the literature, many times dealing with rather complex processes.

Besides applications in biology, applications were reported in computer graphics, linguistics (both as a representation language for various concepts related to language evolution, dialogue, semantics, and making use of the parallelism, in solving parsing problems in an efficient way), economics (where many biochemical metaphors find a natural counterpart, with the mentioning that the “reactions” that take place in economics, for instance, in market-like frameworks, are not driven only by probabilities/stoichiometric calculations, but also by psychological influences, which makes the modeling still more difficult than in biology), computer science (in devising sorting and ranking algorithms), cryptography, etc.

A very promising direction of research, namely, applying membrane computing in devising approximate algorithms for hard optimization problems, was initiated in Nishida (2004),

who proposed *membrane algorithms* as a new class of distributed evolutionary algorithms. These algorithms can be considered as high-level (distributed and dynamically evolving their structure during the computation) evolutionary algorithms. In short, candidate solutions evolve in compartments of a (dynamical) membrane structure according to local algorithms, with better solutions migrating down in the membrane structure; after a specified halting condition is met, the current best solution is extracted as the result of the algorithm.

This strategy was checked for several optimization problems, and the results were more than encouraging for a series of benchmark problems: The convergence is very fast, the number of membranes is rather influential on the quality of the solution, the method is reliable, both the average quality and the worst solutions were good enough and always better than the average and the worst solutions given by existing optimization procedures.

8 Closing Remarks

This chapter aimed to provide only a quick presentation of membrane computing, of basic ideas and of types of results and applications. Many more things are available in the literature: further classes of P systems (e.g., we said nothing about conformon-P systems, discussed in detail in Frisco (2008)), other problems to investigate (e.g., normal forms, semantics), links with other areas (e.g., X-machines, Petri nets), software (many programs are available, most of them also on www.ppage.psystems.eu, together with examples of applications), and so on. The area also has many unsolved problems and directions for research that wait for further efforts.

We mentioned before the borderline between universality and non-universality and between efficiency and non-efficiency concerning the succinctness of universal P systems or P systems able to solve hard problems in polynomial time. Then, because universality implies undecidability of all nontrivial questions, an important issue is that of finding classes of P systems with decidable properties.

This is also related to the use of membrane computing as a modeling framework: If no insights can be obtained in an analytical manner algorithmically, then what remains is to simulate the system on a computer. To this aim, better programs are still needed, maybe parallel implementations able to handle real-life questions.

Several research topics concern complexity investigations: uniform versus semiuniform solutions, the role of unary encoding, confluent versus deterministic solutions, the possibility of using precomputed resources, activated during the computation (as done for SN P systems in Chen et al. (2006)), etc.

We conclude by stating that membrane computing is a young and well-developed branch of natural computing, rather promising for applications, which still needs considerable research efforts – which might be a challenge for the reader.

Abstract

Information processing in the physical world must be based on a physical system representing the information. If such a system has a quantum physical description, then one talks about *quantum information processing*. The mathematics needed to handle quantum information is somewhat more complicated than that used for classical information. The purpose of this chapter is to introduce the basic mathematical machinery used to describe quantum systems with finitely many potential observable values. A typical example of such a system is the *quantum bit* (or *qubit*, for short), which has at most two potential values for any physical observable. The mathematics for quantum information processing is based on vector spaces over complex numbers, and can be seen as a straightforward generalization of linear algebra of real vector spaces.

1 History

The earliest ideas on *quantum information* theory were introduced by von Neumann very soon after the initial mathematical machinery of quantum mechanics was developed (von Neumann 1927). On the other hand, the upcoming ideas of *quantum information processing* were still decades away. In the 1980s Paul Benioff presented the first ideas of computing in microsystems obeying quantum mechanics (Benioff 1980, 1982).

From the point of view of modern quantum information processing, the most important early idea was that of Richard Feynman. In his seminal article (Feynman 1982), he introduced a most interesting idea: that it may be impossible to simulate quantum mechanical systems with classical computers without an exponential slowdown (when the simulation efficiency is measured with respect to the number of particles in the system to be simulated).

The next important step toward quantum computing was taken by David Deutsch. In (Deutsch 1985), the aim was to address the Church–Turing thesis from the physical point of view. The Church–Turing thesis (see, e.g., Papadimitriou (1994)) says roughly that a Turing machine is the mathematical counterpart of the intuitive notion of an algorithm: For any intuitive algorithm, there exists a Turing machine performing the same task. Briefly, Deutsch’s argument is as follows: Computation of any form is a physical process anyway, and to prove the Church–Turing thesis it is therefore enough to show that there is a physical system capable of simulating all other physical systems. Deutsch did not pay attention to the complexity of computation, and the pillars of quantum complexity theory were later established by Bernstein and Vazirani (1997).

Interesting quantum algorithms were already introduced by Deutsch and subsequently by Simon (1994), but the most famous quantum algorithms, polynomial-time factoring and the discrete logarithm, were designed by Shor (1994).

2 Hilbert Space Formalism

The mathematical objects that establish the basis for Newtonian mechanics are not very complicated: everything can be laid on the notion of vectors. To describe a point-sized body in a three-dimensional space, one can give the *position* $\mathbf{x} \in \mathbb{R}^3$ and *momentum* $\mathbf{p} \in \mathbb{R}^3$, related

via $\mathbf{p} = m \frac{d}{dt} \mathbf{x}$, where m is the mass of the body. The dynamics of this very simple system is described by the Newtonian equation of motion

$$\mathbf{F} = \frac{d}{dt} \mathbf{p}$$

where \mathbf{F} is the force affecting the body.

Toward a more holistic approach to mechanics, consider first a one-dimensional motion of a particle. The *total energy* of the system in this simple case is $H = \frac{1}{2}mv^2 + V(x) = \frac{p^2}{2m} + V(x)$, where $\frac{1}{2}mv^2$ is the *kinetic energy* and $V(x) = -\int_{x_0}^x F(s)ds$ is the *potential energy* of the particle depending only on the position x . Hence

$$\frac{\partial}{\partial x} H = V'(x) = -F(x) = -\frac{d}{dt} p$$

and

$$\frac{\partial}{\partial p} H = \frac{p}{m} = v = \frac{d}{dt} x$$

Differential equations

$$\frac{d}{dt} x = \frac{\partial}{\partial p} H, \quad \frac{d}{dt} p = -\frac{\partial}{\partial x} H$$

thus obtained are an example of *Hamiltonian reformulation* of classical mechanics. A general mechanical system can consist of many bodies, and the bodies themselves need not be point-like, but they may have internal degrees of freedom (such as capability of rotating).

- It is possible to formulate a general mechanical system in terms of Hamiltonian mechanics, and the equation of motion becomes

$$\begin{aligned}\frac{d}{dt} x_i &= \frac{\partial}{\partial p_i} H \\ \frac{d}{dt} p_i &= -\frac{\partial}{\partial x_i} H\end{aligned}$$

where $H = H(x_1, \dots, x_n, p_1, \dots, p_n, t)$ is the *Hamiltonian function* of the system, describing the total energy.

Variables x_1, \dots, x_m are called *generalized coordinates* and may involve, for example, the usual spatial coordinates and angles of rotation, whereas p_1, \dots, p_n are called *generalized momenta* (may include the usual momenta and the angular momenta, for instance).

The general form of Hamiltonian mechanics thus contains $\mathbf{x} = (x_1, \dots, x_n)$, and $\mathbf{p} = (p_1, \dots, p_n)$ (both vectors in \mathbb{R}^n) as a description of the *system state* at a specified moment of time. Collecting these two, one can say that the pair $(\mathbf{x}, \mathbf{p}) \in \mathbb{R}^{2n}$ is the *state vector* of the system. One can also say the system has n *degrees of freedom*.

It should not then come as a surprise that the description of quantum mechanics also needs vector spaces. However, it is not evident that quantum mechanics should be based on *complex* vector spaces. In fact, to introduce complex numbers is not unavoidable (this is trivial, as a complex number can be presented as a pair of real numbers), but mathematically very helpful. In what follows we will introduce the basic ingredients needed for the Hilbert space formalism of quantum mechanics.

The formalism of quantum mechanics was developed from *wave mechanics* (due to Erwin Schrödinger) and *matrix mechanics* (credited to Werner Heisenberg, Max Born, and Pascual Jordan). These mathematically equivalent formalisms were developed most notably by von Neumann (1932) into a Hilbert space formalism, the major topic of this chapter. It is noteworthy that, in general, the most interesting features emerge in *infinite-dimensional* Hilbert spaces, whereas from the quantum computational point of view, usually finite-dimensional Hilbert spaces are satisfactory enough.

To follow this representation, it is assumed that the reader has a basic knowledge of finite-dimensional *real* vector spaces \mathbb{R}^n strong enough to cover objects such as vectors, linear mappings, matrices, bases, eigenvalues, eigenvectors, inner products, orthogonality, and subspaces. These notions can be found in many basic linear algebra textbooks, for instance in Cohn (1994). In the following, these notions are generalized to *complex* vector spaces. The resulting mathematical objects obtained are then used to describe quantum mechanics.

Definition 1 A *Hilbert space* is a vector space over complex numbers, equipped with a Hermitian inner product, complete with respect to the metric induced by the inner product.

To explain the terminology of the above definition, we choose the standpoint of quantum computing, and then the most important examples of Hilbert spaces are the finite-dimensional ones. As a prototype of such, one can introduce the following: Let

$$\mathbb{C}^n = \{(x_1, \dots, x_n) \mid x_i \in \mathbb{C}\}$$

be the set of all n -tuples of complex numbers. When equipped with pointwise scalar multiplication

$$a(x_1, \dots, x_n) = (ax_1, \dots, ax_n)$$

and pointwise vector addition

$$(x_1, \dots, x_n) + (y_1, \dots, y_n) = (x_1 + y_1, \dots, x_n + y_n)$$

set \mathbb{C}^n evidently becomes a vector space. The (Hermitian) inner product in \mathbb{C}^n is defined by

$$\langle x | y \rangle = x_1^* y_1 + \dots + x_n^* y_n$$

where x^* means the complex conjugate of x . Defined as above, the inner product obviously satisfies the following properties.

► Hermitian Inner Product

- $\langle x | y \rangle = \langle y | x \rangle^*$
- $\langle x | x \rangle \geq 0$ and $\langle x | x \rangle = 0$ if and only if $x = 0$
- $\langle x | ay + bz \rangle = a\langle x | y \rangle + b\langle x | z \rangle$

According to our definition, the Hermitian inner product is linear with respect to the second argument, and *antilinear* with respect to the first one (meaning that $\langle ax + by | z \rangle = a^* \langle x | z \rangle + b^* \langle y | z \rangle$). In the mathematics literature, the Hermitian inner product is usually linear with respect to the first argument, but the convention chosen here is more familiar to quantum physics.

The inner product induces a *norm* by $\|x\| = \sqrt{\langle x | x \rangle}$, and the completeness of Definition 1 means completeness with respect to this norm. That is, for each sequence x_n satisfying

$\lim_{n,m \rightarrow \infty} ||\mathbf{x}_n - \mathbf{x}_m|| = 0$, there is a limit $\mathbf{x} = \lim_{n \rightarrow \infty} \mathbf{x}_n$ also belonging to the space. It should be noted that the completeness is self-evident in the finite-dimensional case. In fact, the following theorem is not very difficult to prove.

Theorem 1 *An n-dimensional Hilbert space H_n (n finite) is isomorphic to \mathbb{C}^n .*

Hence the basic structure of quantum computing, a finite-dimensional Hilbert space, can in practice be treated as \mathbb{C}^n , the set of n -tuples of complex numbers. However, it is not only the space H_n on which the formalism of quantum mechanics will be based, but space $L(H_n)$, the set of all linear mappings $H_n \rightarrow H_n$, will be needed for the description. But when restricting to so-called *pure states* (defined later), space H_n is (almost) sufficient to accommodate the mathematical description of quantum mechanics. Especially in the theory of quantum computing, this is frequently the case. In any case, H_n is called the *state space* of an n -level quantum system. Here and hereafter, the dimension n of H_n equals the number of the *perfectly distinguishable states* of the system to be described. This means that there are n states of the system that can be mutually separated by observations with 100% accuracy.

In quantum computing, the spatial location of the system under investigation is not usually the most essential one; more frequently, the system's internal degrees of freedom are those of interest. This can be compared to a classical system, which, in addition to its position, has also its dynamics of rotation. Analogously, in quantum systems there can be internal degrees of freedom, and in current physical realizations of quantum computing, one of the most noteworthy is the *spin* of a particle. (As the name suggests, spin is closely related to the rotation of the particle around its axis, but spin has also nonclassical features.) It should be remembered that the Hamiltonian reformulation of classical mechanics can treat *all degrees of freedom* in an equal way, and the same is true also in quantum mechanics: the *Schrödinger equation of motion* treats all the degrees of freedom in an analogous way; the position of a particle would involve potentially an infinite number of potential values, but there are also internal properties (such as the spin) that can assume only a finite number of measurable values. It is also noteworthy that obviously one can concentrate only on one degree of freedom of a given system, leaving a lot of system information out. This means, for example, that it is evidently possible to create a mathematical description of a particle spin only, leaving out the particle position and other properties.

Before going into the formalism, it is useful to present some notation. So-called Dirac notation will be useful: for a vector $\mathbf{x} = (x_1, \dots, x_n) \in \mathbb{C}^n$, notation

$$|\mathbf{x}\rangle = \begin{pmatrix} x_1 \\ \vdots \\ x_n \end{pmatrix} \quad (1)$$

stands for a column vector, and notation

$$\langle \mathbf{x}| = (x_1^*, \dots, x_n^*) \quad (2)$$

for the row vector, the *adjoint* version of [Eq. 1](#). Adjointness for matrices will be treated in more detail later.

For \mathbf{x} and $\mathbf{y} \in \mathbb{C}^n$, notations $|\mathbf{x}\rangle\langle\mathbf{y}|$ and $\langle\mathbf{x}||\mathbf{y}\rangle$ are both interpreted as *tensor products* (alternative term: *Kronecker product*).

Definition 2 The tensor product of matrices A ($k \times l$) and B ($m \times n$) is a $km \times ln$ -matrix defined as (in block form).

$$A \otimes B = \begin{pmatrix} a_{11}B & a_{12}B & \dots & a_{1l}B \\ a_{21}B & a_{22}B & \dots & a_{2l}B \\ \vdots & \vdots & \ddots & \vdots \\ a_{k1}B & a_{k2}B & \dots & a_{kl}B \end{pmatrix}$$

For vectors $\mathbf{x}=(x_1, \dots, x_n)$ and $\mathbf{y}=(y_1, \dots, y_n)$, we can hence write (identifying 1×1 matrices and real numbers)

$$\langle \mathbf{x} \| \mathbf{y} \rangle = (x_1^*, x_2^*, \dots, x_n^*) \otimes \begin{pmatrix} y_1 \\ y_2 \\ \vdots \\ y_n \end{pmatrix} = x_1^*y_1 + x_2^*y_2 + \dots + x_n^*y_n$$

which is exactly the same as given by the definition of inner product $\langle \mathbf{x} | \mathbf{y} \rangle$.

The tensor product, on the other hand,

$$| \mathbf{x} \rangle \langle \mathbf{y} | = \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{pmatrix} \otimes (y_1^*, y_2^*, \dots, y_n^*) = \begin{pmatrix} x_1 y_1^* & x_1 y_2^* & \dots & x_1 y_n^* \\ x_2 y_1^* & x_2 y_2^* & \dots & x_2 y_n^* \\ \vdots & \vdots & \ddots & \vdots \\ x_n y_1^* & x_n y_2^* & \dots & x_n y_n^* \end{pmatrix} \quad (3)$$

is not so evident, but also this matrix has a clear interpretation. Indeed, [Definition 3](#) speaks about the *linear mapping*, whose matrix is in line ([Eq. 3](#)).

Definition 3 The set of linear mappings $H_n \rightarrow H_n$ is denoted by $L(H_n)$. For any pair of vectors $\mathbf{x}, \mathbf{y} \in H_n$ we define $| \mathbf{x} \rangle \langle \mathbf{y} | \in L(H_n)$ by

$$| \mathbf{x} \rangle \langle \mathbf{y} | \mathbf{z} = \langle \mathbf{y} | \mathbf{z} \rangle | \mathbf{x} \rangle$$

As mentioned, the matrix ([Eq. 3](#)) is the matrix of linear mapping $| \mathbf{x} \rangle \langle \mathbf{y} |$, with respect to the natural basis (i.e., the basis $\mathbf{e}_1=(1, 0, \dots, 0), \dots, \mathbf{e}_n=(0, 0, \dots, 1)$). Recalling that $| \mathbf{z} \rangle$ actually represents the column vector consisting of the coordinates of \mathbf{z} (with respect to the natural basis), we can also write

$$| \mathbf{x} \rangle \langle \mathbf{y} | \mathbf{z} = \langle \mathbf{y} | \mathbf{z} \rangle | \mathbf{x} \rangle \quad (4)$$

which differs from Definition 3 only in the following way: in Definition 3, $| \mathbf{x} \rangle \langle \mathbf{y} |$ stands for the *linear mapping*, whereas in ([Eq. 4](#)), the same notation stands for a matrix. While mathematically the linear mapping and its matrix are certainly distinct objects, it is customary to identify them when the basis is fixed and clear from the context. Unless otherwise stated, this identification will be used in what follows.

For later purposes, special attention should be paid to mapping $| \mathbf{x} \rangle \langle \mathbf{x} |$ (assuming $\| \mathbf{x} \| = 1$). As $| \mathbf{x} \rangle \langle \mathbf{x} | \mathbf{y} = \langle \mathbf{x} | \mathbf{y} | \mathbf{x} \rangle$, it is obvious that $| \mathbf{x} \rangle \langle \mathbf{x} |$ is the projection onto the one-dimensional space spanned by \mathbf{x} .

When given a fixed orthonormal basis $\{\mathbf{e}_1, \dots, \mathbf{e}_n\}$ of H_n , one can represent any mapping $A \in L(H_n)$ uniquely as

$$A = \sum_{i=1}^n \sum_{j=1}^n A_{ij} | \mathbf{e}_i \rangle \langle \mathbf{e}_j | \quad (5)$$

where $A_{ij} = \langle \mathbf{e}_i | A \mathbf{e}_j \rangle$. Equation (2.5) is hence nothing more than the matrix representation of mapping A (with respect to basis $\{\mathbf{e}_1, \dots, \mathbf{e}_n\}$). It is evident that also $L(H_n)$ is a vector space, and from representation (2.5) one can directly read its dimension, which is n^2 . The advantage of representation (2.5) lies in the fact that, unlike in the ordinary matrix representation, here we have also the basis \mathbf{e}_i explicitly shown.

Definition 4 The adjoint mapping A^* of A is defined by $\langle \mathbf{x} | A \mathbf{y} \rangle = \langle A^* \mathbf{x} | \mathbf{y} \rangle$ for any vectors $\mathbf{x}, \mathbf{y} \in L(H_n)$.

In the matrix form, the adjoint mapping is easy to recover

$$\left(\sum_{i=1}^n \sum_{j=1}^n A_{ij} |\mathbf{e}_i\rangle \langle \mathbf{e}_j| \right)^* = \sum_{i=1}^n \sum_{j=1}^n A_{ji}^* |\mathbf{e}_i\rangle \langle \mathbf{e}_j|$$

which means that the matrix of an adjoint mapping is obtained by transposing and conjugating the original matrix. It is an easy exercise to verify that taking the adjoint mapping is a linear mapping $L(H_n) \rightarrow L(H_n)$, that is, an element of $L(L(H_n))$. This means that $(A+B)^* = A^* + B^*$, and $(cA)^* = c^* A^*$. In addition to that, it is easy to see that $(AB)^* = B^* A^*$. Moreover, the definitions presented above imply directly that $A|\mathbf{x}\rangle \langle \mathbf{x}|B^* = |A\mathbf{x}\rangle \langle B\mathbf{y}|$, no matter which particular interpretation (matrices of mappings) the mentioned objects possess.

Definition 5 Mapping $A \in L(H_n)$ is self-adjoint, if $A^* = A$.

The following analogy may be useful sometimes: Self-adjoint mappings relate to $L(H_n)$ as real numbers relate to complex numbers. To be more precise, we have the following representation theorem.

Theorem 2 For any $A \in L(H_n)$, there are unique self-adjoint mappings B and C so that

$$A = B + iC.$$

Proof If such a presentation exists, then $A^* = B - iC$, and addition gives $B = \frac{1}{2}(A + A^*)$, whereas subtraction shows $C = \frac{1}{2i}(A - A^*)$. This proves the existence and uniqueness of self-adjoint mappings B and C .

A polar representation analogous to $z = |z| e^{i\theta}$ also exists, but will be represented later. At this moment, it is worth mentioning that the analogy between real numbers and self-adjoint mappings becomes more concrete in the following proposition.

Proposition 1 All eigenvalues of a self-adjoint mapping $A \in L(H_n)$ are real.

Proof Let λ be an eigenvalue of A and \mathbf{x} an eigenvector belonging to λ . Then

$$\lambda \langle \mathbf{x} | \mathbf{x} \rangle = \langle \mathbf{x} | \lambda \mathbf{x} \rangle = \langle \mathbf{x} | A \mathbf{x} \rangle = \langle A^* \mathbf{x} | \mathbf{x} \rangle = \langle A \mathbf{x} | \mathbf{x} \rangle = \langle \lambda \mathbf{x} | \mathbf{x} \rangle = \lambda^* \langle \mathbf{x} | \mathbf{x} \rangle$$

which implies $\lambda = \lambda^*$.

Definition 6 A mapping $A \in L(H_n)$ is positive, if $\langle \mathbf{x} | A \mathbf{x} \rangle \geq 0$ for each $\mathbf{x} \in L(H_n)$.

In the terminology more familiar to mathematicians, “positive” is replaced with “positive semidefinite.” It is easy to see that the converse to the above theorem also holds: if $\langle \mathbf{x} | A \mathbf{x} \rangle \in \mathbb{R}$

for each $\mathbf{x} \in H_n$, then A is necessarily self-adjoint. Hence Definition 6 necessarily speaks only about self-adjoint mappings. The previously mentioned analogy has its extension here: Positive mappings relate to self-adjoint mappings as the nonnegative real numbers relate to all real numbers, since it is easy to see that a mapping is positive if and only if all of its eigenvalues are nonnegative.

One more definition is needed before introducing the quantum mechanical counterpart of the state vector (\mathbf{x}, \mathbf{p}) of classical mechanics.

Definition 7 For any mapping $A \in L(H_n)$, the *trace* is defined as

$$\text{Tr}(A) = \sum_{i=1}^n \langle \mathbf{e}_i | A \mathbf{e}_i \rangle$$

where $\{\mathbf{e}_1, \dots, \mathbf{e}_n\}$ is an orthonormal basis of H_n .

It is possible to show that the trace is independent of the orthonormal basis chosen, and by the definition the trace equals the sum of the diagonal elements of the matrix. The trace also equals the sum of the eigenvalues (see Axler (1997), for example).

Definition 8 A *state* of an n -level quantum system is a self-adjoint, unit-trace, positive mapping $A \in L(H_n)$. A *density matrix* is a matrix representation of a state.

Recall that in classical mechanics one can represent the state of a physical system as $(\mathbf{x}, \mathbf{p}) \in \mathbb{R}^{2n}$, where \mathbf{x} stands for the (generalized) coordinates and \mathbf{p} for the (generalized) momentum. In quantum mechanics, a state is represented as linear mapping $A \in L(H_n)$ satisfying the conditions of Definition 8.

However, it should be noted carefully that n in the description of classical mechanics has a very different role than n in quantum mechanics. Recall that in classical descriptions n (the number of coordinates of \mathbf{x} and \mathbf{p}) stands for the degrees of freedom of the system under investigation, and in quantum mechanics n , the dimension of H_n , stands for the maximal number of perfectly distinguishable measurement results that can be extracted from the system, for a suitably chosen measurement. The Hilbert space H_n can stand for a *single* degree of freedom: It accommodates the mathematical structure describing how the value of anything observable on this specific degree of freedom is produced.

To describe *various* degrees of freedom in quantum mechanics, one should set up a Hilbert space individually for any such degree. The total description is then in the Hilbert space obtained as a *tensor product* of all “component spaces.” It should be noted that usually observables with an infinite number of potential values (and consequently infinite-dimensional Hilbert spaces) are needed, but in the context of quantum computing physical objects with a finite number of potential values are satisfactory: to describe a *bit*, one needs only a physical system capable of existing in two perfectly distinguishable states.

In the classical description (\mathbf{x}, \mathbf{p}) the value of any observable can be calculated directly from the coordinates of \mathbf{x} and \mathbf{p} . In quantum mechanics, the setup is dramatically different: quantum mechanics is a fundamentally stochastic theory, and for any state of the system there are always observables with values not definitely prescribed, but obtained stochastically. Conversely, for any observable, there are even *pure states* (introduced later) of the system for which the measurement result is not determined uniquely.

A very important structural property of the state set is given in the following proposition, whose proof is actually straightforward from the definitions.

Proposition 2 All states of an n -level quantum system form a convex set, meaning that if S_1 and S_2 are states then their convex combination

$$pS_1 + (1 - p)S_2$$

with $p \in [0,1]$ also is a state.

The above proposition actually expresses the principle that it is possible to obtain new states from previous ones as a *stochastic mixture*: the new state $pS_1 + (1 - p)S_2$ can be seen as a description of the stochastic process, where S_1 occurs with probability p , and S_2 with a complementary probability $1 - p$.

The *extreme points* of the state set deserve special attention.

Definition 9 State S is *pure* if it cannot be presented as a convex combination $S = pS_1 + (1 - p)S_2$, where $S_1 \neq S_2$. A state that is not pure is *mixed*.

There exists a well-known and simple mathematical characterization for pure quantum states, but to introduce that we need to define one more notion.

Definition 10 Mapping $A \in L(H_n)$ is an (*orthogonal*) *projection* if $A^* = A$ and $A^2 = A$.

Hereafter, the attribute “orthogonal” will be ignored as all projections treated in this chapter will be indeed orthogonal. It can be shown that there is one-to-one correspondence between projections and subspaces of H_n . This connection can be briefly explained as follows: for any subspace $W \subseteq H_n$ there exists an *orthogonal complement* W^\perp , also a subspace of H_n , which has the property that any $\mathbf{x} \in W$ and any $\mathbf{y} \in W^\perp$ are orthogonal: $\langle \mathbf{x} | \mathbf{y} \rangle = 0$. Moreover, H_n can be represented as a *direct sum* of the subspaces, $H_n = W \oplus W^\perp$, which means that each $\mathbf{x} \in H_n$ can be uniquely represented as $\mathbf{x} = \mathbf{x}_W + \mathbf{x}_{W^\perp}$, where $\mathbf{x}_W \in W$ and $\mathbf{x}_{W^\perp} \in W^\perp$. Now if A is a projection, then there exists a unique subspace W so that $A\mathbf{x} = \mathbf{x}_W$. Conversely, for any subspace $W \subseteq H_n$ there exists a unique projection A so that $A\mathbf{x} = \mathbf{x}_W$.

We conclude this section with the well-known characterization of pure states.

Proposition 3 A state $A \in L(H_n)$ of a quantum system is pure if $A = |\mathbf{x}\rangle\langle \mathbf{x}|$ is a projection onto a one-dimensional subspace (here $\|\mathbf{x}\| = 1$).

3 Spectral Representation

Spectral representation, also known as *spectral decomposition*, is a very powerful tool of matrix theory. It also provides a representation for an arbitrary quantum state as a convex combination of pure states, as will be shortly seen.

Definition 11 A matrix A is *normal* if it commutes with its adjoint, that is $AA^* = A^*A$.

Especially, self-adjoint mappings are normal, since then $AA^* = A^2 = A^*A$. Normal matrices have the property that they can be diagonalized unitarily, meaning that there exists a possibility to rotate the natural basis of H_n so that the matrix in the new basis is diagonal. Indeed, we understand “rotate” here a bit more generally, meaning that for any normal

matrix A , there is a unitary matrix U (defined later in [Section 7.1.1](#)) so that UAU^* is diagonal. This can also be expressed in the following theorem.

Theorem 3 (Spectral representation) *Let $A \in L(H_n)$ be normal. Then there exists an orthonormal basis $\{\mathbf{x}_1, \dots, \mathbf{x}_n\}$ of H_n so that*

$$A = \lambda_1 |\mathbf{x}_1\rangle\langle\mathbf{x}_1| + \dots + \lambda_n |\mathbf{x}_n\rangle\langle\mathbf{x}_n| \quad (6)$$

It is noteworthy that in the spectral representation numbers λ_i are the eigenvalues of A and \mathbf{x}_i is an eigenvector belonging to λ_i (the set of the eigenvalues is also called the *spectrum* of the matrix or a mapping). Equation [\(6\)](#) hence simply means that the spectral representation corresponds to choosing an orthonormal basis $\mathbf{x}_1, \dots, \mathbf{x}_n$ in which the matrix A is diagonal. The above theorem just states that for normal matrices (or mappings as well), there always exists an orthonormal basis allowing a diagonal presentation. The proof of the spectral representation theorem for *self-adjoint* mappings can be found in Axler ([1997](#)), for instance, and its extension to normal mappings is quite an easy exercise when we know that all mappings can be represented as $C = A + iB$, where A and B are self-adjoint.

Definition 12 Let $f : \mathbb{C} \rightarrow \mathbb{C}$ be an arbitrary function. Then f is defined on normal mappings by

$$f(A) = f(\lambda_1) |\mathbf{x}_1\rangle\langle\mathbf{x}_1| + \dots + f(\lambda_n) |\mathbf{x}_n\rangle\langle\mathbf{x}_n| \quad (7)$$

if A has spectral representation [\(6\)](#).

It is an easy exercise to show that the above definition is independent of the choice of the spectral representation.

Example 1 Matrix $\begin{pmatrix} \frac{\pi}{2} & 0 \\ 0 & -\frac{\pi}{2} \end{pmatrix}$ defines a normal mapping. By fixing the basis of H_2 as $|0\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$ and $|1\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix}$ we can represent this mapping as $A = \frac{\pi}{2} \cdot |0\rangle\langle 0| - \frac{\pi}{2} \cdot |1\rangle\langle 1|$. Now

$$e^{iA} = e^{i\frac{\pi}{2}}|0\rangle\langle 0| + e^{i(-\frac{\pi}{2})}|1\rangle\langle 1| = i|0\rangle\langle 0| - i|1\rangle\langle 1|$$

which can be represented as a matrix $\begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix}$ as well.

As the states of quantum systems are depicted by self-adjoint, positive, unit-trace operators, we will be interested especially in their representations. Since self-adjoint mappings are normal, they admit a spectral representation. Moreover, it should be noted that the eigenvalues λ of self-adjoint operators in presentation [\(6\)](#) are real.

The positivity $\langle \mathbf{x} | Ax \rangle \geq 0$ always implies that for each i , $\lambda_i \geq 0$. As representation [\(6\)](#) corresponds to a diagonal matrix, it is also easy to verify that $\text{Tr}(A) = \lambda_1 + \dots + \lambda_n$. We can conclude this as follows:

- ▶ A state A of an n -level quantum system can be represented as

$$A = \lambda_1 |\mathbf{x}_1\rangle\langle\mathbf{x}_1| + \dots + \lambda_n |\mathbf{x}_n\rangle\langle\mathbf{x}_n| \quad (8)$$

where $\lambda_i \geq 0$, and $\lambda_1 + \dots + \lambda_n = 1$. This is to say that each state $A \in L(H_n)$ can be represented as a convex combination of at most n pure states, and, moreover, the pure states can be found by searching the eigenvectors of A .

Representation (2.8) may recommend that we interpret a general quantum state A as a probability distribution over pure states $|\mathbf{x}_1\rangle\langle\mathbf{x}_1|, \dots, |\mathbf{x}_n\rangle\langle\mathbf{x}_n|$. Unfortunately, representation (2.8) is not always unique.

Example 2 Let $|0'\rangle = \frac{1}{\sqrt{2}}|0\rangle + \frac{1}{\sqrt{2}}|1\rangle$ and $|1'\rangle = \frac{1}{\sqrt{2}}|0\rangle - \frac{1}{\sqrt{2}}|1\rangle$. Then

$$\begin{aligned} |0'\rangle\langle 0'| + |1'\rangle\langle 1'| &= \left| \frac{1}{\sqrt{2}}|0\rangle + \frac{1}{\sqrt{2}}|1\rangle \right\rangle \left\langle \frac{1}{\sqrt{2}}|0\rangle + \frac{1}{\sqrt{2}}|1\rangle \right| \\ &\quad + \left| \frac{1}{\sqrt{2}}|0\rangle - \frac{1}{\sqrt{2}}|1\rangle \right\rangle \left\langle \frac{1}{\sqrt{2}}|0\rangle - \frac{1}{\sqrt{2}}|1\rangle \right| \\ &= \frac{1}{2}|0\rangle\langle 0| + \frac{1}{2}|0\rangle\langle 1| + \frac{1}{2}|1\rangle\langle 0| + \frac{1}{2}|1\rangle\langle 1| \\ &\quad + \frac{1}{2}|0\rangle\langle 0| - \frac{1}{2}|0\rangle\langle 1| - \frac{1}{2}|1\rangle\langle 0| + \frac{1}{2}|1\rangle\langle 1| \\ &= |0\rangle\langle 0| + |1\rangle\langle 1| \end{aligned}$$

Let $\|\mathbf{x}\| = 1$. A simple calculation shows that $|\mathbf{ax}\rangle\langle\mathbf{ax}| = |a|^2|\mathbf{x}\rangle\langle\mathbf{x}|$, which implies that vectors \mathbf{x} and $e^{i\theta}\mathbf{x}$ (with $\theta \in \mathbb{R}$) specify exactly the same projection onto a one-dimensional vector space. Recall that those projections are special cases of quantum states (pure states), and they play an important role in quantum computing and in general quantum theory: most quantum computing models are based on pure states only. Quantum information processing in general will of course require more than pure states.

A pure state $A = |\mathbf{x}\rangle\langle\mathbf{x}|$ is often identified with a unit-length *state vector* or *vector state* \mathbf{x} , but it should be noted that this identification is not unambiguous: Vectors $e^{i\theta}\mathbf{x}$ with $\theta \in \mathbb{R}$ are all vector representations of the same pure state.

A notion constantly present in quantum physics (as well as in classical wave theory) is that of *superposition*.

Definition 13 Let $\{\mathbf{x}_1, \dots, \mathbf{x}_n\}$ be an orthonormal basis of H_n and

$$\mathbf{x} = \alpha_1\mathbf{x}_1 + \dots + \alpha_n\mathbf{x}_n$$

a unit-length vector describing a pure state. We say then that \mathbf{x} is a *superposition* of vector states $\mathbf{x}_1, \dots, \mathbf{x}_n$ with *amplitudes* $\alpha_1, \dots, \alpha_n$.

In classical mechanics, one can always introduce a mixed state when two pure states T_1 and T_2 are given: The new mixed state is a statistical combination $pT_1 + (1-p)T_2$ of the pure ones, meaning that T_1 is present with probability p , and T_2 with the complementary probability $1-p$.

In quantum mechanics, one can also create mixtures from the pure state analogously to the classical case, but a very important nonclassical feature is that from given pure states one can form another pure state by superposition: If \mathbf{x}_1 and \mathbf{x}_2 are perpendicular unit-length vectors representing pure states $|\mathbf{x}_1\rangle\langle\mathbf{x}_1|$ and $|\mathbf{x}_2\rangle\langle\mathbf{x}_2|$, then their linear combination $\alpha_1\mathbf{x}_1 + \alpha_2\mathbf{x}_2$ (where $|\alpha_1|^2 + |\alpha_2|^2 = 1$) is again a pure (vector) state, the superposition of vector states \mathbf{x}_1 and \mathbf{x}_2 .

A simple calculation shows that

$$\begin{aligned} &|\alpha_1\mathbf{x}_1 + \alpha_2\mathbf{x}_2\rangle\langle\alpha_1\mathbf{x}_1 + \alpha_2\mathbf{x}_2| \\ &= |\alpha_1|^2|\mathbf{x}_1\rangle\langle\mathbf{x}_1| + \alpha_1\alpha_2^*|\mathbf{x}_1\rangle\langle\mathbf{x}_2| + \alpha_2\alpha_1^*|\mathbf{x}_2\rangle\langle\mathbf{x}_1| + |\alpha_2|^2|\mathbf{x}_2\rangle\langle\mathbf{x}_2| \end{aligned}$$

Term $\alpha_1\alpha_2^*|\mathbf{x}_1\rangle\langle\mathbf{x}_2| + \alpha_2\alpha_1^*|\mathbf{x}_2\rangle\langle\mathbf{x}_1|$ in the above superposition is called then an *interference term*, whereas the remaining term

$$|\alpha_1|^2|\mathbf{x}_1\rangle\langle\mathbf{x}_1| + |\alpha_2|^2|\mathbf{x}_2\rangle\langle\mathbf{x}_2|$$

is indeed a statistical mixture of the original states $|\mathbf{x}_1\rangle\langle\mathbf{x}_1|$ and $|\mathbf{x}_2\rangle\langle\mathbf{x}_2|$.

To create a superposition state, unfortunately the vector representatives of pure states $|\mathbf{x}_1\rangle\langle\mathbf{x}_1|$ and $|\mathbf{x}_2\rangle\langle\mathbf{x}_2|$ are needed. Recall that for example \mathbf{x}_2 and $-\mathbf{x}_2$ both define the same pure state, meaning that $|\mathbf{x}_2\rangle\langle\mathbf{x}_2| = |-\mathbf{x}_2\rangle\langle-\mathbf{x}_2|$, but nevertheless the state vectors $\frac{1}{\sqrt{2}}\mathbf{x}_1 + \frac{1}{\sqrt{2}}\mathbf{x}_2$ and $\frac{1}{\sqrt{2}}\mathbf{x}_1 - \frac{1}{\sqrt{2}}\mathbf{x}_2$ obtained from the different representations for $|\mathbf{x}_2\rangle\langle\mathbf{x}_2|$ are completely different objects.

4 The Meaning of the Quantum States

Quantum physics is structurally a stochastic theory. The stochastic nature comes into the picture when observing a quantum system in a fixed state; there is not usually a single outcome, but only a probability distribution of potential outcomes. By saying that the stochastic nature is structurally built in quantum theory, we mean that the outcome distribution instead of a single outcome does not emerge from the ignorance: even the most accurate knowledge of the system does not admit more than a distribution of the outcomes. The pure states correspond, in a sense, to maximal information about the quantum system, but even in a pure state one must accept a probability distribution of the potential outcomes.

In this section, the *minimal interpretation* of quantum mechanics will be presented, which actually is an axiom describing how the probabilities will be calculated from the mathematical objects describing quantum systems. For that purpose, we need to describe how *observables* are specified in this formalism. This is of course similar to classical physics: For instance, pair (\mathbf{x}, \mathbf{p}) describes the state of a classical system, but the value of the position is revealed from the state by projection $(\mathbf{x}, \mathbf{p}) \mapsto \mathbf{x}$.

Definition 14 An *observable* of a quantum system H_n is a collection P_1, \dots, P_k of projections onto mutually orthogonal subspaces so that $P_1 + \dots + P_k = I$ (the identity mapping), equipped with a collection of real numbers $\lambda_1, \dots, \lambda_k$.

Another equivalent viewpoint is offered in the following definition.

Definition 15 An *observable* of a quantum system H_n is a self-adjoint mapping $A \in L(H_n)$.

It is not difficult to see that the above two definitions speak about the same object. Indeed, if A is a self-adjoint mapping, then it admits a spectral representation

$$A = \sum_{k=1}^n \lambda_k |\mathbf{x}_k\rangle\langle\mathbf{x}_k|$$

which can also be written in the form

$$A = \sum_{k=1}^{n'} \lambda'_k P_k$$

where $\lambda'_1, \dots, \lambda'_{n'}$ are the distinct eigenvalues of A , and

$$P_k = \sum_{l=1}^{d_l} |\mathbf{x}_{k_l}\rangle\langle\mathbf{x}_{k_l}|$$

is the projection onto the eigenspace V_k of λ'_k . As eigenspaces belonging to distinct eigenvalues of a self-adjoint operator A are orthogonal (Axler 1997), the projections satisfy the orthogonality required in the first definition.

On the other hand, a collection P_1, \dots, P_k of projections of H_n onto orthonormal subspaces of H_n together with real numbers $\lambda_1, \dots, \lambda_k$ evidently define a self-adjoint mapping

$$A = \lambda_1 P_1 + \dots + \lambda_k P_k$$

If $P_1 + \dots + P_k \neq I$, then another projection $P_{k+1} = I - (P_1 + \dots + P_k)$ with $\lambda_{k+1} = 0$ is introduced to satisfy the requirement $P_1 + \dots + P_{k+1} = I$.

Remark 1 The notion of “a collection of projections equipped with real numbers” can be expressed by using the notion of *projection-valued measure*. A projection-valued measure on the real line is a mapping $E : \mathbb{R} \rightarrow L(H_n)$ which, in the case of Definition 14, satisfies $E(\lambda_i) = P_i$ and $E(\lambda) = 0$ for $\lambda \notin \{\lambda_1, \dots, \lambda_k\}$. In general, a projection-valued measure must satisfy conditions similar to an ordinary measure on a real line (see Hirvensalo (2004), for instance).

Whichever definition is used for an observable, the intuitive meaning will be that the values $\lambda_1, \dots, \lambda_k$ are the *potential* values of observable A , and probability distributions of the values are expressed in the following definition.

Definition 16 (Minimal interpretation of quantum mechanics)

Let $T \in L(H_n)$ be a state of a quantum system and $A = \lambda_1 P_1 + \dots + \lambda_k P_k$ be an observable, where P_i are mutually orthogonal projections summing up to the identity mapping. Then the probability that λ_i will be observed when the system is in state T is

$$\mathbb{P}_T(\lambda_i) = \text{Tr}(P_i T)$$

The minimal interpretation has its mathematical basis in Gleason’s theorem (Gleason 1957), which shows that for dimension $n \geq 3$ all probability measures in $L(H_n)$ are of the above form.

Example 3 The presentation of an observable as a self-adjoint mapping A is useful when talking about the *expected value* of the observable. Indeed, the expectation (in state T) is given by

$$\mathbb{E}_T(A) = \sum_{i=1}^k \mathbb{P}_T(\lambda_i) \lambda_i = \sum_{i=1}^k \lambda_i \text{Tr}(P_i T) = \text{Tr}(AT)$$

$$\text{since } A = \sum_{i=1}^k \lambda_i P_i.$$

The mathematical formalism presented so far implies rather easily quite deep consequences. One such is the famous *Heisenberg uncertainty relation* (see Hirvensalo (2004) for the proof of the next proposition).

Proposition 4 (Uncertainty relation) Let A and B be any observables. Then the product of variances $\mathbb{V}_T(A)$ and $\mathbb{V}_T(B)$ in a pure state $T = |\mathbf{x}\rangle\langle \mathbf{x}|$ can be bounded below as

$$\mathbb{V}_T(A)\mathbb{V}_T(B) \geq \frac{1}{4}|\langle \mathbf{x}|[A, B]\mathbf{x}\rangle|^2$$

where $[A, B] = AB - BA$ is the commutator of A and B .

The above uncertainty relation, however, has its greatest importance in infinite-dimensional vector spaces: in such cases it is possible that $[A, B] = cI$, a multiple of the identity mapping, and then the lower bound would be state-independent. A traditional example is the commutator of the position and momentum $[X, P] = i\hbar I$.

Let $\mathbf{x} \in H_n$ be a unit-length vector and $T = |\mathbf{x}\rangle\langle \mathbf{x}|$ a pure state determined by \mathbf{x} . Fix also an observable $A = \lambda_1 |\mathbf{x}_1\rangle\langle \mathbf{x}_1| + \dots + \lambda_n |\mathbf{x}_n\rangle\langle \mathbf{x}_n|$ with n distinct eigenvalues (potential values of observable A). As $\{\mathbf{x}_1, \dots, \mathbf{x}_n\}$ is an orthonormal basis of H_n , we can always write

$$\mathbf{x} = \alpha_1 \mathbf{x}_1 + \dots + \alpha_n \mathbf{x}_n$$

and the probability to observe λ_i is given by

$$P(\lambda_i) = \text{Tr}(|\mathbf{x}_i\rangle\langle \mathbf{x}_i||\mathbf{x}\rangle\langle \mathbf{x}|) = |\alpha_i|^2$$

as easily verified. To express this in other words: assume that a quantum system is in a vector state

$$\mathbf{x} = \alpha_1 \mathbf{x}_1 + \dots + \alpha_n \mathbf{x}_n$$

and the observable studied is

$$A = \lambda_1 |\mathbf{x}_1\rangle\langle \mathbf{x}_1| + \dots + \lambda_n |\mathbf{x}_n\rangle\langle \mathbf{x}_n|$$

(distinct eigenvalues λ_i). Then the probability that value λ_i is observed is $|\alpha_i|^2$. For such an observable, it is also typical to omit also the *value* of the observable and merely to refer to the vector \mathbf{x}_i (intuitively one could think about observing \mathbf{x}_i instead of value λ_i) generating a one-dimensional subspace of H_n . The following version of the minimal interpretation is written for pure states, the aforementioned special type of observables, and for ignoring the (eigen)values of the observables.

Definition 17 (Minimal interpretation, special version) Let

$$\mathbf{x} = \alpha_1 \mathbf{x}_1 + \dots + \alpha_n \mathbf{x}_n$$

be a vector representation of a pure quantum state. Then the probability of observing \mathbf{x}_i is $|\alpha_i|^2$.

5 Quantum Bits

When speaking about computation, bits are a most interesting object. Therefore it is worth devoting a section to their quantum physical representations, *quantum bits* or *qubits* for short.

A physical system capable of representing a bit must have two distinguishable states, but there are no further restrictions on the nature of the system. The mathematical description of the system therefore lives in H_2 , two-dimensional Hilbert space.

Definition 18 A *computational basis* of H_2 refers to a fixed orthonormal basis $\{|0\rangle, |1\rangle\}$ of H_2 .

The above definition refers rather to a physical nature and interpretation of the quantum system than to any mathematical properties of H_2 . Indeed, in a physical realization there may be some preferred states that are more natural to interpret as 0 and 1 than any other states. For instance, if representing quantum bits with electron energy states, one may want to associate logical zero with the ground state, and logical one with an excited state.

Mathematically, it is always possible to construct H_2 as the Cartesian product $\mathbb{C} \times \mathbb{C}$ and choose $|0\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$ and $|1\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix}$. Of course, any other choice for the computational basis is equally good, and hence the notion “computational basis” should be understood only contextually. However, in this chapter the aforementioned choice is used for the computational basis.

A *state* of the qubit is, according to the previous definition, a self-adjoint, positive, unit-trace mapping in $L(H_2)$. When thinking about the matrix representation

$$S = \begin{pmatrix} a & b \\ c & d \end{pmatrix} = a|0\rangle\langle 0| + b|0\rangle\langle 1| + c|1\rangle\langle 0| + d|1\rangle\langle 1|$$

one sees that the self-adjointness immediately imposes restrictions such as $a, d \in \mathbb{R}$, and that $c = b^*$. Furthermore, from the unit trace condition we see that $a + d = 1$, so a general form of a self-adjoint mapping with unit trace must be of the form

$$S = \begin{pmatrix} a & b \\ b^* & 1-a \end{pmatrix}$$

where $a \in \mathbb{R}$. Hence there are three real numbers (a and the real and imaginary parts of b) that specify a unit-trace self-adjoint mapping. The positivity obviously imposes extra conditions, and for finding them we choose a slightly different approach.

Definition 19 The *Pauli spin matrices* are defined as follows:

$$\sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \sigma_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$$

Yet adding the identity matrix $I = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$ we get an interesting set: it is easy to prove that $\{I, \sigma_x, \sigma_y, \sigma_z\}$ is a basis of $L(H_2)$, when regarding $L(H_2)$ as a vector space over \mathbb{C} . Especially this means that any 2×2 complex matrix S can be uniquely represented as

$$S = wI + x\sigma_x + y\sigma_y + z\sigma_z \quad (9)$$

where w, x, y , and $z \in \mathbb{C}$. Furthermore, all matrices in $\{I, \sigma_x, \sigma_y, \sigma_z\}$ are self-adjoint, which implies that

$$S^* = w^*I + x^*\sigma_x + y^*\sigma_y + z^*\sigma_z$$

Now because the representation is unique, we conclude that if S is self-adjoint, then necessarily coefficients w, x, y , and z in [Eq. 9](#) are real. A further observation shows that σ_x, σ_y , and σ_z have zero trace, meaning that the trace of [Eq. 9](#) is $\text{Tr}(wI) = 2w$. This shows that a unit-trace, self-adjoint mapping in $L(H_2)$ has a unique representation

$$S = \frac{1}{2}(I + x\sigma_x + y\sigma_y + z\sigma_z) \quad (10)$$

where x, y , and $z \in \mathbb{R}$. This is perfectly compatible with the aforementioned fact that unit-trace self-adjoint mappings in $L(H_2)$ have three real degrees of freedom: via representation (Eq. 10) we can identify such a mapping with a point in \mathbb{R}^3 , but the restrictions imposed by the positivity condition are still to be discovered.

For that, we notice first that the spectral representation directly implies that a matrix is positive if and only if its eigenvalues are nonnegative. To discover the characteristic polynomial of (Eq. 10), we write explicitly

$$S = \frac{1}{2}(I + x\sigma_x + y\sigma_y + z\sigma_z) = \frac{1}{2} \begin{pmatrix} 1+z & x-iy \\ x+iy & 1-z \end{pmatrix}$$

and find the roots of the characteristic polynomial

$$\lambda = \frac{1}{2} \left(1 \pm \sqrt{x^2 + y^2 + z^2} \right) \quad (11)$$

Both roots are nonnegative if and only if $x^2 + y^2 + z^2 \leq 1$, and hence we see that there is one-to-one correspondence between the points of the unit sphere in \mathbb{R}^3 and pure states of a qubit.

Definition 20 The *Bloch sphere* (also known as the *Poincaré sphere*) is the image of the sphere

$$\{(x, y, z) \mid x^2 + y^2 + z^2 \leq 1\} \subseteq \mathbb{R}^3$$

in $L(H_2)$ under mapping

$$(x, y, z) \mapsto \frac{1}{2}(I + x\sigma_x + y\sigma_y + z\sigma_z) \quad (12)$$

Even more information is easily available: A pure state $|\mathbf{x}\rangle\langle\mathbf{x}|$ is a projection onto a one-dimensional subspace, and the sole eigenvalues of such a mapping are hence 1 and 0. By (Eq. 11) this is possible only if $x^2 + y^2 + z^2 = 1$. This fact, which would as well follow from the convexity-preserving nature of mapping (Eq. 12), shows that the *pure states of a quantum bit lie exactly on the surface of the Bloch sphere*. By using the standard spherical coordinate representation, we can say that the pure states of a quantum bit have two real degrees of freedom; indeed the use of spherical coordinates result in a vector state $\cos\theta|0\rangle + e^{i\phi}\sin\theta|1\rangle$.

Example 4 Pure state $|0\rangle$ corresponds to the projection $|0\rangle\langle 0|$, whose matrix representation is

$$(1, 0) \otimes \begin{pmatrix} 1 \\ 0 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} = \frac{1}{2}(I + \sigma_z) = \frac{1}{2}(I + 0 \cdot \sigma_x + 0 \cdot \sigma_y + 1 \cdot \sigma_z)$$

so the Bloch sphere point $(0, 0, 1)$ corresponds to the pure state $|0\rangle$. This point is referred to as the *north pole* of the Bloch sphere. Analogously one can see that the *south pole* of the Bloch sphere corresponds to the pure state $|1\rangle$.

Let us find the point corresponding to the pure state $\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$. The density matrix of this state is

$$\left(\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}\right) \otimes \begin{pmatrix} \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} \end{pmatrix} = \frac{1}{2} \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} = \frac{1}{2}(I + \sigma_x) = \frac{1}{2}(I + 1 \cdot \sigma_x + 0 \cdot \sigma_y + 0 \cdot \sigma_z)$$

so the point $(1, 0, 0)$ corresponding to this state is found on the equator of the Bloch sphere.

For finding the point corresponding to $\frac{1}{2}|0\rangle\langle 0| + \frac{1}{2}|1\rangle\langle 1|$, we first find the matrix

$$\frac{1}{2}\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} + \frac{1}{2}\begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} \frac{1}{2} & 0 \\ 0 & \frac{1}{2} \end{pmatrix} = \frac{1}{2}I + 0 \cdot \sigma_x + 0 \cdot \sigma_y + 0 \cdot \sigma_z$$

which means that the center $(0,0,0)$ corresponds to the mixed state $\frac{1}{2}|0\rangle\langle 0| + \frac{1}{2}|1\rangle\langle 1|$.

What is then, for example, the pure state corresponding to the equator point $(0,1,0)$? This is easily found, as

$$\frac{1}{2}(I + 0 \cdot \sigma_x + 1 \cdot \sigma_y + 0 \cdot \sigma_z) = \frac{1}{2}\begin{pmatrix} 1 & -i \\ i & 1 \end{pmatrix}$$

This matrix is self-adjoint, so it admits a spectral representation, which can be found by finding its eigenvectors: Vector $\frac{1}{\sqrt{2}}\begin{pmatrix} i \\ 1 \end{pmatrix}$ belongs to the eigenvalue 0, and $\frac{1}{\sqrt{2}}\begin{pmatrix} -i \\ 1 \end{pmatrix}$ to eigenvalue 1. Hence (note that the factor $\frac{1}{2}$ is omitted now)

$$\begin{aligned} \begin{pmatrix} 1 & -i \\ i & 1 \end{pmatrix} &= 0 \cdot \begin{pmatrix} i \\ 1 \end{pmatrix}^* \otimes \begin{pmatrix} i \\ 1 \end{pmatrix} + 1 \cdot \begin{pmatrix} -i \\ 1 \end{pmatrix}^* \otimes \begin{pmatrix} -i \\ 1 \end{pmatrix} \\ &= 0 \cdot (-i, 1) \otimes \begin{pmatrix} i \\ 1 \end{pmatrix} + 1 \cdot (i, 1) \otimes \begin{pmatrix} -i \\ 1 \end{pmatrix} \end{aligned}$$

and we can see that the state vector corresponding to point $(0,1,0)$ can be chosen as $\frac{1}{\sqrt{2}}\begin{pmatrix} -i \\ 1 \end{pmatrix} = \frac{-i}{\sqrt{2}}|0\rangle + \frac{1}{\sqrt{2}}|1\rangle$.

6 Compound Systems

The notion of a *joint quantum system* or *compound quantum system* is established via tensor product construction.

Definition 21 Let \mathcal{S}_1 and \mathcal{S}_2 be quantum systems with state spaces H_n and H_m , respectively. Then the state space of the compound system \mathcal{S}_{12} is the mn -dimensional tensor product $H_n \otimes H_m$.

The tensor product is actually a very clever construction in algebra allowing us to represent bilinear mappings as linear ones preceded by a very natural bilinear embedding. However, this sophisticated algebraic definition is not needed to perform the necessary calculations. Hence we take a constructive approach and merely mention the following facts: if $\mathbf{x}_1, \dots, \mathbf{x}_n$ and $\mathbf{y}_1, \dots, \mathbf{y}_m$ are the orthonormal bases of H_n and H_m , respectively, then $\{\mathbf{x}_i \otimes \mathbf{y}_j \mid i \in \{1, \dots, n\}, j \in \{1, \dots, m\}\}$ is an orthonormal basis of $H_n \otimes H_m$ as the inner product takes the form

$$\langle \mathbf{x}_1 \otimes \mathbf{y}_1 \mid \mathbf{x}_2 \otimes \mathbf{y}_2 \rangle = \langle \mathbf{x}_1 \mid \mathbf{x}_2 \rangle \langle \mathbf{y}_1 \mid \mathbf{y}_2 \rangle$$

Any pair of linear mappings $A \in L(H_n)$, $B \in L(H_m)$ together define a linear mapping $A \otimes B \in L(H_n \otimes H_m)$ via

$$(A \otimes B)(\mathbf{x}_i \otimes \mathbf{y}_j) = A\mathbf{x}_i \otimes B\mathbf{y}_j$$

for basis vectors $\mathbf{x}_i \otimes \mathbf{y}_j$, and the extension to the whole space is straightforwardly done by linearity. It should already here be carefully noted that as there are vectors other than $\mathbf{x} \otimes \mathbf{y} \in H_n \otimes H_m$ (so-called *decomposable vectors*), there are also linear mappings other than those of the form $A \otimes B$ in $L(H_n \otimes H_m)$. In the next section, this very evident fact will be examined again, but another identity very useful for the continuation follows easily from the previous ones:

$$\mathrm{Tr}(A \otimes B) = \mathrm{Tr}(A)\mathrm{Tr}(B)$$

It must of course be mentioned here that in the field of quantum computing the tensor sign is very generally omitted. For example, let $\{|0\rangle, |1\rangle\}$ be an orthonormal basis of H_2 . Then the orthonormal basis of $H_4 \simeq H_2 \otimes H_2$ can be constructed as $\{|0\rangle \otimes |0\rangle, |0\rangle \otimes |1\rangle, |1\rangle \otimes |0\rangle, |1\rangle \otimes |1\rangle\}$, but the abbreviations $\{|0\rangle|0\rangle, |0\rangle|1\rangle, |1\rangle|0\rangle, |1\rangle|1\rangle\}$ and $\{|00\rangle, |01\rangle, |10\rangle, |11\rangle\}$ are very frequent.

Example 5 Using the notations $|0\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$ and $|1\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix}$ one can get concrete representations for the aforementioned vectors:

$$|00\rangle = |0\rangle \otimes |0\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \otimes \begin{pmatrix} 1 \\ 0 \end{pmatrix} = \begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \end{pmatrix}, \quad |01\rangle = |0\rangle \otimes |1\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \otimes \begin{pmatrix} 0 \\ 1 \end{pmatrix} = \begin{pmatrix} 0 \\ 1 \\ 0 \\ 0 \end{pmatrix},$$

$$|10\rangle = |1\rangle \otimes |0\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix} \otimes \begin{pmatrix} 1 \\ 0 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \end{pmatrix}, \quad |11\rangle = |1\rangle \otimes |1\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix} \otimes \begin{pmatrix} 0 \\ 1 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}.$$

The tensor product of two vector spaces generalizes to that of three or more spaces by defining $H_n \otimes H_m \otimes H_l = H_n \otimes (H_m \otimes H_l)$, which can be shown to be isomorphic to $(H_n \otimes H_m) \otimes H_l$. Subsequently, the notations such as $|0\rangle \otimes |1\rangle \otimes |0\rangle$ are abbreviated in quantum computing as $|0\rangle|1\rangle|0\rangle$, or as $|010\rangle$.

7 Subsystem States

In order to call a system \mathcal{S}_1 a *subsystem* of a quantum system \mathcal{S} , it is necessary that \mathcal{S}_1 must be *identifiable* as a quantum system itself.

Let \mathcal{S}_1 and \mathcal{S}_2 be identifiable quantum systems, and S_1 and S_2 their states, respectively. From the previous section it is known that for example $S_1 \otimes S_2$ is an eligible state of the compound system \mathcal{S}_{12} . State $S_1 \otimes S_2$ is an example of a *decomposable state*.

Example 6 Let H_2 be equipped with an orthonormal basis $(|0\rangle, |1\rangle)$. Then the basis vectors $|0\rangle$ and $|1\rangle$ determine pure states of the system, and states other than these can be obtained for example by superposition: any vector $\alpha|0\rangle + \beta|1\rangle$ with $|\alpha|^2 + |\beta|^2 = 1$ determines a pure state as well.

In the tensor product $H_2 \otimes H_2$, states $|0\rangle \otimes |0\rangle$ (abbreviated as $|00\rangle$) and $|11\rangle$ are pure states, and so is their superposition $\frac{1}{\sqrt{2}}|00\rangle + \frac{1}{\sqrt{2}}|11\rangle$. But unlike original states $|00\rangle$ and

$|11\rangle$, (pure) state $\frac{1}{\sqrt{2}}|00\rangle + \frac{1}{\sqrt{2}}|11\rangle$ cannot be represented as a tensor product of pure states in H_2 (which can be verified easily). It even turns out that the pure state $\frac{1}{\sqrt{2}}|00\rangle + \frac{1}{\sqrt{2}}|11\rangle$ cannot be represented in the form

$$\sum_i p_i S_i \otimes T_i$$

where S_i and T_i are states of H_2 (pure or mixed) and $\sum_i p_i = 1$. Pure state

$$\frac{1}{\sqrt{2}}|00\rangle + \frac{1}{\sqrt{2}}|11\rangle$$

is hence called *entangled*.

- A state $V \in L(H_n \otimes H_m)$ is said to be *decomposable* if V can be expressed as a finite sum

$$V = \sum_i p_i S_i \otimes T_i$$

where $S_i \in L(H_n)$ and $T_i \in L(H_m)$. A state that is not decomposable is *entangled*.

The fact that the trace of a state must be 1 implies that $\sum_i p_i$ must equal to 1 in the above representation, if such a representation is possible. For pure states, the entanglement appears to be a bit simpler than for general states: in fact, a pure state $\mathbf{z} \in H_n \otimes H_m$ is decomposable if and only if \mathbf{z} is of the form $\mathbf{x} \otimes \mathbf{y}$ ($\mathbf{x} \in H_n$, $\mathbf{y} \in H_m$, and entangled otherwise).

Decomposable pure states of compound quantum systems are the easiest ones when determining the subsystem states: if $\mathbf{z} = \mathbf{x} \otimes \mathbf{y}$ is a state of a compound system, then the (pure) subsystem states are (trivially) \mathbf{x} and \mathbf{y} . On the other hand, for an entangled state it is not clear, from an algebraic viewpoint, how to fix the subsystem states, even when the compound system state is pure.

Example 7 Let $\frac{1}{\sqrt{2}}|00\rangle + \frac{1}{\sqrt{2}}|11\rangle$ be a (pure) state of $H_2 \otimes H_2$. What should the subsystem states look like? As mentioned previously, it is not possible to find pure states $\mathbf{x}, \mathbf{y} \in H_2$ to satisfy $\mathbf{x} \otimes \mathbf{y} = \frac{1}{\sqrt{2}}|00\rangle + \frac{1}{\sqrt{2}}|11\rangle$.

The way to extract the subsystem states from the compound state is based on the statistical interpretation of quantum states. To begin with, consider any observable A on the subsystem \mathcal{S}_1 . Clearly A can be extended into an observable on the whole system \mathcal{S}_{12} as $A \otimes I$, whatever the observable B of the subsystem \mathcal{S}_2 , but choice $B = I$ serves a very special purpose. Indeed, the observable I on the subsystem \mathcal{S}_2 has always value 1 in any state, which means that statistically observable $A \otimes I$ of the compound system does not differ from the observable A of the subsystem \mathcal{S}_1 . With the minimal interpretation of quantum mechanics (Definition 16), this is enough to give the firm mathematical basis for the following definition.

Definition 22 Let \mathcal{S}_1 and \mathcal{S}_2 be quantum systems with state spaces H_n and H_m , respectively. Let also $S \in L(H_n \otimes H_m)$ be the state of a compound quantum system. Then the subsystem \mathcal{S}_1 state is $S_1 \in L(H_n)$, which satisfies

$$\text{Tr}(S_1 A) = \text{Tr}(S(A \otimes I))$$

for all observables $A \in L(H_n)$. We say that the subsystem state S_1 is obtained by *tracing over H_m* and denote

$$S_1 = \text{Tr}_{H_m}(S)$$

The states of the subsystem \mathcal{S}_2 have an analogous definition and notation. The result of tracing over is also known as a *partial trace*.

For the proof of the following proposition, see Hirvensalo (2004), for instance.

Proposition 5 *State S_1 of the previous definition exists and is unique. It can be expressed as*

$$\mathrm{Tr}_{H_m}(S) = \sum_{i=1}^n \sum_{j=1}^n \sum_{k=1}^m \langle \mathbf{x}_i \otimes \mathbf{y}_k | T(\mathbf{x}_j \otimes \mathbf{y}_k) \rangle |\mathbf{x}_i\rangle\langle\mathbf{x}_j|$$

where $\{\mathbf{x}_1, \dots, \mathbf{x}_n\}$ is an orthonormal basis of H_n and $\{\mathbf{y}_1, \dots, \mathbf{y}_m\}$ an orthonormal basis of H_n .

Example 8 It follows directly from the above proposition that $\mathrm{Tr}_{H_m}(S_1 \otimes S_2) = S_1$. Another easy corollary is the linearity of tracing over: $\mathrm{Tr}_{H_m}(p_1 S + p_2 T) = p_1 \mathrm{Tr}_{H_m}(S) + p_2 \mathrm{Tr}_{H_m}(T)$, which subsequently implies that $\mathrm{Tr}_{H_m}(p_1 S_1 \otimes S_2 + p_2 T_1 \otimes S_2) = p_1 S_1 + p_2 T_1$.

By the above proposition, one can compute the subsystem states for a pure state

$$\frac{1}{\sqrt{2}} |00\rangle + \frac{1}{\sqrt{2}} |11\rangle \quad (13)$$

They both are

$$\frac{1}{2} |0\rangle\langle 0| + \frac{1}{2} |1\rangle\langle 1| = \frac{1}{2} I_2 \quad (14)$$

a mixed state. On the other hand, a reconstruction of [Eq. 13](#) from subsystem states ([Eq. 14](#)) is doomed to fail:

$$\begin{aligned} & \left(\frac{1}{2} |0\rangle\langle 0| + \frac{1}{2} |1\rangle\langle 1| \right) \otimes \left(\frac{1}{2} |0\rangle\langle 0| + \frac{1}{2} |1\rangle\langle 1| \right) \\ &= \frac{1}{4} |00\rangle\langle 00| + \frac{1}{4} |01\rangle\langle 01| + \frac{1}{4} |10\rangle\langle 10| + \frac{1}{4} |11\rangle\langle 11| = \frac{1}{4} I_4 \end{aligned}$$

which is different from the pure state determined by $\frac{1}{\sqrt{2}} |00\rangle + \frac{1}{\sqrt{2}} |11\rangle$:

$$\begin{aligned} & \left| \frac{1}{\sqrt{2}} |00\rangle + \frac{1}{\sqrt{2}} |11\rangle \right\rangle \langle \frac{1}{\sqrt{2}} |00\rangle + \frac{1}{\sqrt{2}} |11\rangle | \\ &= \frac{1}{2} |00\rangle\langle 00| + \frac{1}{2} |00\rangle\langle 11| + \frac{1}{2} |11\rangle\langle 00| + \frac{1}{2} |11\rangle\langle 11| \end{aligned}$$

The above observations can be expressed as follows: A compound quantum system \mathcal{S}_{12} always determines its subsystem states, but if states of the subsystems \mathcal{S}_1 and \mathcal{S}_2 are known, it is not possible to determine the state of the compound system uniquely without further information. A further analysis in fact shows that the case where both subsystem states are pure is the only one when the (decomposable) compound system state can be determined uniquely.

7.1 Transformations of Quantum States

Since unitary mappings play an important role in quantum systems, we will first devote a section to them.

7.1.1 Unitary Mappings

Definition 23 Mapping $U \in L(H_n)$ is *unitary* if $U^* = U^{-1}$.

Another equivalent form of the definition is as follows.

Definition 24 Mapping U is *unitary* if it preserves the inner products, meaning that $\langle U\mathbf{x} | U\mathbf{y} \rangle = \langle \mathbf{x} | \mathbf{y} \rangle$ for all $\mathbf{x}, \mathbf{y} \in H_n$.

The equivalence of the above two definitions is obvious, since

$$\langle U\mathbf{x} | U\mathbf{y} \rangle = \langle U^*U\mathbf{x} | \mathbf{y} \rangle$$

The latter form of the definition directly implies that unitary mappings also preserve the norms of the vectors: $\|U\mathbf{x}\|^2 = \langle U\mathbf{x} | U\mathbf{x} \rangle = \langle \mathbf{x} | \mathbf{x} \rangle = \|\mathbf{x}\|^2$, hence $\|U\mathbf{x}\| = \|\mathbf{x}\|$. The latter form can also be interpreted so that the unitary mappings preserve the angles between vectors; hence it is justified to say that unitary mappings are *rigid motions* or *rotations* of H_n . What is not so straightforward is that the condition $\|U\mathbf{x}\| = \|\mathbf{x}\|$ for each $\mathbf{x} \in H_n$ is also enough to guarantee the unitarity of mapping U . This follows from the so-called *polarization identity*; for the proof, see Hirvensalo (2004) for instance.

Recall from [Sect. 2](#) that the self-adjoint mappings of H_n are, in a sense, extensions of real numbers. We will shortly see that the unitary mappings relate to the unit circle of complex numbers in the same way as self-adjoint mappings relate to real numbers. The following simple proposition draws the first connection.

Proposition 6 *The eigenvalues of unitary mappings lie in the unit circle.*

Proof If $U\mathbf{x} = \lambda\mathbf{x}$, then by a direct consequence of [Definition 24](#),

$$|\lambda|\|\mathbf{x}\| = \|\lambda\mathbf{x}\| = \|U\mathbf{x}\| = \|\mathbf{x}\|$$

hence $|\lambda| = 1$.

Like self-adjoint operators, also the unitary ones are normal: $U^*U = I = UU^*$, hence unitary mappings admit a spectral representation

$$U = \lambda_1 |\mathbf{x}_1\rangle\langle\mathbf{x}_1| + \dots + \lambda_n |\mathbf{x}_n\rangle\langle\mathbf{x}_n| \quad (15)$$

and from Proposition 6 we know that each eigenvalue λ_k lies in the unit circle. Conversely, since any λ in the unit circle satisfies $\lambda^* = \lambda^{-1}$, we see that any mapping of form [Eq. 15](#) with $|\lambda_i| = 1$ is indeed unitary. Since any unit circle number λ_k can be represented as $\lambda_k = e^{i\theta_k}$, where $\theta_k \in \mathbb{R}$, we get the following proposition.

Proposition 7 *If H is a self-adjoint mapping, then e^{iH} is unitary. Conversely, for any unitary mapping $U \in L(H_n)$ there exists a self-adjoint mapping H so that $U = e^{iH}$.*

We will present another analogy between unitary mappings and unit circle complex numbers. For that purpose, the notion of the absolute value defined for the operators will be needed.

Definition 25 Let $A \in L(H_n)$. Then the *absolute value* of A is defined as

$$|A| = \sqrt{A^*A}$$

Notice that this definition makes perfect sense: As $(A^*A)^* = A^*(A^*)^* = A^*A$, operator A^*A is self-adjoint and hence normal. Moreover $\langle \mathbf{x} | A^*A\mathbf{x} \rangle = \langle A\mathbf{x} | A\mathbf{x} \rangle = \|A\mathbf{x}\|^2 \geq 0$, which means that A^*A is a positive mapping; hence its eigenvalues are nonnegative, and the square root can be defined via spectral decomposition: if

$$A^*A = \sum_{k=1}^n \lambda_k |\mathbf{x}_k\rangle\langle\mathbf{x}_k|$$

then

$$\sqrt{A^*A} = \sum_{k=1}^n \sqrt{\lambda_k} |\mathbf{x}_k\rangle\langle\mathbf{x}_k|$$

Numbers $\sqrt{\lambda_1}, \dots, \sqrt{\lambda_n}$ (the eigenvalues of $|A|$) are called the *singular values* of matrix A and are frequently denoted by symbols s_1, \dots, s_k .

The next proposition, whose proof will be omitted, establishes another analogue between unitary mappings and unit circle numbers.

Proposition 8 (Polar decomposition) *Each $A \in L(H_n)$ can be represented as $A = U|A|$, where U is a unitary mapping. However, U is unique only if A is invertible.*

In an infinite-dimensional vector space, the above proposition does not necessarily hold, but “unitary” must be replaced with “partial isometry.”

7.1.2 State Transformations

As the state of a quantum system \mathcal{S} with state space H_n corresponds to a linear mapping in $L(H_n)$, it is natural to understand a state transformation (also called *discrete time evolution*) as a mapping $V: L(H_n) \rightarrow L(H_n)$, which takes the state S_1 of system \mathcal{S} at time t_1 into the state S_2 at time t_2 : $V(S_1) = S_2$.

To discover the nature of mapping V , we can think about the obvious constraints. As the most obvious one, $S_2 = V(S_1)$ should be a quantum state if S_1 is. This means that V should at least preserve the positivity and the unit trace. Already these requirements impose some restrictions on the form of mapping V , but the heaviest constraint comes from the linearity assumption. Typically, mapping $V: L(H_n) \rightarrow L(H_n)$ is assumed to be linear, and this assumption is supported, among others, by the idea of mixing states: the statistical mixture $T = pT_1 + (1-p)T_2$ should evolve so that T_1 and T_2 are kept independent, meaning that $V(T) = pV(T_1) + (1-p)V(T_2)$. By questioning the very ontology of the mixed quantum states, one can obviously present arguments against the linearity, too, but such a discussion is not the purpose of this chapter. Instead, this presentation follows the mainstream, accepting the linearity of state transformations. Already these ideas give rise to the following definition.

Definition 26 A linear mapping $V: L(H_n) \rightarrow L(H_n)$ is *positive* if $V(A)$ is a positive mapping whenever A is.

When accepting the aforementioned conditions (positivity and preserving the unit trace, plus the linearity) on the state transformations, we could imagine that no other conditions are needed. However, this is not the case. Indeed, it is possible to imagine a compound system \mathcal{S}_{12} with quantum state transformation $V \otimes I$ that leaves the subsystem \mathcal{S}_2 virtually untouched.

Example 9 Mapping $V: L(H_n) \rightarrow L(H_n)$ defined by $V(A) = A^*$ preserves positivity: Indeed, if A is positive, then $\langle \mathbf{x} | A\mathbf{x} \rangle \geq 0$ for any \mathbf{x} . Then also $\langle \mathbf{x} | V(A)\mathbf{x} \rangle = \langle \mathbf{x} | A^*\mathbf{x} \rangle = \langle A\mathbf{x} | \mathbf{x} \rangle = \langle \mathbf{x} | A\mathbf{x} \rangle^* = \langle \mathbf{x} | A\mathbf{x} \rangle \geq 0$.

Now in the case $n = 2$ V takes the form $V(|0\rangle\langle 0|) = |0\rangle\langle 0|$, $V(|0\rangle\langle 1|) = |1\rangle\langle 0|$, $V(|1\rangle\langle 0|) = |0\rangle\langle 1|$, and $V(|1\rangle\langle 1|) = |1\rangle\langle 1|$. Mapping

$$A = |00\rangle\langle 00| + |00\rangle\langle 11| + |11\rangle\langle 00| + |11\rangle\langle 11| \in L(H_2 \otimes H_2)$$

is positive, as easily seen from the spectral representation $A = |00\rangle\langle 00| + |11\rangle\langle 11| + |01\rangle\langle 01| + |10\rangle\langle 10|$. But $V \otimes I_2$ takes $|00\rangle\langle 11| = |0\rangle\langle 1| \otimes |0\rangle\langle 1|$ into $|1\rangle\langle 0| \otimes |0\rangle\langle 1| = |10\rangle\langle 01|$ and $|11\rangle\langle 00| = |1\rangle\langle 0| \otimes |1\rangle\langle 0|$ into $|0\rangle\langle 1| \otimes |1\rangle\langle 0| = |01\rangle\langle 10|$, hence

$$(V \otimes I_2)(A) = |00\rangle\langle 00| + |10\rangle\langle 01| + |01\rangle\langle 10| + |11\rangle\langle 11|$$

but the mapping thus obtained is *not positive*, as it has -1 as an eigenvalue:

$$(V \otimes I_2)(A)(|10\rangle - |01\rangle) = |01\rangle - |10\rangle = -(|10\rangle - |01\rangle)$$

The above example shows that we should impose a heavier restriction on mapping V to be an eligible quantum state transform. This stronger condition is expressed in the definition below.

Definition 27 Linear mapping $V: L(H_n) \rightarrow L(H_n)$ is a *completely positive mapping* if $V \otimes I_k$ is a positive mapping for any k (here I_k stands for the identity mapping on k -dimensional Hilbert space).

The above definition completes the characterization of discrete quantum time evolutions (quantum state transformations).

Definition 28 The discrete time evolution operator of a quantum system with state space H_n is the completely positive, trace-preserving linear mapping $L(H_n) \rightarrow L(H_n)$.

The discrete quantum time evolution operators are also known as *superoperators*. There are two well-known characterizations for them, both of which follow from the *Stinespring dilation theorem* (Stinespring 1955). The first characterization is known as the *Kraus representation*.

Theorem 4 A completely positive mapping $V: L(H_n) \rightarrow L(H_n)$ can be represented as

$$V(A) = \sum_{k=1}^m V_k A V_k^* \tag{16}$$

where each $V_k \in L(H_n)$ and $m \leq n^2$. V is trace-preserving if and only if

$$\sum_{k=1}^m V_k^* V_k = I$$

Even though the second characterization also follows from the Stinespring dilation theorem as does the first one, this second one is more frequently known as the *Stinespring representation*. Another name for the representation below is the *Ozawa representation* (Ozawa 1984).

Theorem 5 *For any completely positive, trace-preserving mapping $V : L(H_n) \rightarrow L(H_n)$ there exists a Hilbert space H_m with $m \leq n^2$, pure state $|0\rangle\langle 0| \in H_m$, and a unitary mapping $U \in L(H_n \otimes H_m)$ so that*

$$V(A) = \text{Tr}_{H_m}(U(A \otimes |0\rangle\langle 0|) U^*) \quad (17)$$

Representation (17) offers an interesting interpretation, which will be discussed after introducing a special case in the next section.

7.1.3 Closed Systems

The state transformation as introduced in the previous chapter can be irreversible in general. For instance, $V: L(H_2) \rightarrow L(H_2)$ defined via Kraus representation

$$V(A) = |0\rangle\langle 0|A|0\rangle\langle 0| + |1\rangle\langle 1|A|1\rangle\langle 1|$$

is clearly a completely positive, trace-preserving mapping. The images of the basis elements of $L(H_2)$ under V can be easily computed:

$$V(|0\rangle\langle 0|) = |0\rangle\langle 0|0\rangle\langle 0|0\rangle\langle 0| + |1\rangle\langle 1|0\rangle\langle 0|1\rangle\langle 1| = |0\rangle\langle 0|$$

and similarly $V(|0\rangle\langle 1|) = 0$, $V(|1\rangle\langle 0|) = 0$, and $V(|1\rangle\langle 1|) = |1\rangle\langle 1|$. We can readily observe that V is not injective, hence V^{-1} does not exist. It is also noteworthy that the action of V on a pure (vector) state $\frac{1}{\sqrt{2}}|0\rangle + \frac{1}{\sqrt{2}}|1\rangle$ yields

$$\begin{aligned} V\left(\frac{1}{\sqrt{2}}|0\rangle + \frac{1}{\sqrt{2}}|1\rangle\right) &= \frac{1}{\sqrt{2}}|0\rangle\langle 0| + \frac{1}{\sqrt{2}}|1\rangle\langle 1| \\ &= |0\rangle\langle 0|\left(\frac{1}{\sqrt{2}}|0\rangle + \frac{1}{\sqrt{2}}|1\rangle\right)\left(\frac{1}{\sqrt{2}}|0\rangle + \frac{1}{\sqrt{2}}|1\rangle\right)|0\rangle\langle 0| \\ &\quad + |1\rangle\langle 1|\left(\frac{1}{\sqrt{2}}|0\rangle + \frac{1}{\sqrt{2}}|1\rangle\right)\left(\frac{1}{\sqrt{2}}|0\rangle + \frac{1}{\sqrt{2}}|1\rangle\right)|1\rangle\langle 1| \\ &= \frac{1}{2}|0\rangle\langle 0| + \frac{1}{2}|1\rangle\langle 1| \end{aligned}$$

a mixed state (analogously one can see that V turns vector state $\frac{1}{\sqrt{2}}|0\rangle - \frac{1}{\sqrt{2}}|1\rangle$ into a mixed state $\frac{1}{2}|0\rangle\langle 0| + \frac{1}{2}|1\rangle\langle 1|$).

In general, a quantum system is called *closed* if it does not interact with any other system and if it is not entangled with another system. In this chapter, however, the following definition will be taken for a closed system.

Definition 29 Discrete time evolution in $L(H_n)$ is called *closed* if it is of the form

$$V(A) = UAU^* \quad (18)$$

where $U \in L(H_n)$ is unitary. A quantum system with closed (discrete) time evolution is called *closed*. A system that is not closed is called *open*.

Notice that both the Kraus representation and the Stinespring representation are extensions of [Eq. 18](#). Indeed, [Eq. 18](#) is a Kraus representation with $m=1$ and a Stinespring representation with $m=0$.

Closed discrete time evolution $V(A)=UAU^*$ on a pure (vector) state \mathbf{x} especially means that $|\mathbf{x}\rangle\langle\mathbf{x}|$ is converted into $U|\mathbf{x}\rangle\langle\mathbf{x}|U^* = |U\mathbf{x}\rangle\langle U\mathbf{x}|$, which is another pure state. Moreover, a closed discrete evolution is always invertible: A can be recovered as $A=U^*V(A)U$, which even reveals that the inverse of a closed state transformation is obtained by replacing U with $U^*=U^{-1}$. A closed state transformation means that the state vector turns into another state vector $U\mathbf{x}$.

- ▶ In the theory of quantum computing, it frequently assumed that the computational device has only closed state transformations and handles only pure states. In particular, this implies that one can then remain in the vector state formalism, and any state transformation takes the form

$$\mathbf{x} \mapsto U\mathbf{x}$$

where U is a unitary mapping. This is usually referred to by saying that (discrete) quantum evolution is *unitary*.

It is now interesting to see that the Stinespring representation ([17](#)) can be interpreted as follows: a quantum system with an open state transformation can be augmented with an auxiliary system, and the state transformation in the compound system is closed. Open state transformations of the subsystem hence result from watching the system only partially; the state transformation is closed in a larger system.

7.1.4 Schrödinger Equation

Previously, only the state transformations of quantum systems were considered. In other words, the evolution studied so far has been discrete, meaning that in a fixed time interval state S turns into $V(S)$ when the time has elapsed. There is nothing wrong with such an approach, but evidently it gives only part of the picture. For a refinement, one should learn how to approach *continuous state transformations*. Continuous state transformations are referred to generally as the *time evolution*.

To establish the mathematical machinery for that purpose, we restrict ourselves, for the sake of simplicity, to the closed systems beginning on a pure state. In particular this means that the images of the initial state vector \mathbf{x}_0 are studied under unitary mappings U_t for $t \in \mathbb{R}$; the state at time t is $\mathbf{x}_t = U_t\mathbf{x}_0$. How to continue from this is briefly, but not very thoroughly, described as follows: It is natural to require that $U_{t_1+t_2}\mathbf{x} = U_{t_1}U_{t_2}\mathbf{x}$, which is not far from saying that there is a morphism $t \mapsto U_t$ from real numbers to unitary mappings. Together with a continuity assumption, such a morphism can in fact be represented as $U_t = e^{itH}$, where H is a fixed self-adjoint mapping (Hamiltonian of the quantum system) ([Stone 1932](#)). Consequently,

$$\mathbf{x}_t = U_t\mathbf{x}_0 = e^{itH}\mathbf{x}_0$$

and componentwise differentiation gives

$$\frac{d}{dt}\mathbf{x}_t = iHe^{itH}\mathbf{x}_0 = iHU_t\mathbf{x}_0 = iH\mathbf{x}_t$$

► The equation

$$\frac{d}{dt} \mathbf{x}_t = iH\mathbf{x}_t$$

is called the *Schrödinger* equation.

The Schrödinger equation is a description of how the pure state of a closed system evolves continuously in time. The above form is frequently called the *abstract Schrödinger equation*, but the “concrete” ones can be obtained by substituting “concrete” Hamiltonians for H .

7.2 Models for Quantum Computing

Any classical model of computing also has a quantum version. There is in fact almost a “canonical” way of converting a classical model into a quantum version, namely that of replacing the classical description of the physical objects by the quantum description. In this section, the quantum time evolution means *discrete* time evolution, that is, the state transformation.

7.2.1 Finite Automata

Finite automata are models for real-time computation with a finite memory. The automaton reads the input word one letter at a time. Reading of a letter imposes a change of the internal state of the automaton (there are only finitely many of them), and having read the whole input word, the state of the automaton is observed. If the automaton has then reached a *final state* (can also be called *accepting state*), then the input word is accepted, otherwise rejected. Hence finite automata classify all potential input words into two piles: accepted and rejected. This can be expressed in other words by saying that the finite automata solve computational problems with yes/no answers: The problem instance is encoded into the input word, and the accept/reject behavior of the automaton is interpreted as the yes/no answer.

It turns out that finite automata can solve only a very restricted class of computational problems. Nevertheless, the research community has shown (and still shows) enormous interest in them. This is due to the following facts: the finite automata offer a very simple computational model with a huge number of connections to algebra, logic, combinatorics, logic, etc., not forgetting that the basic model of the finite automaton has beautiful closure properties; for example, constructing new automata of known ones for simultaneous computation or sequential computation is a straightforward task. Moreover, it is easy to present the generalizations and variants of finite automata: nondeterministic, probabilistic, and even quantum, as will be shortly seen. In addition, comparison between the different variants has been relatively successful, a natural measure for the complexity is the number of the states, and, for instance, a classical result shows that nondeterministic finite automata recognizing a language can have exponentially fewer states than the minimal deterministic one (Yu 1997). Even further, almost all classical models of computing (including the Turing machines in the next section) can be obtained by starting with finite automata, then augmenting them with an extra part. A wider description of finite automata can be found in Yu (1997), here we present only the definition.

A finite automaton A is a fivetuple $A=(Q,\Sigma,\delta,q_0,F)$, where Σ is a finite alphabet, Q is the state set, $\delta : Q \times \Sigma \rightarrow Q$ is the transition function, $q_0 \in Q$ the initial state, and $F \subseteq Q$ the set of final (accepting) states.

A *probabilistic finite automaton* (see Paz (1971) for more details) is obtained by replacing the transition function $\delta : Q \times \Sigma \rightarrow Q$ by the transition function $\delta : Q \times \Sigma \times Q \rightarrow [0, 1]$ whose value at triplet (q, σ, p) is interpreted as the probability of entering state p when being in state q and reading σ as an input letter. Equivalently, one can describe a probabilistic finite automaton as a collection of $|Q| \times |Q|$ probabilistic matrices $(M_a)_{ij} = \delta(q_j, a, q_i)$ together with an initial probability distribution.

To get a *quantum finite automaton*, we assume that the set of states is described by a quantum mechanical systems. Consequently, we can fix a Hilbert space H_n ($n = |Q|$) together with an orthonormal basis $\{|q\rangle |q \in Q\}$. For each $a \in \Sigma$, we define a set of completely positive mappings $V_a : L(H_n) \rightarrow L(H_n)$, fix an *initial state* $S \in L(H_n)$, and a *final projection* $P \in L(H_n)$. The *acceptance probability* $p(w)$ for a word $w = a_1 \dots a_k \in \Sigma^*$ (note that in the previous sections notion A^* was used for the adjoint mapping and here, as in theoretical computer science generally, Σ^* stands for the free monoid generated by Σ) is then computed as

$$p(w) = \text{Tr}(PV_n \dots V_1 S)$$

A *measure once* quantum automaton (introduced in Moore and Crutchfield (2000)) is obtained from the above description by assuming that the initial state is pure, and that each mapping V_a is indeed closed time evolution $V_a(T) = U_a T U_a^*$ (unitary time evolution).

In the model of the *measure many* quantum automaton (introduced in Kondacs and Watrous (1997)), one also assumes a pure initial state and unitary time evolution. The state set is divided into accepting, neutral, and rejecting states, and the subspaces generated by them are denoted by H_A , H_N , and H_R , respectively. For an input letter a , the model includes unitary time evolution V_a followed by a measurement of the observable defined by mutually orthogonal subspaces H_A , H_N , and H_R . If the state observed was accepting (resp. rejecting), then the input word is accepted (resp. rejected), but if the observed state was neutral, then the computation is continued with the next input letter.

It is trivial to note that measure-once quantum automata are subcases of the measure many automata, but it also turns out that both quantum automata models together with the model of probabilistic automata are subcases of the general model with an open time evolution (Hirvensalo (2008)).

7.2.2 Quantum Turing Machines

While finite automata are very restricted in their computational power, *Turing machines* can compute anything one can even imagine to be computed. Or at least this is a very sincere hope expressed in the famous *Church–Turing thesis* (see Papadimitriou (1994) for discussion), which essentially says that for any intuitive algorithm there is a Turing machine doing the same job. Turing machines were introduced by Turing (1936) to satisfy the need for a formal definition of *algorithm*.

Turing machines extend the notion of finite automata by an *infinite memory*, which, in the basic model, is a linear array of memory cells, each capable of containing a symbol from a finite alphabet. This infinite memory of the Turing machine is called the *tape*, and it is accessed via a *read–write head* that can point only at one particular cell at a time, and on a single computational step can move to point at most to the adjacent cells.

Besides the tape, the Turing machines have, as finite automata do, their finite set of internal states. The computation of a Turing machine runs as follows: The input word is initially written on the tape, but all other tape cells are empty. At the initial stage of computation, the

read–write head is set to point at the cell containing the first letter of the input word. A computational step of a Turing machine then can change the internal state of the machine, the content of the tape cell being scanned, and the position of the read–write head. The computational steps follow each other until the machine reaches an internal final state, which can be either of accepting or rejecting type. It may also happen that the final state is never reached, but the computation continues forever.

It can be understood that Turing machines, unlike finite automata, classify the input words into rejected, accepted, and neutral (for which the computation never ends), but also other classifications are possible: we could for example group together rejecting and unending computations to get a yes/no answer when solving computational problems. On the other hand, there is no way to tell in general whether a Turing machine computation is going to halt or not (Papadimitriou 1994).

As a theoretical model of computing, Turing machines do not have intuitively good programming properties. In fact, almost the converse holds true: The program of a Turing machine, which is encoded in the transition function, is usually the most unintuitive one could ever imagine. But, on the other hand, the Turing machine formalism offers the clearest picture on the computational resources one could ever imagine: The time needed for the computation is just the number of the computational steps from the beginning to the end, and the space devoured by the computation is the number of tape cells used during it.

Just as with finite automata, Turing machines also bear notable closure properties: For example, given two Turing machines, it is possible to construct a new machine for parallel computations, as well as for consecutive computation. Moreover, it is possible to construct a single Turing machine acting as a *clock* in the following sense: For an input of length n , the machine performs computations for exactly $f(n)$ steps, and then halts (the construction can be made for a large class of functions f , but of course not for all functions). This offers a potential way of handling nonfinishing computations: Given a Turing machine M , one can construct a time-counting machine T , and join them into a new machine M' , which halts either when the input word is accepted or when the time limit is reached. This construction is particularly good for algorithms with a known time complexity function, as the termination of the computation can then be always guaranteed.

For an extensive exposure on Turing machines, we refer to Papadimitriou (1994), but a brief formal definition follows immediately.

Definition 30 A Turing machine is a sextuple $T = (Q, \Gamma, \delta, q_0, q_a, q_r)$, where Q is the set of the machine’s internal states, $\Gamma = \Sigma \cup \{\square\}$ is the input alphabet Σ augmented with the blank symbol \square , and q_0 , q_a , and q_r are the initial, accepting, and rejecting states, respectively.

The transition function $\delta : Q \times \Sigma \mapsto Q \times \Sigma \times \{L, S, R\}$ specifies the action of the machine: if $\delta(q_1, \sigma_1) = (q_2, \sigma_2, L)$, then the machine being in state q_1 and reading σ_1 writes σ_2 in the memory cell being scanned, enters state q_2 , and moves the read–write head to the left. Correspondingly, values S and R would order the read–write head to stay, and move to the right, respectively.

Now the memory of a Turing machine consists of the finite set of internal states together with the tape content. As the tape is initially assumed to contain only the (finite) input word, there are at any moment of the computation only finitely many non-blank symbols on the tape. This implies that the number of potential *configurations* of the machine is countable. To specify what a configuration of the Turing machine means, there are two traditional ways.

The first one is a triplet (q, i, w) , where $q \in Q$ is the state of the machine, $i \in \mathbb{Z}$ tells the number of the memory cell being scanned by the read–write head (initially assumed 0), and $w \in \Gamma^*$ is the nonblank content of the tape presented in the shortest way. In the second representation, the position of the read–write head is indicated by splitting the content of the tape into two sections: configuration (q, w_1, w_2) then means that the state of the machine is q , the non-blank content of the tape is $w_1 w_2$, and that the read–write head is scanning the first symbol of w_2 .

The quantum version of Turing machines, first introduced by David Deutsch and subsequently analyzed in Bernstein and Vazirani (1997) is obtained by assuming that both the tape and the set of internal states are quantum physical. The internal state set will be obviously described as in the case of finite automata: Hilbert space $H_{|Q|}$ with an orthonormal basis $\{|q\rangle | q \in Q\}$ will serve as a quantum mechanical description of the state set. The tape itself, being an infinite object, is a bit more complicated. A single tape cell can of course be described by using Hilbert space $H_{|\Gamma|}$ with an orthonormal basis $\{|\gamma\rangle | \gamma \in \Gamma\}$, two tape cells as $H_{|\Gamma|} \otimes H_{|\Gamma|}$, three cells as $H_{|\Gamma|} \otimes H_{|\Gamma|} \otimes H_{|\Gamma|}$, etc. The quantum physical description of the tape is hence given by an infinite tensor product of finite dimensional Hilbert spaces $H_{|\Gamma|}$ called T , but the action of the machine is nevertheless defined by a local rule.

Deutsch's model presented the configuration of the machine as (q, i, w) , where i presents the number of the cell being scanned. To get a quantum version of this, one needs to introduce an infinite-dimensional Hilbert space $H_{\mathbb{Z}}$ with orthonormal basis $\{|i\rangle | i \in \mathbb{Z}\}$, and the quantum version of the configuration is simply a state in space $H_{|Q|} \otimes H_{\mathbb{Z}} \otimes T$.

The other model, see Hirvensalo (2004) for instance, uses configurations of the form (q, w_1, w_2) . There are only numerable many of those configurations, and we set up a Hilbert space H_C (the configuration space) with an orthonormal basis $\{(q, w_1, w_2) | q \in Q, w_1, w_2 \in \Gamma^*\}$.

If open time evolution is allowed, then the relationship between classical and quantum Turing machines is not a very problematic one: it is possible to interpret an ordinary Turing machine as a special case of quantum Turing machines merely by defining the time evolution by $V |c\rangle = |c'\rangle$, where c' is the configuration obtained from c by transition function δ .

On the other hand, most papers on quantum computing, including the pioneering articles, assume that the quantum Turing machine model operates with *closed (unitary) time evolution*, V which imposes a heavy restriction on δ . In general it is possible that δ does not specify any reversible time evolution. Fortunately it has been thoroughly examined to what extent the computation allows reversibility. A classical result (Bennett 1973) showed that *all computation* whatsoever can be performed also in a reversible manner, if extra workspace is available. In particular, the result of Bennett (1973) implies that an arbitrary computation can be simulated by a reversible one with the cost of a polynomial space increase.

7.2.3 Quantum Circuits

Quantum Turing machines offer, as their classical counterparts do, a good theoretical model for computation, as they provide a clear idea of the space and time required by computation. However, as in the classical case, it is very difficult to express even simple algorithms by means of a quantum Turing machine. For that purpose, *quantum circuits* are much better. They were first introduced by Deutsch (1989) and provide an easy way of expressing the technical details of quantum algorithms.

Boolean circuits (see Papadimitriou (1994) or Hirvensalo (2004) for instance) can be seen as acyclic graphs with nodes labeled by logical gates. A typical selection of gates includes AND,

NOT, and OR. The idea of the circuit computation is to encode the input into a binary string, and then let the circuit decide whether or not the input is accepted. Hence one needs actually a family C_1, C_2, C_3, \dots , of circuits so that circuit C_n , which takes the inputs of length n , has n input wires and one output wire. C_n then computes the output value 1 or 0 (yes/no) plainly obeying the structure of the Boolean circuit, using the gates as elementary computational devices.

Computation by circuits differs essentially from finite automata and Turing machines. As the latter devices can handle inputs of all lengths by a single machine, the circuit model assumes a particular circuit C_n for each input word length n . This is usually expressed by saying that finite automata and Turing machines are *uniform* computational devices, and the set of circuits is not.

Furthermore, it turns out that for *any* subset $L \subseteq \{0,1\}^*$ there is a family C_1, C_2, C_3, \dots of circuits accepting L , meaning that for a string w of length n , C_n outputs 1 if and only if $w \in L$ (Papadimitriou 1994; Hirvensalo 2004). On the contrary, it is clear that for an arbitrary subset $L \subseteq \{0,1\}^*$ there does not exist a Turing machine accepting L . This does not contradict the Church–Turing thesis claiming that the Turing machines possess the ultimate computational power, as only the *existence* of the circuit family C_1, C_2, C_3, \dots is guaranteed no construction. Without a construction, a circuit family cannot be regarded as a computational device at all, but when the construction is included, circuit formalism can have great advantage over the sole Turing machine formalism, especially in the theory of quantum computing.

The construction of circuit C_n requires an algorithm: given n , the task is to produce the graph of C_n , hopefully in a very efficient manner. As an algorithm is called for, one immediately realizes that we are again speaking of Turing machines (or of some equivalent uniform computational model). One could hence again question the meaningfulness of the circuit model, but it has turned out that splitting the algorithm into two major parts (construction of the circuit and the computation performed by the circuit) can offer understanding, which outperforms that given by a direct uniform computational model.

The aforementioned division (construction of the circuit followed by circuit computation) seems to work especially well in quantum computing. The famous quantum algorithms for integer factoring by Peter W. Shor (Shor 1994) and quadratic speedup for search problems by Lov Grover (Grover 1996) can be very well explained using the quantum circuit model (see Hirvensalo (2004)). Indeed, the construction of the quantum circuit for both tasks turns out to be very easy, and the quantum effects (interference and entanglement) can be explored in the circuit computation.

By allowing open time evolution, one gets the notion of *quantum circuits with mixed states* introduced in Aharonov et al. (1998). Quantum circuits with open time evolution can simulate effectively ordinary Boolean circuits, but when restricted to closed time evolution, the computational power seemingly diminishes. However, such a great variety of research papers use quantum circuits with closed (unitary) time evolution that it is worth concentrating on them in more detail.

A *quantum circuit* with unitary time evolution is a sequence U_1, \dots, U_k of unitary mappings acting on $H_{2^n} = H_2 \otimes \dots \otimes H_2$ (n terms), where n is the number of input qubits. Mappings U_1, \dots, U_k have the following restrictions: there is a finite set $\{G_1, \dots, G_m\}$ of *quantum gates* (unitary mappings), from which mappings U_i are constructed. This means each U_i is one of the mappings G_j operating on some of the n qubits and leaving all others untouched.

The computation of the circuit is then very straightforward: Initially, the qubits contain the input word $\mathbf{x} \in \{0, 1\}^n$, so that the initial state of the circuit is $|\mathbf{x}\rangle$. Then mappings U_1, \dots, U_k are applied to get the final state

$$U_k \dots U_1 |\mathbf{x}\rangle$$

and the output qubits can be observed. Number k is called the *depth* of the circuit.

Note that as the time evolution is reversible, one must have equally many input and output qubits, but of course one can restrict this to read only one of the output bits. In the second place, the finite set $G = \{G_1, \dots, G_m\}$ is the counterpart of classical AND, NOT, and OR gates, and it is natural to assume that G is *universal* in the sense that all unitary mappings $U \in L(H_{2^n})$ can be approximated by gates in set G . The actual choice of G does not matter so much. One can also note that in the classical case one of the gates AND and OR could be omitted, or it could be possible to use only a single gate NAND. In the quantum context, universality must mean approximability: set $L(H_{2^n})$ has continuum cardinality, but mappings obtained from a finite set G in the above fashion form only a numerable set, implying that *most* unitary mappings cannot be represented exactly.

The question of universality has been studied very thoroughly. Already in his seminal paper (Deutsch 1989) Deutsch proved that there is a single three-qubit universal quantum gate. Later, it was shown in Barenco et al. (1995) that unary gates (those acting only on one qubit) together with controlled NOT gate form a universal set even in the strict sense (exact representation). A very simple set of universal gates was given in Shi (2003): the Toffoli gate together with the Hadamard–Walsh gate is a universal set. Another very important point is the approximation efficiency: how many gates from a universal set are needed in general to approximate a given gate with accuracy ε ? The famous Solovay–Kitaev theorem (see Nielsen and Chuang (2000)) implies that only $O(n \log^c \frac{n}{\varepsilon})$ gates from *any* universal gate set are needed to simulate (within accuracy ε) a quantum circuit with n arbitrary gates. (In the Solovay–Kitaev theorem, $c \in [1, 2]$ is a constant whose optimal value is not known.)

To conclude this section, we discuss briefly the relationship between quantum circuits with mixed states (open time evolution) and quantum circuits with closed (unitary) time evolution. As mentioned previously, quantum circuits with unitary time evolution are apparently more restricted than those with open time evolution, but there is a standard way of circumventing this restriction, namely the *ancilla bits*. This means that in addition to the n input qubits, there will be a number, say $a(n)$, of ancilla qubits initially all set to state $|0\rangle$, so that the initial state of the circuit is $|\mathbf{x}\rangle |0\rangle$. Then an extended circuit operates on $n + a(n)$ qubits to get the desired result, and it can be shown that an arbitrary quantum circuit with open time evolution can be simulated in this manner, using $a(n)$ (where a is a polynomial) ancilla qubits (Aharonov et al. 1998).

Abstract

For individual events, quantum mechanics makes only probabilistic predictions. Can one go beyond quantum mechanics in this respect? This question has been a subject of debate and research since the early days of the theory. Efforts to construct a deeper, realistic level of physical description, in which individual systems have, like in classical physics, preexisting properties revealed by measurements are known as hidden-variable programs. Demonstrations that a hidden-variable program necessarily requires outcomes of certain experiments to disagree with the predictions of quantum theory are called “no-go theorems.” The Bell theorem excludes local hidden variable theories. The Kochen–Specker theorem excludes non-contextual hidden variable theories. In local hidden-variable theories faster-than-light-influences are forbidden, thus the results for a given measurement (actual, or just potentially possible) are independent of the settings of other measurement devices which are at space-like separation. In non-contextual hidden-variable theories, the predetermined results of a (degenerate) observable are independent of any other observables that are measured jointly with it.

It is a fundamental doctrine of quantum information science that quantum communication and quantum computation outperform their classical counterparts. If this is to be true, some fundamental quantum characteristics must be behind the better-than-classical performance of information-processing tasks. This chapter aims at establishing connections between certain quantum information protocols and foundational issues in quantum theory. After a brief discussion of the most common misinterpretations of Bell’s theorem and a discussion of what its real meaning is, we will demonstrate *how quantum contextuality and violation of local realism can be used as useful resources* in quantum information applications. In any case, the readers should bear in mind that this chapter is not a review of the literature of the subject, but rather a quick introduction to it.

1 Introduction

Which quantum states are useful for quantum information processing? All non-separable states? Only distillable non-separable states? Only those which violate constraints imposed by local realism? Entanglement is the most distinct feature of quantum physics with respect to the classical world (Schrödinger 1935). On the one hand, entangled states violate Bell’s inequalities, and thus rule out a local realistic explanation of quantum mechanics. On the other hand, they enable certain communication and computation tasks to have an efficiency not achievable by the laws of classical physics. Intuition suggests that these two aspects, the fundamental one, and the one associated with applications, are intimately linked. It is natural to assume that the quantum states, which allow the no-go theorems of quantum theory, such as Kochen–Specker, Bell’s or the Greenberger–Horne–Zeilinger theorem should also be useful for quantum information processing. If this were not true, one might expect that the efficiency of quantum information protocols could be simulatable by classical, local realistic or non-contextual models, and thus achievable already via classical means. This intuitive reasoning is supported by the results of, for example, Ekert (1991), Scarani and Gisin (2001) and Acin et al. (2006): violation of a Bell’s inequality is a criterion for the security of quantum key distribution protocols. Also, it was shown that violation of Bell’s inequalities by a quantum state implies that pure-state entanglement can be distilled from it (Acin et al. 2002) and

that Bell's inequalities are related to optimal solutions of quantum state targeting (Bechmann-Pasquinucci 2005). This overview will give other examples that demonstrate the strong link between fundamental features of quantum states and their applicabilities in quantum information protocols, such as in quantum communication complexity problems, quantum random access coding, or certain quantum games.

2 Quantum Predictions for Two-Qubit Systems

To set the stage for the story first, a description of two-qubit systems is given in full detail.

Predictions shall be presented for all possible local yes–no experiments on two spin-1/2 systems (in modern terminology, qubits) for all possible quantum states, that is, from the pure maximally entangled singlet state (or the Bohm-EPR state), via factorizable (i.e., non-entangled) states, up to any mixed state. This will enable us to reveal the distinguishing traits of the quantum predictions for entangled states of the simplest possible compound quantum system. The formalism can be applied to any system consisting of two subsystems, such that each of them is described by a two-dimensional Hilbert space. The spin-1/2 convention is chosen to simplify the description.

2.1 Pure States

An important tool simplifying the analysis of the pure states of two subsystems is the so-called Schmidt decomposition.

2.1.1 Schmidt Decomposition

For any nonfactorizable (i.e., entangled) pure state, $|\psi\rangle$ of a pair of quantum subsystems, one described by a Hilbert space of dimension N , the other by space of dimension M , $N \leq M$, it is always possible to find preferred bases, one basis for the first system, another one for the second, such that the state becomes a sum of bi-orthogonal terms, that is

$$|\psi\rangle = \sum_{i=1}^N c_i |a_i\rangle_1 |b_i\rangle_2 \quad (1)$$

with $n\langle x_i|x_j\rangle_n = \delta_{ij}$ for $x = a, b$ and $n = 1, 2$. It is important to stress that the appropriate single subsystem bases, here $|a_i\rangle_1$ and $|b_j\rangle_2$, depend upon the state that we want to Schmidt decompose.

The ability to Schmidt decompose the state is equivalent to a well-known fact from matrix algebra, that any $N \times M$ matrix \hat{A} can be always put into a diagonal form \hat{D} , by applying a pair of unitary transformations, U and V such that: $\sum_{j=1}^N \sum_{k=1}^M U_{ij} A_{jk} V_{kl} = D_l \delta_{il}$.

The interpretation of the above formula could be put as follows. If the quantum pure state of two systems is non-factorizable, then there exists a pair of local observables (for system 1 with eigenstates $|a_i\rangle$, and for system 2 with eigenstates $|b_i\rangle$) such that the results of their measurements are perfectly correlated.

The method of the Schmidt decomposition allows us to put every pure normalized state of two spins into

$$|\psi\rangle = \cos\alpha/2|+\rangle_1|+\rangle_2 + \sin\alpha/2|-\rangle_1|-\rangle_2 \quad (2)$$

for some angle α and local bases spent by states $|+\rangle_i$ and $|-\rangle_i$, $i=1,2$. The Schmidt decomposition generally allows the coefficients to be real. This is achievable via trivial phase transformations of the preferred bases.

2.2 Arbitrary States

Systems can be in mixed states. Such states describe situations in which there does not exist any *nondegenerate* observable for which the measurement result is deterministic. This is the case when the system can be with various probabilities $P(x) \geq 0$ in some nonequivalent states $|\psi(x)\rangle$, with $\sum_x P(x) = 1$. Mixed states are represented by self-adjoint nonnegative (density) operators $\rho = \sum_x P(x)|\psi(x)\rangle\langle\psi(x)|$. As $\text{Tr}|\psi(x)\rangle\langle\psi(x)| = 1$ one has $\text{Tr}\rho = 1$.

The properties of mixed states of the two spin-1/2 systems will now be presented in detail. Any self-adjoint operator for one spin-1/2 particle is a linear combination of the Pauli matrices σ_i , $i = 1, 2, 3$, and the identity operator, $\sigma_0 = \mathbf{1}$, with *real* coefficients. Thus, any self-adjoint operator in the tensor product of the two spin-1/2 Hilbert spaces must be a real linear combination of all possible products of the operators $\sigma_\mu^1 \sigma_\nu^2$, where the Greek indices run from 0 to 3, and the superscripts denote the particle. As the trace of σ_i is zero, we arrive at the following form of the general density operator for two spin 1/2 systems:

$$\rho = \frac{1}{4} \left(\sigma_0^{(1)} \sigma_0^{(2)} + \mathbf{r} \cdot \boldsymbol{\sigma}^{(1)} \sigma_0^{(2)} + \sigma_0^{(1)} \mathbf{s} \cdot \boldsymbol{\sigma}^{(2)} + \sum_{m,n=1}^3 T_{nm} \sigma_n^{(1)} \sigma_m^{(2)} \right) \quad (3)$$

where \mathbf{r} and \mathbf{s} are real three-dimensional (Bloch) vectors and $\mathbf{r} \cdot \boldsymbol{\sigma} \equiv \sum_{i=1}^3 r_i \sigma_i$ is the scalar product between vectors \mathbf{r} and $\boldsymbol{\sigma}$. The tensor product symbol \otimes shall be used only sparingly, only whenever it is deemed necessary. The condition $\text{Tr}\rho = 1$ is satisfied, thanks to the first term.

Since the average of any real variable which can have only two values +1 and -1 cannot be larger than 1 and less than -1, the real coefficients T_{mn} satisfy relations

$$-1 \leq T_{mn} = \text{Tr}\rho\sigma_n^{(1)}\sigma_m^{(2)} \leq 1 \quad (4)$$

and they form a matrix (also called a correlation tensor), which will be denoted by $\hat{\mathbf{T}}$. One also has

$$-1 \leq r_n = \text{Tr}\rho\sigma_n^{(1)} \leq 1 \quad (5)$$

and

$$-1 \leq s_m = \text{Tr}\rho\sigma_m^{(2)} \leq 1 \quad (6)$$

2.2.1 Reduced Density Matrices for Subsystems

A reduced density matrix represents the local state of a compound system. If there are two subsystems, then the average of any observable, which pertains to the first system only, that is, of the form $A \otimes \mathbf{1}$, where $\mathbf{1}$ is the identity operation for system 2, can be expressed as follows

$\text{Tr}_{12}(A \otimes 1\rho) = \text{Tr}_1[A(\text{Tr}_2\rho)]$. Here, Tr_i represents a trace with respect to system i . As trace is a basis independent notion, one can always choose a factorizable basis, and therefore split the trace calculation into two stages.

The reduced one particle matrices for spins 1/2, are of the following form:

$$\rho_1 \equiv \text{Tr}_2\rho = \frac{1}{2}(\mathbf{1} + \mathbf{r} \cdot \boldsymbol{\sigma}^{(1)}) \quad (7)$$

$$\rho_2 \equiv \text{Tr}_1\rho = \frac{1}{2}(\mathbf{1} + \mathbf{s} \cdot \boldsymbol{\sigma}^{(2)}) \quad (8)$$

with \mathbf{r} and \mathbf{s} the two local Bloch vectors of the spins.

Let us denote the eigenvectors of the spin projection along direction \mathbf{a} of the first spin as: $|\psi(\pm 1, \mathbf{a})\rangle_1$. They are defined by the relation

$$\mathbf{a} \cdot \boldsymbol{\sigma}^{(1)} |\psi(\pm 1, \mathbf{a})\rangle_1 = \pm 1 |\psi(\pm 1, \mathbf{a})\rangle_1 \quad (9)$$

where \mathbf{a} is a real vector of unit length (i.e., $\mathbf{a} \cdot \boldsymbol{\sigma}^{(1)}$ is a Pauli operator in the direction of \mathbf{a}). The probability of a measurement of this Pauli observable to give a result ± 1 is given by

$$P(\pm 1|\mathbf{a})_1 = \text{Tr}_1 \rho_1 \pi_{(\mathbf{a}, \pm 1)}^{(1)} = \frac{1}{2}(1 \pm \mathbf{a} \cdot \mathbf{r}) \quad (10)$$

and it is positive for arbitrary \mathbf{a} , if and only if, the norm of \mathbf{r} satisfies

$$|\mathbf{r}| \leq 1 \quad (11)$$

Here $\pi_{(\mathbf{a}, \pm 1)}^{(1)}$ is the projector $|\psi(\pm 1, \mathbf{a})\rangle_{11} \langle \psi(\pm 1, \mathbf{a})|$

2.3 Local Measurements on Two Qubits

The probabilities for local measurements to give the result $l = \pm 1$ for particle 1 and the result $m = \pm 1$ for particle 2, under specified local settings, \mathbf{a} and \mathbf{b} respectively, are given by:

$$P(l, m|\mathbf{a}, \mathbf{b})_{1,2} = \text{Tr} \rho \pi_{(\mathbf{a}, l)}^{(1)} \pi_{(\mathbf{b}, m)}^{(2)} = \frac{1}{4}(1 + l\mathbf{a} \cdot \mathbf{r} + m\mathbf{b} \cdot \mathbf{s} + lm\mathbf{a} \cdot \hat{\mathbf{T}}\mathbf{b}) \quad (12)$$

where $\hat{\mathbf{T}}\mathbf{b}$ denotes the transformation of the column vector \mathbf{b} by the matrix $\hat{\mathbf{T}}$ (Euclidean vectors are treated here as column matrices).

One can simplify all these relations by performing suitable local unitary transformations upon each of the subsystems, that is, via factorizable unitary operators $U^{(1)}U^{(2)}$. It is well known that any unitary operation upon a spin 1/2 is equivalent to a three-dimensional rotation in the space of Bloch vectors. In other words, for any real vector \mathbf{w}

$$U(\hat{\mathbf{O}})\mathbf{w} \cdot \boldsymbol{\sigma} U(\hat{\mathbf{O}})^\dagger = (\hat{\mathbf{O}}\mathbf{w}) \cdot \boldsymbol{\sigma} \quad (13)$$

where $\hat{\mathbf{O}}$ is the orthogonal matrix of the rotation. If the density matrix is subjected to such a transformation on either spins subsystem, that is, to the $U^1(\hat{\mathbf{O}}_1)U^2(\hat{\mathbf{O}}_2)$ transformation, the parameters \mathbf{r} , \mathbf{s} , and $\hat{\mathbf{T}}$ transform themselves as follows

$$\begin{aligned} \mathbf{r}' &= \hat{\mathbf{O}}_1 \mathbf{r} \\ \mathbf{s}' &= \hat{\mathbf{O}}_2 \mathbf{s} \\ \hat{\mathbf{T}}' &= \hat{\mathbf{O}}_1 \hat{\mathbf{T}} \hat{\mathbf{O}}_2^T \end{aligned} \quad (14)$$

Thus, for an arbitrary state, we can always choose such factorizable unitary transformation that the corresponding rotations (i.e., orthogonal transformations) will diagonalize the correlation tensor (matrix) \hat{T} . This can be seen as another application of Schmidt's decomposition, this time in the case of the second rank tensors.

The physical interpretation of the above is that one can always choose two (local) systems of coordinates, one for the first particle, the other for the second particle, in such a way that the \hat{T} matrix will be diagonal.

Let us note that one can decompose the two spin density matrices into:

$$\rho = \rho_1 \otimes \rho_2 + \frac{1}{4} \sum_{m,n=1}^3 C_{nm} \sigma_n^1 \otimes \sigma_m^2 \quad (15)$$

that is, it is a sum of the product of the two reduced density matrices and a term $\hat{C} = \hat{T} - \mathbf{r}\mathbf{s}^T$, which is responsible for the correlation effects.

Any density operator satisfies the inequality $\frac{1}{d} < \text{Tr}\rho^2 \leq 1$, where d is the dimension of the Hilbert space in which it acts, that is, of the system it describes. The value of $\text{Tr}\rho^2$ is a measure of the purity of the quantum state. It is equal to 1 only for single dimensional projectors, that is, the pure states. In the studied case of two qubits one must have

$$|\mathbf{r}|^2 + |\mathbf{s}|^2 + ||\hat{\mathbf{T}}||^2 \leq 3 \quad (16)$$

For pure states, represented by Schmidt decomposition (🔗 2), \hat{T} is diagonal with entries $T_{xx} = -\sin\alpha$, $T_{yy} = \sin\alpha$, and $T_{zz} = 1$, whereas $\mathbf{r} = \mathbf{s}$, and their z component is nonzero: $s_z = m_z = \cos\alpha$. Thus, in the case of a maximally entangled state, \hat{T} has only diagonal entries equal to +1 and -1. In the case of the singlet state,

$$|\psi\rangle = \frac{1}{\sqrt{2}} (|+\rangle_1 |-\rangle_2 - |-\rangle_1 |+\rangle_2) \quad (17)$$

which can be obtained from (🔗 Eq. 2), by putting $\alpha = -\frac{\pi}{2}$ and rotating one of the subsystems such that $|+\rangle$ and $|-\rangle$ interchange (this is equivalent to a 180° rotation with respect to the axis x where $|+\rangle$ and $|-\rangle$ are eigenstates of spin along z ; see above (🔗 Eq. 14)), the diagonal elements of the correlation tensor are all -1.

3 Einstein–Podolsky–Rosen Experiment

In their seminal 1935 paper (Einstein et al. 1935) entitled “*Can quantum-mechanical description of physical reality be considered complete?*” Einstein, Podolsky, and Rosen (EPR) consider quantum systems consisting of two particles such that, while neither position nor momentum of either particle is well-defined, the difference of their positions and the sum of their momenta are both precisely defined. It then follows that measurement of either position or momentum performed on, say, particle 1 immediately implies, for particle 2, a precise position or momentum, respectively, even when the two particles are separated by arbitrary distances without any actual interaction between them.

We shall present the EPR argumentation for incompleteness of quantum mechanics in the language of spins 1/2. This was done by Bohm (1952) in 1952. A two-qubit example of an EPR state is the singlet state (🔗 Eq. 17). The properties of a singlet can be inferred without mathematical considerations given above. This is a state of zero total spin. Thus, measurements of the same component of the two spins must always give opposite values – this is

simply the conservation of angular momentum at work. In terms of the language of Pauli matrices the product of the local results is then always -1 . We have (infinitely many) *perfect (anti-)correlations* for every possible choice of spin component. We assume that the two spins are very far away, but nevertheless in the singlet state.

After the translation into Bohm's example, the EPR argument runs as follows. Here are their premises:

1. *Perfect correlations*: If whatever spin components of particles 1 and 2 are measured, and the settings are identical for both particles, then with certainty the outcomes will be found to be perfectly anti-correlated.
2. *Locality*: "Since at the time of measurements the two systems no longer interact, no real change can take place in the second system in consequence of anything that may be done to the first system."
3. *Reality*: "If, without in any way disturbing a system, we can predict with certainty (i.e., with probability equal to unity) the value of a physical quantity, then there exists an element of physical reality corresponding to this physical quantity."
4. *Completeness*: "Every element of the physical reality must have a counterpart in the [complete] physical theory."

In contrast to the last three premises, which though they are quite plausible are still indications of a certain philosophical viewpoint, the first premise is a statement about a well-established property of a singlet state.

The EPR argument is as follows. Because of the perfect anti-correlations (1), we can predict with certainty the result of measuring either the x component or the y component of the spin of particle 2 by previously choosing to measure the same quantity of particle 1. By locality (2), the measurement of particle 1 cannot cause any real change in particle 2. This implies that by the premise (3) both the x and the y components of the spin of particle 2 are elements of reality. This is also the case for particle 1 by a parallel argument where particle 1 and 2 interchange their roles. Yet, (according to Heisenberg's uncertainty principle) there is no quantum state of a single spin in which both x and y spin components have definite values. Therefore, by premise (4), quantum mechanics cannot be a complete theory.

In his answer (Bohr 1935), published in the same year and under the same title as the EPR paper, Bohr criticized the EPR concept of "reality" as assuming the systems have intrinsic properties independently of whether they are observed or not and he argued for "the necessity of a final renunciation of the classical ideal of causality and a radical revision of one's attitude toward the problem of physical reality." Bohr pointed out that the wording of the criterion of physical reality (3) proposed by EPR contains an ambiguity with respect to the expression, "without in any way disturbing the system." And, while, as Bohr wrote, there is "no question of mechanical disturbance of the system," there is "the question of *an influence on the very conditions, which define the possible types of predictions regarding the future behavior of the system*." Bohr thus pointed out that the results of quantum measurements, in contrast to those of classical measurements, depend on the complete experimental arrangement (*context*), which can even be nonlocal as in the EPR case. Before any measurement is performed, only the correlations between the spin components of two particles, but not spin components of individual particles, are defined. The x or y component (but never both) of an individual particle becomes defined only when the respective observable of the distant particle is measured.

Perhaps the clearest way to see how strongly the philosophical viewpoints of EPR and Bohr differ is in their visions of the future development of quantum physics. While EPR wrote: "We

believe that such a [complete] theory is possible,” Bohr’s opinion is that (his) complementarity “provides room for new physical law, the coexistence of which might at first sight appear irreconcilable with the basic principles of science.”

4 Bell's Theorem

Bell's theorem can be thought of as a disproof of the validity of the EPR ideas. The elements of physical reality cannot be an internally consistent notion. A broader interpretation of this result is that a local and realistic description of nature, at the fundamental level, is untenable. Further consequences are that there exist quantum processes, which cannot be modeled by any classical ones, not necessarily physical processes, but also some classical computer simulations with a communication constraint. This opened up the possibility of the development of quantum communication.

We shall now present a derivation of Bell's inequalities. The stress will be put on clarification of the underlying assumptions. These will be presented in the most reduced form.

4.1 Thought Experiment

At two measuring stations A and B , which are far away from each other, two characters Alice and Bob observe simultaneous flashy appearances of numbers $+1$ or -1 at the displays of their local devices (or the monitoring computers). The flashes appear in perfect coincidence (with respect to a certain reference frame). In the middle, between the stations, is something that they call “source.” When it is absent, or switched off, the numbers ± 1 's do not appear at the displays. The activated source always causes two flashes, one at A , and one at B . They appear slightly after a relativistic retardation time with respect to the activation of the source, never before. Thus there is enough “evidence” for Alice and Bob that the source causes the flashes. The devices at the stations have a knob, which can be put in two positions: $m = 1$ or 2 at A station, and $n = 1$ or 2 at B . Local procedures used to generate random choices of local knob positions are equivalent to *independent, fair coin tosses*. Thus, each of the four possible values of the pair n, m are equally likely, that is, the probability $P(n, m) = P(n)P(m) = \frac{1}{4}$. The “tosses,” and knob settings, are made at random times, and often enough, so that the information on these is never available at the source during its activation periods (the tosses and settings cannot have a causal influence on the workings of source). The local measurement data (setting, result, and moment of measurement) are stored and very many runs of the experiment are performed (☞ [Fig. 1](#)).

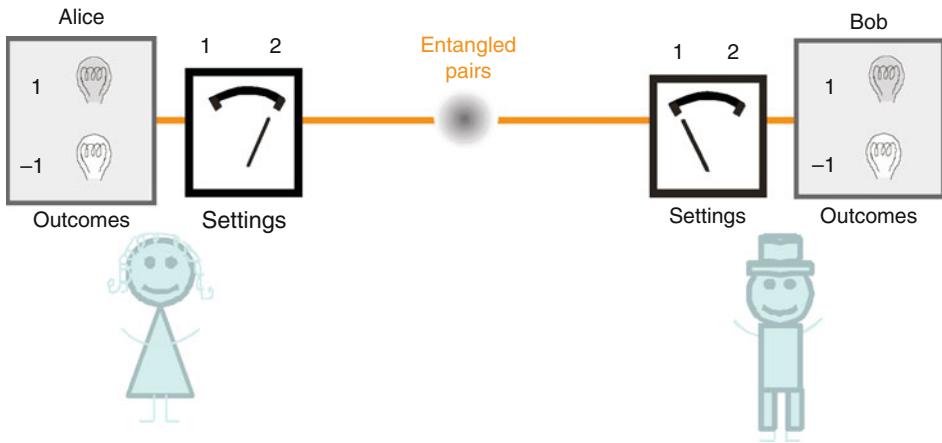

4.1.1 Assumptions Leading to Bell's Inequalities

A concise *local realistic* description of such an experiment would use the following assumptions (Gill et al. 2002, 2003):

1. We assume *realism*, which is any logically self-consistent model that allows one to use *eight* variables in the theoretical description of the experiment: $A_{m,n}, B_{n,m}$, where $n, m = 1, 2$. The variable $A_{m,n}$ gives the value, ± 1 , which could be obtained at station A , if the knob settings, at A and B , were at positions n, m , respectively. Similarly, $B_{n,m}$ plays the same role for station B , under the same settings. This is equivalent to the assumption that a joint (nonnegative, properly normalized) probability distribution of these variables,

Fig. 1

Test of Bell's inequalities. Alice and Bob are two separated parties who share entangled particles. Each of them is free to choose two measurement settings 1 and 2 and they observe flashes in their detection stations, which indicate one of the two possible measurement outcomes +1 or -1.

$P(A_{1,1}, A_{1,2}, A_{2,1}, A_{2,2}; B_{1,1}, B_{1,2}, B_{2,1}, B_{2,2}, n, m)$, is always allowed to exist. (Note, that no hidden variables appear, beyond these ten. However, given a (possibly stochastic) hidden variables theory, one will be able to define the ten variables as (possibly random) functions of the variables in that theory.)

2. The assumption of *locality* does not allow influences to go outside the light cone.
3. Alice and Bob are free to choose their settings “at the whim.” This is the *freedom*, or “*free will*,” often only a tacit assumption (Bell 1985, Kofler et al. 2006). A less provocative version of this assumption: *There exist stochastic processes, which could be used to choose the values of the local settings of the devices which are independent of the workings of the source, that is, they neither influence it nor are influenced by it.* By the previous assumptions, the events of activation of the source and of the choice and fixing of the local settings must be space-like separated and they furthermore cannot have common cause in the past.

Note that when setting labels m, n are sent to the measurement devices, they are likely to cause some unintended disturbance: by these assumptions, *any disturbance at A, as far as it influences the outcome at A, is not related to the coin toss nor to the potential outcomes at B, and vice versa.*

Note further, that $A_{n,m}$ and $B_{n,m}$ are not necessarily actual properties of the systems. The only thing that is assumed is that there is a theoretical description, which allows one to use all these *eight* values.

4.1.2 First Consequences

Let us write down the immediate consequences of these assumptions:

- By *locality*: for all n, m :

$$A_{m,n} = A_m, \quad B_{n,m} = B_n \quad (18)$$

That is, the outcome which would appear at A does not depend on which setting might be chosen at B , and vice versa. Thus $P(A_{1,1}, \dots, B_{2,2}, n, m)$ can be reduced to $P(A_1, A_2, B_1, B_2, n, m)$.

- By freedom

$$(n, m) \text{ is statistically independent of } (A_1, A_2, B_1, B_2) \quad (19)$$

Thus, the *overall* probability distributions for potential settings and potential outcomes satisfy

$$P(n, m, A_1, A_2, B_1, B_2) = P(n, m)P(A_1, A_2, B_1, B_2) \quad (20)$$

The choice of settings in the two randomizes, A and B , is causally separated from the local realistic mechanism, which produces the potential outcomes.

4.1.3 Lemma: Bell's Inequality

The probabilities, \Pr , of the four logical propositions, $A_n = B_m$, satisfy

$$\Pr\{A_1 = B_2\} - \Pr\{A_1 = B_1\} - \Pr\{A_2 = B_1\} - \Pr\{A_2 = B_2\} \leq 0 \quad (21)$$

Proof: Only four, or two, or none of the propositions in the left-hand side of the inequality can be true, thus (21). QED.

Now, if the observation settings are totally random (dictated by “coin tosses”), $P(n, m) = \frac{1}{4}$. Then, according to all the assumptions

$$P(A_n = B_m | n, m) = P(n, m) \Pr\{A_n = B_m\} = \frac{1}{4} \Pr\{A_n = B_m\} \quad (22)$$

Therefore, we have a Bell's inequality: under the *conjunction* of the assumptions for the *experimentally accessible* probabilities one has

$$P(A_1 = B_2 | 1, 2) - P(A_1 = B_1 | 1, 1) - P(A_2 = B_1 | 2, 1) - P(A_2 = B_2 | 2, 2) \leq 0 \quad (23)$$

This is the well-known Clauser–Horne–Shimony–Holt (CHSH) inequality (Clauser et al. 1969).

4.2 Bell's Theorem

Quantum mechanics predicts for experiments satisfying all the features of the thought experiment the left-hand side of inequality (23) to be as high as $\sqrt{2} - 1$, which is larger than the local realistic bound 0. Hence, one has Bell's theorem (Bell 1964): if quantum mechanics holds, local realism, defined by the full set of the above assumptions, is untenable. But, how does nature behave – according to local realism or quantum mechanics? It seems that we are approaching the moment in which one could have, as perfect as possible, a laboratory realization of the thought experiment (the locality loophole was closed in Weihs et al. (1998) and Aspect et al. (1982), the detection loophole was closed in Rowe et al. (2001), and in recent experiments measurement settings were space-like separated from the photon pair emission (Scheidl et al. 2008)). Hence, the local realistic approach to the description of physical phenomena is close to being shown untenable, too.

4.2.1 The Assumptions as a Communication Complexity Problem

Assume that we have two programmers P_k , where $k = 1, 2$, each possessing an enormously powerful computer. They share certain joint classically correlated strings of arbitrary lengths and/or some computer programs. All these will be collectively denoted as λ . But, once they both possess λ , no communication whatsoever between them is allowed. After this initial stage, each one of them gets from a referee a one-bit random number $x_k \in \{0, 1\}$, known only to him/her (P_1 knows only x_1 , P_2 knows only x_2). The *individual* task of each of them is to produce, via whatever computational program, a one-bit number $I_k(x_k, \lambda)$, and communicate only this one bit to a Referee, who just compares the received bits. There is no restriction on the form and complication of the *possibly stochastic* functions I_k , or any actions taken to define the values, but any communication between the partners is absolutely not allowed. The *joint* task of the partners is to devise a computer code which, under the constraints listed above and without any cheating, allows them to have, after very many repetitions of the procedures (each starting with establishing a new shared λ), the following functional dependence of the probability that their bits sent back to the Referee are equal:

$$P\{I_1(x_1) = I_2(x_2)\} = \frac{1}{2} + \frac{1}{2} \cos [-\pi/4 + (\pi/2)(x_1 + x_2)] \quad (24)$$

This is a variant of communication complexity problems. The current task is absolutely impossible to achieve with the classical means at their disposal, and without communication. Simply because whatever the protocol

$$\Pr\{I_1(1) = I_2(1)\} - \Pr\{I_1(0) = I_2(0)\} - \Pr\{I_1(1) = I_2(0)\} - \Pr\{I_1(0) = I_2(1)\} \leq 0 \quad (25)$$

whereas the value of this expression in the quantum strategy can be as high as $\sqrt{2} - 1$. This value can be obtained on average if the programmers use entanglement as a resource and receive their respective qubits from an entangled pair (e.g., singlet) during the communication stages (when λ is established). Instead of computing, the partners make a local measurement on their qubits. They measure Pauli observables $\mathbf{n} \cdot \boldsymbol{\sigma}$, where $\|\mathbf{n}\| = 1$. Since the probability for them to get identical results, r_1, r_2 , for observation directions $\mathbf{n}_1, \mathbf{n}_2$ is

$$P_Q\{r_1 = r_2 | \mathbf{n}_1, \mathbf{n}_2\} = \frac{1}{2} - \frac{1}{2} \mathbf{n}_1 \cdot \mathbf{n}_2 \quad (26)$$

for suitably chosen $\mathbf{n}_1(x_1), \mathbf{n}_2(x_2)$, they get values of P_Q equal to those in (Eq. 24). The messages sent back to the Referee encode the local results of measurements of $\mathbf{n}_1 \cdot \boldsymbol{\sigma} \otimes \mathbf{n}_2 \cdot \boldsymbol{\sigma}$, and the local measurement directions are suitably chosen as functions of x_1 and x_2 . The relation between Bell's inequalities and quantum communication complexity problems will be reviewed in more detail in (Sect. 6).

4.2.2 Philosophy or Physics? Which Assumptions?

The assumptions behind Bell's inequalities are often criticized as being “philosophical.” If we remind ourselves about Mach's influence on Einstein, philosophical discussions related to physics may be very fruitful.

For those who are, however, still skeptical one can argue as follows. The whole (relativistic) classical theory of physics is realistic (and local). Thus, we have an important exemplary realization of the postulates of local realism. Philosophical propositions could be defined as those which *are not* observationally or experimentally falsifiable at the given moment of the development of human knowledge or, in pure mathematical theory, are not logically derivable. Therefore, the *conjunction* of all assumptions of Bell's inequalities is not a philosophical statement, as it is *testable* both experimentally and logically (within the known current mathematical formulation of the fundamental laws of physics). Thus, Bell's theorem removed the question of the possibility of a local realistic description from the realm of philosophy. Now, this is just a question of a good experiment.

The other criticism is formulated in the following way. Bell's inequalities can be derived using a single assumption of the existence of a joint probability distribution for the observables involved in them, or that the probability calculus of the experimental propositions involved in the inequalities is of Kolmogorovian nature, and nothing more. But if we want to understand the violation of Bell's inequalities, we stumble on the following question: *Does the joint probability take into account the full experimental context or not?* The experimental context is in the present case (at least) the full state of the settings (m, n). Thus, if we use the same notation as above for the realistic values, this time applied to the possible results of measurements of observables, initially we can assume the existence of only $p(A_{1,1}, A_{1,2}, A_{2,1}, A_{2,2}; B_{1,1}, B_{1,2}, B_{2,1}, B_{2,2})$. Note that such a probability could be, for example, factorizable into $\prod_{n,m} P(A_{n,m} | B_{n,m})$. That is, one could, in such a case, have different probability distributions pertaining to different experimental contexts (which can even be defined through the choice of measurement settings in space-like separated laboratories!).

Let the discussion of this be from the quantum mechanical point of view, only because such considerations have a nice formal description within this theory, familiar to all physicists. Two observables, say $\hat{A}_1 \otimes \hat{B}_1$ and $\hat{A}_2 \otimes \hat{B}_2$, as well as other possible pairs are functions of two different *maximal* observables for the whole system (which are nondegenerate by definition). If one denotes such a maximal observable linked with $\hat{A}_m \otimes \hat{B}_n$ by $\hat{M}_{m,n}$ and its eigenvalues by $M_{m,n}$ the existence of the aforementioned joint probability is equivalent to the existence of a $p(M_{1,1}, M_{1,2}, M_{2,1}, M_{2,2})$ in the form of a proper probability distribution. Only if one assumes, additionally, context independence, can this be reduced to the question of the existence of (nonnegative) probabilities $P(A_1, A_2, B_1, B_2)$, where A_m and B_n are eigenvalues of $\hat{A}_m \otimes \mathbf{1}$ and $\mathbf{1} \otimes \hat{B}_n$, where, in turn, $\mathbf{1}$ is the unit operator for the given subsystem. While context independence is physically doubtful when the measurements are not spatially separated, and thus one can have mutual causal dependence, it is well justified for spatially separated measurements. That is, *locality* enters one's reasoning, whether we like it or not. Of course one cannot derive any Bell's inequality of the usual type if the random choice of settings is not independent of the distribution of A_1, A_2, B_1, B_2 , that is without (☞ Eq. 20).

There is yet another challenge to the set of assumptions presented above. It is often claimed that realism can be derived, once one considers the fact that maximally entangled quantum systems reveal perfect correlations, and one additionally assumes locality. Therefore, it would seem that the only basic assumption behind Bell's inequalities is locality, with the other auxiliary one of freedom. Such a claim is based on the ideas of EPR, who conjectured that one can introduce "elements of reality" of a remote system, provided this system is perfectly correlated with another system. To show the fallacy of such a hope, three particle correlations are now discussed, in the case of which consideration of just a few "elements of

“reality” reveals that they are a logically inconsistent notion. Therefore, they cannot be a starting point for deriving a self-consistent realistic theory. The three-particle reasoning is used here because of its beauty and simplicity, not because one cannot reach a similar conclusion for two-particle correlations.

4.3 Bell's Theorem Without Inequalities: Three Entangled Particles or More

As the simplest example, take a Greenberger–Horne–Zeilinger (Greenberger et al. 1989, 1990) (GHZ) state of $N = 3$ particles (Fig. 2):

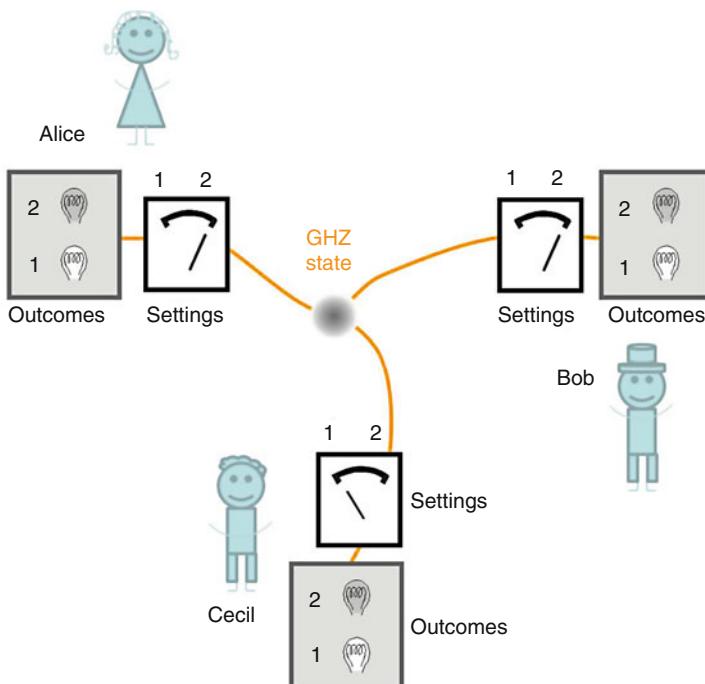

$$|\text{GHZ}\rangle = \frac{1}{\sqrt{2}}(|a\rangle|b\rangle|c\rangle + |a'\rangle|b'\rangle|c'\rangle) \quad (27)$$

where $\langle x|x' \rangle = 0$ ($x = a, b, c$, and kets denoted by one letter pertain to one of the particles). The observers, Alice, Bob, and Cecil measure the observables: $\hat{A}(\phi_A)$, $\hat{B}(\phi_B)$, $\hat{C}(\phi_C)$, defined by

$$\hat{X}(\phi_X) = |+, \phi_X\rangle\langle +, \phi_X| - |-, \phi_X\rangle\langle -, \phi_X| \quad (28)$$

Fig. 2

Test of the GHZ theorem. Alice, Bob, and Cecil are three separated parties who share three entangled particles in the GHZ state. Each of them is free to choose between two measurement settings, 1 and 2, and they observe flashes in their detection stations, which indicate one of the two possible measurement outcomes +1 or -1.

where

$$|\pm, \phi_X\rangle = \frac{1}{\sqrt{2}} (\pm i|x'\rangle + \exp(i\phi_X)|x\rangle) \quad (29)$$

and $\hat{X} = \hat{A}, \hat{B}, \hat{C}$. The quantum prediction for the expectation value of the product of the three local observables is given by

$$E(\phi_A, \phi_B, \phi_C) = \langle \text{GHZ} | \hat{A}(\phi_A) \hat{B}(\phi_B) \hat{C}(\phi_C) | \text{GHZ} \rangle = \sin(\phi_A + \phi_B + \phi_C) \quad (30)$$

Therefore, if $\phi_A + \phi_B + \phi_C = \pi/2 + k\pi$, quantum mechanics predicts perfect (anti)correlations. For example, for $\phi_A = \pi/2$, $\phi_B = 0$ and $\phi_C = 0$, whatever the results of local measurements of the observables, for, say, the particles belonging to the i th triple of the measured ensemble represented by the quantum state $|\text{GHZ}\rangle$, their product must be unity. In a local realistic theory, one would have

$$A^i(\pi/2)B^i(0)C^i(0) = 1 \quad (31)$$

where $X^i(\phi)$, $X = A, B$, or C is the local realistic value of a local measurement of the observable $\hat{X}(\phi)$ that *would have been obtained* for the i th particle triple, if the setting of the measuring device were ϕ . By locality $X^i(\phi)$ depends solely on the local parameter. The \bullet Eq. 31 indicates that we can predict, with certainty, the result of measuring the observable, pertaining to one of the particles (say c), by choosing to measure suitable observables for the other two. Hence, the values $X^i(\phi)$ are EPR elements of reality.

However, if the local apparatus settings are different, one *would have had*, for example,

$$A^i(0)B^i(0)C^i(\pi/2) = 1 \quad (32)$$

$$A^i(0)B^i(\pi/2)C^i(0) = 1 \quad (33)$$

$$A^i(\pi/2)B^i(\pi/2)C^i(\pi/2) = -1 \quad (34)$$

Yet, the four statements (31–34) are inconsistent within local realism. Since $X^i(\phi) = \pm 1$, if one multiplies side by side \bullet Eqs. 31–33, the result is

$$1 = -1 \quad (35)$$

This shows that the mere concept of the existence of “elements of physical reality” as introduced by EPR is in contradiction with quantum mechanical predictions. We have a “Bell’s theorem without inequalities” (Greenberger et al. 1989, 1990).

Some people still claim that EPR correlations together with the assumption of locality allow us to derive realism. The above example clearly shows that such a realism would allow us to infer that $1 = -1$.

4.4 Implications of Bell’s Theorem

Violations of Bell’s inequalities imply that the underlying *conjunction of assumptions of realism, locality, and “free will”* is not valid, and *nothing more*.

It is often said that the violations indicate “(quantum) nonlocality.” However, if one wants *nonlocality* to be *the implication*, one has to assume “free will” and realism. But this is only at the moment a philosophical choice (it seems that there is no way to falsify it). *It is not a necessary condition for violations of Bell’s inequalities.*

Bell's theorem shows that even a local inherently probabilistic hidden-variable theory cannot agree with all the predictions of the quantum theory (considerations are based on $p(A_1, A_2, B_1, B_2)$ without assuming its actual structure, or whether the distribution for a single run is essentially deterministic, all we require is a joint “coexistence” of the variables A_1, \dots, B_2 in a *theoretical* description). Therefore, the above statements cover theories that treat probabilities as irreducible, and for which one can define $p(A_1, A_2, B_1, B_2)$. Such theories contradict quantum predictions. This, for some authors, indicates that nature is nonlocal. While the mere existence of Bohm's model (Bohm 1952) demonstrates that nonlocal hidden-variables are a logically valid option, it is now known that there are plausible models, such as Leggett's crypto-nonlocal hidden-variable model (Leggett 2003), that are in disagreement with both quantum predictions and experiment (Gröblacher et al. 2007; Branciard et al. 2007). But, perhaps more importantly, if one is ready to consider inherently probabilistic theories, then there is no immediate reason to require the existence of (nonnegative and normalized) probabilities $p(A_{1,1}, \dots, B_{2,2})$. Violation of this condition on realism, together with locality, which allows us to reduce the distribution to $p(A_1, \dots, B_2)$, is not in a *direct* conflict with the theory of relativity, as it does not necessarily imply the possibility of signaling superluminally. To the contrary, quantum correlations cannot be used for direct communication between Alice to Bob, but still violate Bell's inequalities. It is therefore legitimate to consider quantum theory as a probability theory subject to, or even derivable from, more general principles, such as the non-signaling condition (Popescu and Rohrlich 1994; Barrett 2007) or information-theoretical principles (von Weizsäcker 1985; Zeilinger 1999; Pawłowski et al. 2009; Dakic and Brukner 2009).

Note that complementarity, inherent in the quantum formalism (which can be mathematically expressed as the nonexistence of joint probabilities for non-commuting, i.e., non-commensurable, observables), completely contradicts the form of realism defined above. So why quantum-nonlocality?

To put it short, Bell's theorem does not imply *any* property of quantum mechanics. It just tells us what it is not.

5 All Bell's Inequalities for Two Possible Settings on Each Side

A general method of deriving *all* standard Bell's inequalities shall now be presented (that is, Bell's inequalities involving two-outcome measurements and with two settings per observer). Although these will not be spelt out explicitly, all the assumptions discussed above are behind the algebraic manipulations leading to the inequalities. A derivation for the two-observer problem is presented in detail, because the generalization to more observers is, surprisingly, obvious.

Consider pairs of particles (say, photons) simultaneously emitted in well-defined opposite directions. After some time, the photons arrive at two very distant measuring devices A and B operated by Alice and Bob. Alice, chooses to measure either observable \hat{A}_1 or \hat{A}_2 , and Bob either \hat{B}_1 or \hat{B}_2 . The hypothetical results that they may get for the j th pair of photons are A_1^j and A_2^j , for Alice's two possible choices, and B_1^j and B_2^j , for Bob's. The numerical values of these results (+1 or -1) are defined by the two eigenvalues of the observables.

Since always either $|B_1^j - B_2^j| = 2$ and $|B_1^j + B_2^j| = 0$, or $|B_1^j - B_2^j| = 0$ and $|B_1^j + B_2^j| = 2$, with a similar property of Alice's hypothetical results, the following relation holds

$$|A_1^j \pm A_2^j| \cdot |B_1^j \pm B_2^j| = 0 \quad (36)$$

for all possible sign choices within $\textcircled{2}$ Eq. 36 except one, for which we have 4. Therefore

$$\sum_{k,l=0}^1 |(A_1^j + (-1)^k A_2^j)(B_1^j + (-1)^l B_2^j)| = 4 \quad (37)$$

or equivalently we have the set of identities

$$\sum_{s_1,s_2=-1}^1 S(s_1,s_2)[(A_1^j + s_1 A_2^j)(B_1^j + s_2 B_2^j)] = \pm 4 \quad (38)$$

with any $S(s_1,s_2) = \pm 1$. There are $2^2 = 16$ such S functions.

Imagine now that N pairs of photons are emitted, pair by pair (N is sufficiently large, such that $\sqrt{1/N} \ll 1$). The average value of the products of the local values is given by

$$E(A_n, B_m) = \frac{1}{N} \sum_{j=1}^N A_n^j B_m^j \quad (39)$$

where $n, m = 1, 2$.

Therefore, after averaging, the following single Bell-type inequality emerges:

$$\sum_{k,l=0}^1 |E(A_1, B_1) + (-1)^l E(A_1, B_2) + (-1)^k E(A_2, B_1) + (-1)^{k+l} E(A_2, B_2)| \leq 4 \quad (40)$$

or, equivalently, a series of inequalities:

$$-4 \leq \sum_{s_1,s_2=-1}^1 S(s_1,s_2)[E(A_1, B_1) + s_2 E(A_1, B_2) + s_1 E(A_2, B_1) + s_1 s_2 E(A_2, B_2)] \leq 4 \quad (41)$$

As the choice of the measurement settings is assumed to be statistically independent of the working of the source, that is, of the distribution of A_1 's, A_2 's, B_1 's, and B_2 's, the averages $E(A_n, B_m)$ cannot differ much, for high N , from the *actually observed* ones in the subsets of runs for which the given pair of settings was selected.

5.1 Completeness of the Inequalities

The inequalities form a complete set. That is, they define the faces of the convex polytope formed out of all possible local realistic models for the given set of measurements. Whenever the local realistic model exists, inequality $(\textcircled{40})$ is satisfied by its predictions. To prove the sufficiency of condition $(\textcircled{40})$, we construct a local realistic model for any correlation functions that satisfy it, that is, we are interested in the local realistic models for $E_{k_1 k_2}^{LR}$, such that they fully agree with the measured correlations $E(k_1, k_2)$ for all possible observables $k_1, k_2 = 1, 2$.

One can introduce \hat{E} which is a “tensor” or matrix built out of E_{ij} with $i, j = 1, 2$. If all its components can be derived from local realism, one must have

$$\hat{E}_{LR} = \sum_{\mathbf{A}, \mathbf{B}} P(\mathbf{A}, \mathbf{B}) \mathbf{A} \otimes \mathbf{B} \quad (42)$$

with $\mathbf{A} = (A_1, A_2)$, $\mathbf{B} = (B_1, B_2)$ and nonnegative probabilities $P(\mathbf{A}, \mathbf{B})$. The summation is over all possible values of \mathbf{A} and \mathbf{B} .

Let us ascribe for fixed s_1, s_2 , a hidden probability that $A_1 = s_1 A_2$ and $B_1 = s_2 B_2$ in the form familiar from [Eq. 40](#):

$$P(s_1, s_2) = \frac{1}{4} \left| \sum_{k_1, k_2=1}^2 s_1^{k_1-1} s_2^{k_2-1} E(k_1, k_2) \right| \quad (43)$$

Obviously these probabilities are positive. However, they sum up to identity only if inequality ([Eq. 40](#)) is saturated, otherwise there is a “probability deficit,” ΔP . This deficit can be compensated without affecting the correlation functions, see below.

First we construct the following structure, which is indeed the local realistic model of the set of correlation functions if the inequality is saturated:

$$\sum_{s_1, s_2=-1}^1 \Sigma(s_1, s_2) P(s_1, s_2) (1, s_1) \otimes (1, s_2) \quad (44)$$

where $\Sigma(s_1, s_2)$ is the sign of the expression within the modulus in [Eq. 43](#).

Now, if $\Delta P > 0$, a “tail” is added to this expression given by:

$$\frac{\Delta P}{16} \sum_{A_1=-1}^1 \sum_{A_2=-1}^1 \sum_{B_1=-1}^1 \sum_{B_2=-1}^1 (A_1, A_2) \otimes (B_1, B_2) \quad (45)$$

This “tail” does not contribute to the values of the correlation functions, because it represents the fully random noise. The sum of [Eq. 44](#) is a valid local realistic model for $\hat{E} = (E(1, 1), E(1, 2), E(2, 1), E(2, 2))$. The sole role of the “tail” is to make all hidden probabilities add up to 1.

To give the reader some intuitive grounds for the actual form and the completeness of the derived inequalities, some remarks shall now be given. The gist is that the consecutive terms in the inequalities are just expansion coefficients of the tensor \hat{E} in terms of a complete orthogonal sequence of basis tensors. Thus, the expansion coefficients represent the tensors in a one-to-one way.

In the four-dimensional real space, where both \hat{E}_{LR} and \hat{E} are defined, one can find an orthonormal basis set $\hat{S}_{s_1 s_2} = \frac{1}{2}(1, s_1) \otimes (1, s_2)$. Within these definitions the hidden probabilities acquire a simple form:

$$P(s_1, s_2) = \frac{1}{2} |\hat{S}_{s_1 s_2} \cdot \hat{E}| \quad (46)$$

where the dot denotes the scalar product in \mathbf{R}^4 . Now the local realistic correlations, \hat{E}_{LR} , can be expressed as:

$$\hat{E}_{LR} = \sum_{s_1, s_2=-1}^1 |\hat{S}_{s_1 s_2} \cdot \hat{E}| \Sigma(s_1, s_2) \hat{S}_{s_1 s_2} \quad (47)$$

The modulus of any number $|x|$ can be split into $|x| = x \operatorname{sign}(x)$, and we can always demand that the product $A_1 B_1$ has the same sign as the expression inside the modulus. Thus, we have

$$\hat{E} = \sum_{s_1, s_2=-1}^1 (\hat{S}_{s_1 s_2} \cdot \hat{E}) \hat{S}_{s_1 s_2} \quad (48)$$

The expression in the bracket is the coefficient of tensor \hat{E} in the basis $\hat{S}_{s_1 s_2}$. These coefficients are then summed over the same basis vectors, therefore the last equality appears.

5.2 Two-Qubit States That Violate the Inequalities

A general two-qubit state can be expressed in the following concise form

$$\hat{\rho} = \frac{1}{4} \sum_{\mu,\nu=0}^3 T_{\mu\nu} (\hat{\sigma}_\mu^1 \otimes \hat{\sigma}_\nu^2) \quad (49)$$

The two-qubit correlation function for measurements of spin 1 along direction $\mathbf{n}(1)$ and of spin 2 along $\mathbf{n}(2)$ is given by

$$E_{QM}(\mathbf{n}(1), \mathbf{n}(2)) = \text{Tr}[\hat{\rho}(\mathbf{n}(1) \cdot \hat{\mathbf{o}}^1 \otimes \mathbf{n}(2) \cdot \hat{\mathbf{o}}^2)] \quad (50)$$

and it reads

$$E_{QM}(\mathbf{n}(1), \mathbf{n}(2)) = \sum_{i,j=1}^3 T_{ij} n(1)_i n(2)_j \quad (51)$$

Two-particle correlations are fully defined once we know the components of T_{ij} , $i, j = 1, 2, 3$, of the tensor $\hat{\mathbf{T}}$. \bullet [Equation 51](#) can be put into a more convenient form:

$$E_{QM}(\mathbf{n}(1), \mathbf{n}(2)) = \hat{\mathbf{T}} \cdot \mathbf{n}(1) \otimes \mathbf{n}(2) \quad (52)$$

where “.” is the scalar product in the space of tensors, which in turn is isomorphic with $\mathbf{R}^3 \otimes \mathbf{R}^3$.

According to (40) the quantum correlation $E_{QM}(\mathbf{n}(1), \mathbf{n}(2))$ can be described by a local realistic model if and only if, for any choice of the settings $\mathbf{n}(1)^{k_1}$ and $\mathbf{n}(2)^{k_2}$, where $k_1, k_2 = 1, 2$, we have

$$\frac{1}{4} \sum_{k,l=1}^2 |\hat{\mathbf{T}} \cdot [\mathbf{n}(1)^1 + (-1)^k \mathbf{n}(1)^2] \otimes [\mathbf{n}(2)^1 + (-1)^l \mathbf{n}(2)^2]| \leq 1 \quad (53)$$

Since there always exist two mutually orthogonal unit vectors $\mathbf{a}(x)^1$ and $\mathbf{a}(x)^2$ such that

$$\mathbf{n}(x)^1 + (-1)^k \mathbf{n}(x)^2 = 2\alpha(x)_k \mathbf{a}(x)^k \text{ with } k = 1, 2 \quad (54)$$

and with $\alpha(x)_1 = \cos \theta(x)$, $\alpha(x)_2 = \sin \theta(x)$, we obtain

$$\sum_{k,l=1}^2 |\alpha(1)_k \alpha(2)_l \hat{\mathbf{T}} \cdot \mathbf{a}(1)^k \otimes \mathbf{a}(2)^l| \leq 1 \quad (55)$$

Note that $\hat{\mathbf{T}} \cdot \mathbf{a}(1)^k \otimes \mathbf{a}(2)^l$ is a component of the tensor $\hat{\mathbf{T}}$ after a transformation of the local coordinate systems of each of the particles into those where the two first basis vectors are $\mathbf{a}(x)^1$ and $\mathbf{a}(x)^2$. We shall denote such transformed components again by T_{kl} .

The necessary and sufficient condition for a two-qubit correlation to be described, within a local realistic model, is that in any plane of observation for each particle (defined by the two observation directions) we must have

$$\sum_{k,l=1}^2 |\alpha(1)_k \alpha(2)_l T_{kl}| \leq 1 \quad (56)$$

for arbitrary $\alpha(1)_k$, $\alpha(2)_l$.

Using the Cauchy inequality, we obtain

$$\sum_{k,l=1}^2 |\alpha(1)_k \alpha(2)_l T_{kl}| \leq \sqrt{\sum_{k,l=1}^2 T_{kl}^2} \quad (57)$$

Therefore, if

$$\sum_{k,l=1}^2 T_{kl}^2 \leq 1 \quad (58)$$

for any set of local coordinate systems, the two-particle correlation functions of the form of \bullet Eq. 51 can be understood within the local realism (in a two-settings-per-observer experiment).

As will be shown below, this condition is both necessary and sufficient.

5.2.1 Sufficient Condition for Violation of the Inequality

The full set of inequalities is derivable from the identity (\bullet 38) where we put non-factorable sign function $S(s_1, s_2) = \frac{1}{2}(1 + s_1) + (1 - s_1)s_2$. In this case, we obtain the CHSH inequality in its standard form

$$\left| \langle (A_1 + A_2)B_1 + (A_1 - A_2)B_2 \rangle_{\text{avg}} \right| \leq 2 \quad (59)$$

where $\langle \dots \rangle_{\text{avg}}$ denotes the average over an ensemble of particles. All other nontrivial inequalities are obtainable by all possible sign changes $X_k \rightarrow -X_k$ (with $k = 1, 2$ and $X = A, B$). It is easy to see that factorizable sign functions, such as, for example, $S(s_1, s_2) = s_1 s_2$, lead to trivial inequalities $|E(A_m, B_m)| \leq 1$. As noted above, the quantum correlation function, $E_Q(\mathbf{a}_k, \mathbf{b}_l)$, is given by the scalar product of the correlation tensor $\hat{\mathbf{T}}$ with the tensor product of the local measurement settings represented by unit vectors $\mathbf{a}_k \otimes \mathbf{b}_l$, that is, $E_Q(\mathbf{a}_k, \mathbf{b}_l) = (\mathbf{a}_k \otimes \mathbf{b}_l) \cdot \hat{\mathbf{T}}$. Thus, the condition for a quantum state endowed with the correlation tensor $\hat{\mathbf{T}}$ to satisfy the inequality (\bullet 59), is that for all directions $\mathbf{a}_1, \mathbf{a}_2, \mathbf{b}_1, \mathbf{b}_2$ we have

$$\left| \left[\left(\frac{\mathbf{a}_1 + \mathbf{a}_2}{2} \right) \otimes \mathbf{b}_1 + \left(\frac{\mathbf{a}_1 - \mathbf{a}_2}{2} \right) \otimes \mathbf{b}_2 \right] \cdot \hat{\mathbf{T}} \right| \leq 1 \quad (60)$$

where both sides of \bullet Eq. 59 were divided by 2.

Next notice that $\mathbf{A}_{\pm} = \frac{1}{2}(\mathbf{a}_1 \pm \mathbf{a}_2)$ satisfy the following relations: $\mathbf{A}_+ \cdot \mathbf{A}_- = 0$ and $\|\mathbf{A}_+\|^2 + \|\mathbf{A}_-\|^2 = 1$. Thus $\mathbf{A}_+ + \mathbf{A}_-$ is a unit vector, and \mathbf{A}_{\pm} represent its decomposition into two orthogonal vectors. If one introduces unit vectors \mathbf{a}_{\pm} such that $\mathbf{A}_{\pm} = a_{\pm}\mathbf{a}_{\pm}$, we have $a_+^2 + a_-^2 = 1$. Thus, we can put inequality (\bullet 60) into the following form:

$$|\hat{\mathbf{S}} \cdot \hat{\mathbf{T}}| \leq 1 \quad (61)$$

where $\hat{\mathbf{S}} = a_+ \mathbf{a}_+ \otimes \mathbf{b}_1 + a_- \mathbf{a}_- \otimes \mathbf{b}_2$. Note that since $\mathbf{a}_+ \cdot \mathbf{a}_- = 0$, we have $\hat{\mathbf{S}} \cdot \hat{\mathbf{S}} = 1$, that is, $\hat{\mathbf{S}}$ is a tensor of unit norm. Any tensor of unit norm, $\hat{\mathbf{U}}$, has the following Schmidt decomposition $\hat{\mathbf{U}} = \lambda_1 \mathbf{v}_1 \otimes \mathbf{w}_1 + \lambda_2 \mathbf{v}_2 \otimes \mathbf{w}_2$, where $\mathbf{v}_i \cdot \mathbf{v}_j = \delta_{ij}$, $\mathbf{w}_i \cdot \mathbf{w}_j = \delta_{ij}$ and $\lambda_1^2 + \lambda_2^2 = 1$. The (complete) freedom of the choice of the measurement directions \mathbf{b}_1 and \mathbf{b}_2 allows us by choosing \mathbf{b}_2 orthogonal to \mathbf{b}_1 to put $\hat{\mathbf{S}}$ in the form isomorphic with $\hat{\mathbf{U}}$, and the freedom of choice of \mathbf{a}_1 and \mathbf{a}_2 allows \mathbf{A}_+ and \mathbf{A}_- to be arbitrary orthogonal unit vectors, and \mathbf{a}_+ and \mathbf{a}_- to also be arbitrary. Thus $\hat{\mathbf{S}}$ can be equal to any unit tensor. To get the maximum of the left-hand side of \bullet Eq. 60, we Schmidt decompose the correlation tensor and take two terms of the decomposition which have the largest coefficients. In this way, we get a tensor $\hat{\mathbf{T}}'$, of Schmidt rank two.

We put $\hat{\mathbf{S}} = \frac{1}{\|\hat{\mathbf{T}}'\|} \hat{\mathbf{T}}'$, and the maximum is $\|\hat{\mathbf{T}}'\| = \sqrt{\hat{\mathbf{T}}' \cdot \hat{\mathbf{T}}'}$. Thus, in other words,

$$\max \left[\sum_{k,l=1}^2 T_{kl}^2 \right] \leq 1 \quad (62)$$

is the necessary and sufficient condition for the inequality (❷ 40) to hold, provided the maximization is taken over all local coordinate systems of two observers. The condition is equivalent to the necessary and sufficient condition of the Horodecki family (Horodecki et al. 1995) for violation of the CHSH inequality.

5.3 Bell's Inequalities for N Particles

Let us consider a Bell's inequality test with N observers. Each of them chooses between two possible observables, determined by local parameters $\mathbf{n}_1(j)$ and $\mathbf{n}_2(j)$, where $j = 1, \dots, N$. Local realism implies the existence of two numbers A_1^j and A_2^j , each taking values +1 or -1, which describe the predetermined result of a measurement by the j th observer for the two observables. The following algebraic identity holds:

$$\sum_{s_1, \dots, s_N=-1}^1 S(s_1, \dots, s_N) \prod_{j=1}^N [A_1^j + s_j A_2^j] = \pm 2^N \quad (63)$$

where $S(s_1, \dots, s_N)$ is an arbitrary “sign” function, that is, $S(s_1, \dots, s_N) = \pm 1$. It is a straightforward generalization of that for two observers as given in ❷ Eq. 38. The correlation function is the average over many runs of the experiment $E_{k_1, \dots, k_N} = \left\langle \prod_{j=1}^N A_{k_j}^j \right\rangle_{\text{avg}}$ with $k_1, \dots, k_N \in \{1, 2\}$. After averaging ❷ Eq. 63 over the ensemble of the runs, we obtain the Bell's inequalities. (This set of inequalities is a sufficient and necessary condition for the correlation functions entering them to have a local realistic model; compare it to the two-particle case in 5.1.)

$$\left| \sum_{s_1, \dots, s_N=-1}^1 S(s_1, \dots, s_N) \sum_{k_1, \dots, k_N=1}^2 s_1^{k_1-1} \dots s_N^{k_N-1} E_{k_1, \dots, k_N} \right| \leq 2^N \quad (64)$$

Since there are 2^{2^N} different functions S , the above inequality represents a set of 2^{2^N} Bell's inequalities.

All these boil down to just one inequality (!):

$$\sum_{s_1, \dots, s_N=-1}^1 \left| \sum_{k_1, \dots, k_N=1}^2 s_1^{k_1-1} \dots s_N^{k_N-1} E_{k_1, \dots, k_N} \right| \leq 2^N \quad (65)$$

The proof of this fact is a trivial exercise with the use of the property that either $|X| = X$ or $|X| = -X$, where X is a real number. An inequality equivalent to (65) was derived independently in Weinfurter and Żukowski (2001) and Werner and Wolf (2001). The presented derivation follows Żukowski and Brukner (2002) where the necessary and sufficient condition for the violation of the inequality was obtained.

5.4 N -Qubit Correlations

A general N -qubit state can be put in the form

$$\hat{\rho} = \frac{1}{2^N} \sum_{\mu_1, \dots, \mu_N=0}^3 T_{\mu_1 \dots \mu_N} (\otimes_{k=1}^N \hat{\sigma}_{\mu_k}^k) \quad (66)$$

Thus, the N qubit correlation function has the following structure

$$E_{QM}(\mathbf{n}(1), \mathbf{n}(2), \dots, \mathbf{n}(N)) = \hat{\mathbf{T}} \cdot \mathbf{n}(1) \otimes \mathbf{n}(2) \dots \otimes \mathbf{n}(N) \quad (67)$$

This expression when inserted into the Bell inequality gives

$$1/2^N \sum_{k_1, \dots, k_N=1} |\hat{\mathbf{T}} \cdot \prod_{x=1}^N (\mathbf{n}^1(x) + (-1)^x \mathbf{n}^2(x))| \leq 1$$

By introducing for every observer $x = 1, \dots, N$ two mutually orthogonal unit vectors $\mathbf{a}^1(x)$ and $\mathbf{a}^2(x)$, just as in (54), and denoting $\hat{\mathbf{T}} \cdot \mathbf{a}^{k_1}(1) \otimes \dots \otimes \mathbf{a}^{k_N}(N) = T_{k_1 \dots k_N}$, where $k_i = 1, 2, 3$, we obtain the necessary and sufficient condition for a description of the correlation function within local realism:

$$\sum_{k_1, k_2, \dots, k_N=1}^2 |\alpha(1)_{k_1} \alpha(2)_{k_2} \dots \alpha(N)_{k_N} T_{k_1 k_2 \dots k_N}| \leq 1 \quad (68)$$

for any possible choice of local coordinate systems for individual particles. Again if

$$\sum_{k_1, \dots, k_N=1}^2 T_{k_1 \dots k_N}^2 \leq 1 \quad (69)$$

for any set of local coordinate systems, the N -qubit correlation function can be described by a local realistic model. The proofs of these facts are generalizations of those presented earlier, pertaining to two particles. The sufficient condition for violation of the general Bell's inequality for N particles by a general state of N qubits can be found in Źukowski and Brukner (2002).

5.5 Concluding Remarks

The inequalities presented above represent the full set of standard “tight” Bell’s inequalities for an arbitrary number of parties. Any non-tight inequality is weaker than tight ones. Such Bell’s inequalities can be used to detect entanglement, however not as efficiently as entanglement witnesses. Nevertheless, they have the advantage over the witnesses, as they are system independent. They detect entanglement no matter the actual Hilbert space which describes the subsystems.

As will be shown below, the entanglement violating Bell’s inequalities analyzed above is directly applicable in some quantum informational protocols that beat any classical ones of the same kind. This will be shown via an explicit construction of such protocols.

6 Quantum Reduction of Communication Complexity

In his review paper entitled “Quantum Communication Complexity (A Survey)” Brassard (2003) posed a question: “*Can entanglement be used to save on classical communication?*” He continued that there are good reasons to believe at first that the answer to the question is negative. Holevo’s theorem (Holevo 1973) states that no more than n bits of classical information can be communicated between parties by the transmission of n qubits regardless of the coding scheme as long as no entanglement is shared between parties. If the

communicating parties share prior entanglement, twice as much classical information can be transmitted (this is the so-called “superdense coding” (Bennett and Wiesner 1992)), but no more. It is thus reasonable to expect that even if the parties share entanglement, no savings in communication can be achieved beyond that of the superdense coding ($2n$ bits per n qubits transmitted).

It is also well known that entanglement alone cannot be used for communication. Local operations performed on any subsystem of an entangled composite system cannot have any observable effect on any other subsystem; otherwise it could be exploited to communicate faster than light. One would thus intuitively conclude that entanglement is useless for saving communication. Brassard, however, concluded “... *all the intuition in this paragraph is wrong.*”

The topic of classical communication complexity was introduced and first studied by Yao (1979). A typical communication complexity problem can be formulated as follows. Let Alice and Bob be two separated parties who receive some input data of which they know only their own data and not the data of the partner. Alice receives an input string x and Bob an input string y and the goal for both of them is to determine the value of a certain function $f(x, y)$. Before they start the protocol, Alice and Bob are even *allowed to share (classically correlated) random strings* or any other data, which might improve the success of the protocols. They are allowed to process their data locally in whatever way. The obvious method to achieve the goal is for Alice to communicate x to Bob, which allows him to compute $f(x, y)$. Once obtained, Bob can then communicate the value $f(x, y)$ back to Alice. It is the topic of communication complexity to address the questions: *Could there be more efficient solutions for some functions $f(x, y)$? What are these functions?*

A trivial example that there could be more efficient solutions than the obvious one given above is a constant function $f(x, y) = c$, where c is a constant. Obviously here Alice and Bob do not need to communicate at all, as they can simply take c for the value of the function. However, there are functions for which the only obvious solution is optimal, that is, only the transmission of x to Bob warrants that he reaches the correct result. For instance, it is shown that n bits of communication are necessary and sufficient for Bob to decide whether or not Alice’s n -bit input is the same as his (Brassard 2003; Kushilevitz and Nisan 1997).

Generally, one might distinguish the following two types of communication complexity problems:

1. What is the minimal amount of communication (minimal number of bits) required for the parties to determine the value of the function with certainty?
2. What is the highest possible probability for the parties to arrive at the correct value for the function if only a *restricted* amount of communication is allowed?

Here, only the second class of problems will be considered. Note that in this case one does not insist on the correct value of the function to be obtained with certainty. While an error in computing the function is allowed, the parties try to compute it correctly with as high probability as possible.

From the perspective of the physics of quantum information processing, the natural question is: *Are there communication complexity tasks for which the parties could increase the success in solving the problem if they share prior entanglement?* In their original paper Cleve and Buhrman (1997) showed that entanglement can indeed be used to save classical communication. They showed that, to solve a certain three-party problem with certainty, the parties need to broadcast at least 4 bits of information in a classical protocol, whereas in the quantum protocol (with entanglement shared), it is sufficient for them to broadcast only 3 bits of

information. This was the first example of a communication complexity problem that could be solved with higher success than would be possible with any classical protocol. Subsequently, Buhrman et al. (1997) found a two-party problem that could be solved with a probability of success exceeding 85% and 2 bits of information communicated if prior shared entanglement is available, whereas the probability of success in a classical protocol could not exceed 75% with the same amount of communication.

The first problem whose quantum solution requires a significantly smaller amount of communication compared to classical solutions was discovered by Buhrman et al. (1999). They considered a k -party task, which requires roughly $k \ln k$ bits of communication in a classical protocol, and exactly k bits of classical communication if the parties are allowed to share prior entanglement. The quantum protocol of Buhrman et al. (1997) is based on the violation of the CHSH inequality by a two-qubit maximally entangled state. Similarly, the quantum protocols for multiparty problems (Buhrman et al. 1997, 1999; Cleve and Buhrman 1997) are based on an application of the GHZ-type argument against local realism for multi-qubit maximally entangled states. Galvao (2001) has shown an equivalence between the CHSH and GHZ tests for three particles and the two- and three-party quantum protocols of Buhrman et al. (1997), respectively. In a series of papers (Brukner et al. 2002, 2003, 2004b; Trojek et al. 2005), it was shown that entanglement violating Bell's inequality can always be exploited to find a better-than-any-classical solution to some communication complexity problems. In this brief overview, the approach mainly followed is the one introduced in these papers. This approach was further developed and applied in Augusiak and Horodecki (2006) and Tamir (2007) (see also Marcovitch and Reznik 2008).

6.1 The Problem and Its Optimal Classical Solution

Imagine several spatially separated partners, P_1 to P_N , each of which has some data known to him/her only, denoted here as X_i , with $i = 1, \dots, N$. They face a joint task: to compute the value of a function $T(X_1, \dots, X_N)$. This function depends on all data. Obviously, they can get the value of T by sending all their data to partner P_N , who does the calculation and announces the result. But are there ways to reduce the amount of communicated bits, that is, to reduce the communication complexity of the problem?

Assume that every partner P_k receives a two-bit string $X_k = (z_k, x_k)$ where $z_k, x_k \in \{0, 1\}$. We shall consider specific binary task functions that have the following form

$$T = f(x_1, \dots, x_N)(-1)^{\sum_{k=1}^N z_k}$$

where $f \in \{-1, 1\}$. The partners also know the probability distribution (“promise”) of the bit strings (“inputs”). There are two constraints on the problem. First, only distributions shall be considered that are completely random with respect to z_k 's, that is a class of the form $p(X_1, \dots, X_N) = 2^{-N} p'(x_1, \dots, x_N)$. Second, communication between the partners is restricted to $N - 1$ bits. Assume that we ask the last partner to give his/her answer $A(X_1, \dots, X_N)$, equal to ± 1 , to the question of what is the functional value of $T(X_1, \dots, X_N)$ in each run for the given set of inputs X_1, \dots, X_N .

For simplicity, we introduce $y_k = (-1)^{z_k}$, $y_k \in \{-1, 1\}$. We shall use y_k as a synonym of z_k . Since T is proportional to $\prod_k y_k$ the final answer A is completely random if it does not depend on *every* y_k . Thus, information on z_k 's from all $N - 1$ partners must somehow reach P_N .

Therefore, the only communication “trees” which might lead to success are those in which each P_k sends only a one-bit message $m_k \in \{0, 1\}$. Again we introduce $e_k = (-1)^{m_k}$ and e_k will be treated as a synonym of m_k .

The average success of a communication protocol can be measured with the following fidelity function

$$F = \sum_{X_1, \dots, X_N} p(X_1, \dots, X_N) T(X_1, \dots, X_N) A(X_1, \dots, X_N) \quad (70)$$

or equivalently

$$F = \frac{1}{2^N} \sum_{x_1, \dots, x_N=0}^1 p'(x_1, \dots, x_N) f(x_1, \dots, x_N) \sum_{y_1, \dots, y_N=-1}^1 \prod_{k=1}^N y_k A(x_1, \dots, x_N; y_1, \dots, y_N) \quad (71)$$

The probability of success is $P = (1 + F)/2$.

The first steps of a derivation of the reduced form of the fidelity function for an optimal classical protocol will now be presented (the reader may reconstruct the other steps or consult references Brukner et al. (2004b) and Trojek et al. (2005)). In a classical protocol, the answer A of the partner P_N can depend on the local input y_N , x_N , and messages, e_{i_1}, \dots, e_{i_l} , received directly from a subset of l partners P_{i_1}, \dots, P_{i_l} :

$$A = A(x_N, y_N, e_{i_1}, \dots, e_{i_l}) \quad (72)$$

Let us fix x_N and treat A as a function A_{x_N} of the remaining $l + 1$ dichotomic variables

$$y_N, e_{i_1}, \dots, e_{i_l}$$

That is, we now treat x_N as a fixed index. All such functions can be thought of as 2^{l+1} -dimensional vectors, because the values of each such function form a sequence of length equal to the number of elements in the domain. In the 2^{l+1} -dimensional space containing such functions, we have an orthogonal basis given by

$$V_{j_1 \dots j_l}(y_N, e_{i_1}, \dots, e_{i_l}) = y_N^j \prod_{k=1}^l e_{i_k}^{j_k} \quad (73)$$

where $j, j_1, \dots, j_l \in \{0, 1\}$. Thus, we can expand $A(x_N, y_N, e_{i_1}, \dots, e_{i_l})$ with respect to this basis and the expansion coefficients read

$$c_{j_1 \dots j_l}(x_N) = \frac{1}{2^{l+1}} \sum_{y_N, e_{i_1}, \dots, e_{i_l}=-1}^1 A(x_N, y_N, e_{i_1}, \dots, e_{i_l}) V_{j_1 \dots j_l}(y_N, e_{i_1}, \dots, e_{i_l}) \quad (74)$$

Since $|A| = |V_{j_1 \dots j_l}| = 1$, we have $|c_{j_1 \dots j_l}(x_N)| \leq 1$. The expansion is put into the expression (71) for F and

$$F = \frac{1}{2^N} \sum_{x_1, \dots, x_N=0}^1 g(x_1, \dots, x_N) \sum_{y_1, \dots, y_N=-1}^1 \prod_{h=1}^N y_h \left[\sum_{j_1, \dots, j_l=0}^1 c_{j_1 \dots j_l}(x_N) y_N^j \prod_{k=1}^l e_{i_k}^{j_k} \right] \quad (75)$$

is obtained, where $g(x_1, \dots, x_N) \equiv f(x_1, \dots, x_N) p'(x_1, \dots, x_N)$. Because $\sum_{y_N=-1}^1 y_N y_N^0 = 0$, and $\sum_{y_k=-1}^1 y_k e_k^0 = 0$, only the term with all j, j_1, \dots, j_l equal to unity can give a nonzero contribution to F . Thus, A in F can be replaced by

$$A' = y_N c_N(x_N) \prod_{k=1}^l e_{i_k} \quad (76)$$

where $c_N(x_N)$ stands for $c_{11\dots 1}(x_N)$. Next, notice that, for example, e_{i_1} , can depend only on local data x_{i_1}, y_{i_1} and the messages obtained by P_{i_1} from a subset of partners: e_{p_1}, \dots, e_{p_m} . This set does not contain any of the e_{i_k} 's of the formula (Eq. 76) above. In analogy with A , the function e_{i_1} , for a fixed x_{i_1} , can be treated as a vector, and thus can be expanded in terms of orthogonal basis functions (of a similar nature as Eq. 73), etc. Again, the expansion coefficients satisfy $|c'_{j_1\dots j_m}(x_{i_1})| \leq 1$. If we put this into A' , we obtain a new form of F , which after a trivial summation over y_N and y_{i_1} depends on $c_N(x_N)c_{i_1}(x_i)\prod_{k=2}^l e_{i_k}$, where $c_{i_1}(x_i)$ stands for $c_{11\dots 1}(x_{i_1})$, and its modulus is again bounded by 1. Note that y_N and y_{i_1} disappear, as $y_k^2 = 1$.

As each message appears in the product only once, we continue this procedure of expanding those messages which depend on earlier messages, till it halts. The final reduced form of the formula for the fidelity of an optimal protocol reads

$$F = \sum_{x_1, \dots, x_N=0}^1 g(x_1, \dots, x_N) \prod_{n=1}^N c_n(x_n) \quad (77)$$

with $|c_n(x_n)| \leq 1$. Since F in Eq. 77 is linear in every $c_n(x_n)$, its extrema are at the limiting values $c_n(x_n) = \pm 1$. In other words, a Bell-like inequality $|F| \leq \text{Max}(F) \equiv B(N)$ gives the upper fidelity bound. Note that the above derivation shows that optimal classical protocols include one in which partners P_1 to P_{N-1} send to P_N one-bit messages which encode the value of $e_k = y_k c(x_k)$, where $k = 1, 2, \dots, N - 1$.

6.2 Quantum Solutions

The inequality for F suggests that some problems may have quantum solutions, which surpass any classical ones in their fidelity. Simply, one may use an entangled state $|\psi\rangle$ of N qubits that violates the inequality. Send to each of the partners one of the qubits. In a protocol run all N partners make measurements on the local qubits, the settings of which are determined by x_k . They measure a certain qubit observable $\mathbf{n}_k(x_k) \cdot \boldsymbol{\sigma}$. The measurement results $\gamma_k = \pm 1$ are multiplied by y_k and the partner P_k for $1 \leq k \leq N - 1$, sends a bit message to P_N encoding the value of $m_k = y_k \gamma_k$. The last partner calculates $y_N \gamma_N \prod_{k=1}^{N-1} m_k$, and announces this as A . The average fidelity of such a process is

$$F = \sum_{x_1, \dots, x_N=0}^1 g(x_1, \dots, x_N) \langle \psi | \otimes_{k=1}^N (\mathbf{n}_k(x_k) \cdot \boldsymbol{\sigma}_k) | \psi \rangle \quad (78)$$

and in certain problems can even reach *unity*.

For some tasks, the quantum versus classical fidelity ratio grows *exponentially* with N . This is the case, for example, for the so-called *modulo-4 sum* problem. Each partner receives a two-bit input string ($X_k = 0, 1, 2, 3$; $k = 1, \dots, N$). The promise is that X_k s are distributed such that $(\sum_{k=1}^N X_k) \bmod 2 = 0$. The task is: P_N must tell whether the sum modulo-4 of all inputs is 0 or 2. (It can be formulated in terms of a task function $T = 1 - (\sum_{k=1}^N X_k) \bmod 4$. An alternative formulation of the problem reads $f = \cos(\frac{\pi}{2} \sum_{k=1}^N X_k)$ with $p' = 2^{-N+1} |\cos(\frac{\pi}{2} \sum_{k=1}^N X_k)|$.)

For this problem, the classical fidelity bounds decrease exponentially with N , that is $B(F) \leq 2^{-K+1}$, where $K = N/2$ for even and $K = (N+1)/2$ for odd number of parties.

If we use the N qubit GHZ states: $|GHZ\rangle = \frac{1}{\sqrt{2}}(|z+, \dots, z+\rangle + |z-, \dots, z-\rangle)$, where $|z\pm\rangle$ is the state of spin ± 1 along the z -axis, and suitable pairs of local settings, the associated Bell's inequality can be violated maximally. Thus, we have a quantum protocol that always gives the correct answer.

In all quantum protocols considered here, entanglement that leads to a violation of Bell's inequality is a resource that allows for better-than-classical efficiency of the protocol. Surprisingly, we can also show a version of a quantum protocol without entanglement (Galvão 2001; Trojek et al. 2005). The partners exchange a single qubit, P_k to P_{k+1} and so on, and each of them makes a suitable unitary transformation on it (which depends on z_k and x_k). The partner P_N , who receives the qubit as the last one, additionally performs a dichotomic measurement. The result we get is equal to T . For details, including an experimental realization, see Trojek et al. (2005). The obvious conceptual advantage of such a procedure is that the partners exchange a single qubit, from which, due to the Holevo bound (Holevo 1973), we can read out at most one bit of information. In contrast with the protocol involving entanglement, no classical transfer of any information is required, except from the announcement by P_N of his measurement result!

In summary, if we have a pure entangled state of many qubits (this can be generalized to higher-dimensional systems and Bell's inequalities involving more than two measurement settings per observer), there exists a Bell's inequality that is violated by this state. This inequality has some coefficients $g(x_1, \dots, x_n)$, in front of correlation functions, that can always be renormalized in such a way that

$$\sum_{x_1, \dots, x_n=0}^1 |g(x_1, \dots, x_n)| = 1$$

The function g can always be interpreted as a product of the dichotomic function $f(x_1, \dots, x_n) = \frac{g(x_1, \dots, x_n)}{|g(x_1, \dots, x_n)|} = \pm 1$ and a probability distribution $p'(x_1, \dots, x_n) = |g(x_1, \dots, x_n)|$. Thus, we can construct a communication complexity problem that is tailored to a given Bell's inequality, with task function $T = \prod_i^N y_i f$. All this can be extended beyond qubits, see Brukner et al. (2002, 2003).

As was shown, for three or more parties, $N \geq 3$, quantum solutions for certain communication complexity problems can achieve probabilities of success of unity. This is not the case for $N = 2$ and the problem based on the CHSH inequality. The maximum quantum value for the left-hand side of the CHSH inequality (► 25) is just $\sqrt{2} - 1$. This is much bigger than the Bell bound of 0, but still not the largest possible value, for an arbitrary theory that is not following local realism, which equals 1. Because the maximum possible violation of the inequality is not attainable by quantum mechanics, several questions arise. Is this limit forced by the theory of probability, or by physical laws? We will address this question in the next section and we will look at the consequences of the maximal logically possible violation of the CHSH inequality.

6.3 Stronger-Than-Quantum Correlations

The Clauser–Horne–Shimony–Holt (CHSH) inequality (Clauser et al. 1969) for local realistic theories gives the upper bound on a certain combination of correlations between two space-like separated experiments. Consider Alice and Bob who independently perform one out of two

measurements on their part of the system, such that in total there are four experimental setups: $(x, y) = (0, 0), (0, 1), (1, 0)$, or $(1, 1)$. For any local hidden variable theory, the CHSH inequality must hold. We put it in the following form:

$$\begin{aligned} p(a = b|x = 0, y = 0) + p(a = b|x = 0, y = 1) + p(a = b|x = 1, y = 0) \\ + p(a = -b|x = 1, y = 1) \leq 3 \end{aligned} \quad (79)$$

or equivalently,

$$\sum_{x,y=0,1} p(a \oplus b = x \cdot y) \leq 3 \quad (80)$$

In the latter form, we interpret the dichotomic measurement results as binary values, 0 or 1, and their relations are “modulo 2 sums,” denoted here by \oplus . We have $0 \oplus 0 = 1 \oplus 1 = 0$ and $0 \oplus 1 = 1$. For example, $p(a = b|x = 0, y = 0)$ is the probability that Alice’s and Bob’s outcomes are the same when she chooses setting $x = 0$ and he setting $y = 0$.

As discussed in previous sections, quantum mechanical correlations can violate the local realistic bound of inequality (• 80) and the limit was proven by Cirel’son (1980) to be $2 + \sqrt{2}$. Popescu and Rohrlich (1994) asked why quantum mechanics allows a violation of the CHSH inequality with a value of $2 + \sqrt{2}$, but not more, though the maximal logically possible value is 4. Would a violation with a value larger than $2 + \sqrt{2}$ lead to (superluminal) signaling? If this were true, then quantum correlations could be understood as maximal allowed correlations respecting non-signaling requirement. This could give us an insight into the origin of quantum correlations, without any use of the Hilbert space formalism.

The non-signaling condition is equivalent to the requirement that the marginals are independent of the partner’s choice of setting

$$p(a|x, y) \equiv \sum_{b=0,1} p(a, b|x, y) = p(a|x) \quad (81)$$

$$p(b|x, y) \equiv \sum_{a=0,1} p(a, b|x, y) = p(b|y) \quad (82)$$

where $p(a, b|x, y)$ is the joint probability for outcomes a and b to occur, given x and y are the choices of measurement settings respectively, $p(a|x)$ is the probability for outcome a , given x is the choice of measurement setting and $p(b|y)$ similarly. Popescu and Rohrlich constructed a toy-theory where the correlations reach the maximal algebraic value of 4 for left-hand expression of the inequality (• 79), but are nevertheless not in contradiction with no-signaling. The probabilities in the toy model are given by

$$\left. \begin{array}{l} p(a = 0, b = 0|x, y) = \frac{1}{2} \\ p(a = 1, b = 1|x, y) = \frac{1}{2} \\ p(a = 1, b = 0|x, y) = \frac{1}{2} \\ p(a = 0, b = 1|x, y) = \frac{1}{2} \end{array} \right\} \begin{array}{l} \text{if } xy \in \{00, 01, 10\} \\ \text{if } xy = 11 \end{array} \quad (83)$$

Indeed we have

$$\sum_{x,y=0,1} p(a \oplus b = x \cdot y) = 4 \quad (84)$$

Van Dam (2000) and, independently, Cleve considered how plausible are stronger-than-quantum correlations from the point of view of communication complexity, which describes how much communication is needed to evaluate a function with distributed inputs. It was shown that the existence of correlations that maximally violate the CHSH inequality would allow us to perform all distributed computations (between two parties) of dichotomic functions with a communication constraint of just one bit. If one is ready to believe that nature should not allow for “easy life” concerning communication problems, this could be a reason why superstrong correlations are indeed not possible.

Instead of superstrong correlations, one usually speaks about a “nonlocal box” (NLB), an imaginary device that takes as inputs x at Alice’s and y at Bob’s side, and outputs a and b at respective sides, such that $a \oplus b = x \cdot y$. Quantum mechanical measurements on a maximally entangled state allow for a success probability of $p = \cos^2 \frac{\pi}{8} = \frac{2+\sqrt{2}}{4} \approx 0.854$ at the game of simulating NLBs. Recently, it was shown that in any “world” in which it is possible to implement an approximation to the NLB, that works correctly with probability greater than $\frac{3+\sqrt{6}}{6} = 90.8\%$, for all distributed computations of dichotomic functions with a one-bit communication constraint, one can find a protocol that always gives the correct values (Brassard et al. 2006). This bound is an improvement over van Dam’s one, but still has a gap with respect to the bound imposed by quantum mechanics.

6.3.1 Superstrong Correlations Trivialize Communication Complexity

We shall present a proof that availability of a perfect NLB would allow for a solution of a general communication complexity problem for a binary function, with an exchange of a single bit of information. The proof is due to van Dam (2000).

Consider a Boolean function $f: \{0, 1\}^n \rightarrow \{0, 1\}$, which has as inputs two n -bit strings $\mathbf{x} = (x_1, \dots, x_n)$ and $\mathbf{y} = (y_1, \dots, y_n)$. Suppose that Alice receives the \mathbf{x} string and Bob, who is separated from Alice, the \mathbf{y} -string, and they are to determine the function value $f(\mathbf{x}, \mathbf{y})$ by communicating as little as possible. They have, however, NLBs as resources.

First, let us notice that any dichotomic function $f(\mathbf{x}, \mathbf{y})$ can be rewritten as a finite summation:

$$f(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{2^n} P_i(\mathbf{x}) Q_i(\mathbf{y}) \quad (85)$$

where $P(\mathbf{x})$ are polynomials in $\mathbf{x} \in \{0, 1\}$ and $Q_i(\mathbf{y}) = y_1^{i_1} \cdot \dots \cdot y_n^{i_n}$ are monomials in $y_i \in \{0, 1\}$ with $i_1, \dots, i_n \in \{0, 1\}$. Note that the latter ones constitute an orthogonal basis in a 2^n -dimensional space of polynomials with no higher power of any variable than 1. The decomposed function f is treated as a function of y ’s, while the inputs x_1, \dots, x_n are considered as indices numbering functions f . Note that there are 2^n different monomials. Alice can locally compute all the P_i values by herself and likewise Bob can compute all Q_i by himself. These values determine the settings of Alice and Bob that will be chosen in the i th run of the experiment. Note that to this end they need, in general, exponentially many NLBs. Alice and Bob perform for every $i \in \{1, \dots, 2^n\}$ a measurement on the i th NLB in order to obtain without any communication a collection of bit values a_i and b_i , with the property $a_i \oplus b_i = P_i(\mathbf{x}) Q_i(\mathbf{y})$. Bob can add all his b_i to $\sum_{i=1}^{2^n} b_i$ values without requiring any information from Alice, and he can broadcast this single bit to Alice. She, on her part, computes the sum of her a_i to $\sum_{i=1}^{2^n} a_i$ and adds Bob’s bit to it. The final result

$$\sum_{i=1}^{2^n} (a_i \oplus b_i) = \sum_{i=1}^{2^n} P_i(\mathbf{x}) Q_i(\mathbf{y}) = f(\mathbf{x}, \mathbf{y}) \quad (86)$$

is the function value. Thus, *superstrong correlations trivialize every communication complexity problem*.

7 The Kochen–Specker Theorem

In the previous sections, we saw that tests of Bell's inequalities are not only theory-independent tests of nonclassicality, but also have applications in quantum information protocols. Examples are communication complexity problems (Brassard 2003, Brukner et al. 2004b), entanglement detection (Hyllus et al. 2005), security of key distribution (Ekert 1991; Scarani and Gisin 2001; Acín et al. 2006), and quantum state discrimination (Schmid et al. 2008). Thus, entanglement which violates local realism can be seen as a resource for efficient information processing. Can quantum contextuality – the fact that quantum predictions disagree from those of non-contextual hidden-variable theories – also be seen as such a resource? An affirmative answer shall be given to this question by considering an explicit example of a quantum game.

The Kochen–Specker theorem is a “no go” theorem that proves a contradiction between predictions of quantum theory and those of *non-contextual* hidden variable theories. It was proved by Bell (1966), and independently by Kochen and Specker (1967). The non-contextual hidden-variable theories are based on the conjecture of the following three assumptions:

1. *Realism*: It is a model that allows us to use all variables $A_m(n)$ in the theoretical description of the experiment, where $A_m(n)$ gives the value of some observable A_m which *could* be obtained if the knob setting were at positions m . The index n describes the entire experimental “context” in which A_m is measured and is operationally defined through the positions of all other knob settings in the experiment, which are used to measure other observables jointly with A_m . All $A_m(n)$'s are treated as, perhaps, unknown, but still fixed, (real) numbers, or variables for which a proper joint probability distribution can be defined.
2. *Non-contextuality*: The value assigned to an observable $A_m(n)$ of an individual system is independent of the experimental context n in which it is measured, in particular of any properties that are measured *jointly* with that property. This implies that $A_m(n) = A_m$ for all contexts n .
3. “Free will.” The experimenter is free to choose the observable and its context. The choices are independent of the actual hidden values of A_m 's, etc.

Note that “non-contextuality” implies locality (i.e., non-contextually with respect to a remote context), but there is no implication the other way round. One might have theories which are local, but locally contextual.

It should be stressed that the local realistic and non-contextual theories provide us with predictions, which can be tested experimentally, and which can be derived *without making any reference to quantum mechanics* (though many derivations in the literature give exactly the opposite impression). In order to achieve this, it is important to realize that predictions for non-contextual realistic theories can be derived in a completely operational way (Simon et al. 2001). For concreteness, imagine that an observer wants to perform a measurement of an

observable, say the square, $S_{\mathbf{n}}^2$, of a spin component of a spin-1 particle along a certain direction \mathbf{n} . There will be an experimental procedure for trying to do this as accurately as possible. This procedure will be referred to by saying that one sets the “control switch” of one’s apparatus to the position \mathbf{n} . In all the experiments that will be discussed, only a finite number of different switch positions is required. By definition, different switch positions are clearly distinguishable for the observer, and the switch position is all he knows about. Therefore, in an operational sense, the measured physical observable is entirely defined by the switch position. From the above definition, it is clear that the same switch position can be chosen again and again in the course of an experiment. Notice that in such an approach as described above, it does not matter which observable is “really” measured and to what precision. One just derives general predictions, provided that certain switch positions are chosen.

In the original Kochen–Specker proof (Kochen and Specker 1968), the observables that are considered are squares of components of spin 1 along various directions. Such observables have values 1 or 0, as the components themselves have values 1, 0, or -1 . The squares of spin components $\hat{S}_{\mathbf{n}_1}^2$, $\hat{S}_{\mathbf{n}_2}^2$, and $\hat{S}_{\mathbf{n}_3}^2$ along any three orthogonal directions \mathbf{n}_1 , \mathbf{n}_2 , and \mathbf{n}_3 can be measured jointly. Simply, the corresponding quantum operators commute with each other. In the framework of a hidden-variable theory, one assigns to an individual system a set of numerical values, say $+1, 0, +1, \dots$ for the square of spin component along each direction $S_{\mathbf{n}_1}^2, S_{\mathbf{n}_2}^2, S_{\mathbf{n}_3}^2, \dots$ that can be measured on the system. If any of the observables is chosen to be measured on the individual system, the result of the measurement would be the corresponding value. In a non-contextual hidden variable theory, one has to assign to an observable, say $S_{\mathbf{n}_1}^2$, the *same* value independently of whether it is measured in an experimental procedure jointly as a part of some set $\{S_{\mathbf{n}_1}^2, S_{\mathbf{n}_2}^2, S_{\mathbf{n}_3}^2\}$ or of some other set $\{S_{\mathbf{n}_1}^2, S_{\mathbf{n}_4}^2, S_{\mathbf{n}_5}^2\}$ of physical observables, where $\{\mathbf{n}_1, \mathbf{n}_2, \mathbf{n}_3\}$ and $\{\mathbf{n}_1, \mathbf{n}_4, \mathbf{n}_5\}$ are triads of orthogonal directions. Note that within quantum theory, some of the operators corresponding to the observables from the first set may *not commute* with some corresponding to the observables from the second set.

The squares of spin components along orthogonal directions satisfy

$$\hat{S}_{\mathbf{n}_1}^2 + \hat{S}_{\mathbf{n}_2}^2 + \hat{S}_{\mathbf{n}_3}^2 = s(s+1) = 2 \quad (87)$$

This is *always* so for a particle of spin 1 ($s = 1$). This implies that for every measurement of three squares of mutually orthogonal spin components, two of the results will be equal to one, and one of them will be equal to zero. The Kochen–Specker theorem considers a set of triads of orthogonal directions $\{\mathbf{n}_1, \mathbf{n}_2, \mathbf{n}_3\}, \{\mathbf{n}_1, \mathbf{n}_4, \mathbf{n}_5\}, \dots$, for which at least some of the directions have to appear in several of the triads. The statement of the theorem is that there are sets of directions for which it is not possible to give any assignment of 1’s and 0’s to the directions consistent with the constraint (87). The original theorem in Kochen and Specker (1968) used 117 vectors, but this was subsequently reduced to 33 vectors (Peres 1991) and 18 vectors (Cabello et al. 1996). Mathematically, the contradiction with quantum predictions has its origin in the fact that the classical structure of non-contextual hidden variable theories is represented by commutative algebra, whereas quantum mechanical observables need not be commutative, making it impossible to embed the algebra of these observables in a commutative algebra.

The disproof of non-contextually relies on the assumption that the same value is assigned to a given physical observable, $\hat{S}_{\mathbf{n}}^2$, regardless with which two other observables the experimenter chooses to measure it. In quantum theory, the additional observables from one of those sets correspond to operators that do not commute with the operators corresponding to additional observables from the other set. As was stressed in a masterly review on hidden

variable theories by Mermin (1993), Bell wrote (Bell 1966): “These different possibilities require different experimental arrangements; there is no *a priori* reason to believe that the results . . . should be the same. The result of observation may reasonably depend not only on the state of the system (including hidden variables) but also on the complete disposition apparatus.” Nevertheless, as Bell himself showed, the disagreement between predictions of quantum mechanics and of the hidden-variables theories can be strengthened if non-contextuality is replaced by a much more compelling assumption of locality. Note that in Bohr’s doctrine of the inseparability of the object and the measuring instrument, an observable *is* defined through the entire measurement procedure applied to measure it. Within this doctrine one would not speak about measuring the same observable in different contexts, but rather about measuring entirely different maximal observables, and deriving from it the value of a degenerate observable. Note that the Kochen–Specker argument necessarily involves degenerate observables. This is why it does not apply to single qubits.

7.1 A Kochen–Specker Game

A quantum game will now be considered which is based on the Kochen–Specker argument strengthened by the locality condition (see Svozil (2004)). A pair of entangled spin 1 particles is considered which forms a singlet state with total spin 0. A formal description of this state is given by

$$|\Psi\rangle = \frac{1}{\sqrt{3}} (|1\rangle_n | -1\rangle_n + | -1\rangle_n | 1\rangle_n - | 0\rangle_n | 0\rangle_n) \quad (88)$$

where, for example, $|1\rangle_n | -1\rangle_n$ is the state of the two particles with spin projection +1 for the first particle and spin projection −1 for the second particle 1 along the same direction \mathbf{n} . It is important to note that this state is invariant under a change of the direction \mathbf{n} . This implies that if the spin components for the two particles are measured along an arbitrary direction, however the same on both sides, the sum of the two local results is always zero. This is a direct consequence of the conservation of angular momentum.

Let us present the quantum game introduced in Cleve et al. (2004). The requirement in the proof of the Kochen–Specker theorem can be formulated as the following problem in geometry. There exists an explicit set of vectors $\{\mathbf{n}_1, \dots, \mathbf{n}_m\}$ in \mathbb{R}^3 that cannot be colored in red (i.e., assign the value 1 to the spin squared component along that direction) or blue (i.e., assign the value 0) such that both of the following conditions hold:

1. For every orthogonal pair of vectors \mathbf{n}_i and \mathbf{n}_j , they are not both colored blue.
2. For every mutually orthogonal triple of vectors \mathbf{n}_i , \mathbf{n}_j , and \mathbf{n}_k , at least one of them is colored blue.

For example, the set of vectors can consist of 117 vectors from the original Kochen–Specker proof (Kochen and Specker 1968), 33 vectors from Peres’ proof or 18 vectors from Cabello’s proof (Cabello et al. 1996).

The Kochen–Specker game employs the above sets of vectors. Consider two separated parties, Alice and Bob. Alice receives a random triple of orthogonal vectors as her input and Bob receives a single vector randomly chosen from the triple as his input. Alice is asked to give a trit indicating which of her three vectors is assigned color red or 1 (implicitly, the other two vectors are assigned color blue or 0). Bob outputs a bit assigning a color to his vector. The

requirement in the game is that Alice and Bob assign the same color to the vector that they receive in common. It is straightforward to show that the existence of a perfect classical strategy in which Alice and Bob can share classically correlated strings for this game would violate the reasoning used in the Kochen–Specker theorem. On the other hand, there is a perfect quantum strategy using the entangled state (☞ Eq. 88). If Alice and Bob share two particles in this state, Alice can perform a measurement of squared spin components pertaining to directions $\{\mathbf{n}_i, \mathbf{n}_j, \mathbf{n}_k\}$, which are equal to those of the three input vectors, and Bob measures squared spin component in direction \mathbf{n}_l for his input. Then Bob's measurement will necessarily yield the same answer as the measurement by Alice along the same direction.

Concluding this section, we note that quantum contextuality is also closely related to quantum error correction (DiVincenzo and Peres 1997), quantum key distribution (Nagata 2005), one-location quantum games (Aharon and Vaidman 2008), and entanglement detection between internal degrees of freedom.

8 Temporal Bell's Inequalities (Leggett–Garg Inequalities)

In the last section, one more basic information-processing task, the random access code problem, will be considered. It can be solved with a quantum setup with a higher efficiency than is classically possible. It will be shown that the resource for better-than-classical efficiency is a violation of “temporal Bell's inequalities” – the inequalities that are satisfied by temporal correlations of certain classes of hidden-variable theories. Instead of considering correlations between measurement results on distantly located physical systems, here the focus is on one and the same physical system and there is an analysis of the correlations between measurement outcomes at different times. The inequalities were first introduced by Leggett and Garg (1985), Leggett (2002) in the context of testing superpositions of macroscopically distinct quantum states. Since the aim here is different, we shall discuss general assumptions which allow us to derive temporal Bell's inequalities irrespective of whether the object under consideration is macroscopic or not. This is why the assumptions differ from the original ones of Leggett and Garg (1985), and Leggett (2002). Compare also to Paz (1993), Shafee and Golshani (2003), and Brukner et al. (2004a).

Theories which are based on the conjunction of the following four assumptions are now considered. (There is one more difference between the present approach and that of Leggett and Garg (1985) and Leggett (2002). While there the observer measures a single observable having a choice between different times of measurement, here, at any given time, the observer has a choice between two (or more) different measurement settings. One can use both approaches to derive temporal Bell's inequalities.)

1. *Realism:* It is a model that allows us to use all variables $A_m(t)$ $m = 1, 2, \dots$ in the theoretical description of the experiment performed at time t , where $A_m(t)$ gives the value of some observable, which *could* be obtained if it were measured at time t . All $A_m(t)$'s are treated as perhaps unknown, but still fixed numbers, or variables for which a proper joint probability distribution can be defined.
2. *Non-invasiveness:* The value assigned to an observable $A_m(t_1)$ at time t_1 is independent whether or not a measurement was performed at some earlier time t_0 or which observable $A_n(t_0)$ $n = 1, 2, \dots$ at that time was measured. In other words, (actual or potential) measurement values $A_m(t_1)$ at time t_1 are *independent* of the measurement settings chosen at earlier times t_0 .

3. *Induction*: The standard arrow of time is assumed. In particular, the values $A_m(t_0)$ at earlier times t_0 do not depend on the choices of measurement settings at later times t_1 . (Note that this already follows from the “noninvasiveness” when applied symmetrically to both arrows of time.)
4. “*Free will*”: The experimenter is free to choose the observable. The choices are independent of the actual hidden values of A_m 's, etc.

Consider an observer and allow her to choose at time t_0 and at some later time t_1 to measure one of two dichotomic observables $A_1(t_i)$ and $A_2(t_i)$, $i \in \{0, 1\}$. The assumptions given above imply the existence of numbers for $A_1(t_i)$ and $A_2(t_i)$, each taking values either +1 or -1, which describe the (potential or actual) predetermined result of the measurement. For the temporal correlations in an individual experimental run, the following identity holds: $A_1(t_0)[A_1(t_1) - A_2(t_1)] + A_2(t_0)[A_1(t_1) + A_2(t_1)] = \pm 2$. With similar steps as in the derivation of the standard Bell's inequalities, one easily obtains:

$$p(A_1A_1 = 1) + p(A_1A_2 = -1) + p(A_2A_1 = 1) + p(A_2A_2 = -1) \leq 3 \quad (89)$$

where we omit the dependence on time.

An important difference between tests of non-contextuality and temporal Bell's inequalities is that the latter are also applicable to single qubits or *two-dimensional* quantum systems. The temporal correlation function will now be calculated for consecutive measurements of a single qubit. Take an arbitrary mixed state of a qubit, written as $\rho = \frac{1}{2}(\mathbf{1} + \mathbf{r} \cdot \boldsymbol{\sigma})$, where $\mathbf{1}$ is the identity operator, $\boldsymbol{\sigma} \equiv (\sigma_x, \sigma_y, \sigma_z)$ are the Pauli operators for three orthogonal directions x, y , and z , and $\mathbf{r} \equiv (r_x, r_y, r_z)$ is the Bloch vector with the components $r_i = \text{Tr}(\rho\sigma_i)$.

Suppose that the measurement of the observable $\boldsymbol{\sigma} \cdot \mathbf{a}$ is performed at time t_0 , followed by the measurement of $\boldsymbol{\sigma} \cdot \mathbf{b}$ at t_1 , where \mathbf{a} and \mathbf{b} are directions at which the spin is measured. The quantum correlation function is given by $E_{QM}(\mathbf{a}, \mathbf{b}) = \sum_{k,l=\pm 1} k l \text{Tr}(\rho\pi_{a,k}) \text{Tr}(\pi_{a,k}\pi_{b,l})$, where, for example, $\pi_{a,k}$ is the projector onto the subspace corresponding to the eigenvalue $k = \pm 1$ of the spin along \mathbf{a} . Here, we use the fact that after the first measurement the state is projected on the new state $\pi_{a,k}$. Therefore, the probability to obtain the result k in the first measurement and l in the second one is given by $\text{Tr}(\rho\pi_{a,k})\text{Tr}(\pi_{a,k}\pi_{b,l})$. Using $\pi_{a,k} = \frac{1}{2}(\mathbf{1} + k\boldsymbol{\sigma} \cdot \mathbf{a})$ and $\frac{1}{2}\text{Tr}[(\boldsymbol{\sigma} \cdot \mathbf{a})(\boldsymbol{\sigma} \cdot \mathbf{b})] = \mathbf{a} \cdot \mathbf{b}$ one can easily show that the quantum correlation function can simply be written as

$$E_{QM}(\mathbf{a}, \mathbf{b}) = \mathbf{a} \cdot \mathbf{b} \quad (90)$$

Note that, in contrast to the usual (spatial) correlation function, the temporal one (Eq. 90) does not depend on the initial state ρ . Note also that a slight modification of the derivation of Eq. 90 can also apply to the cases in which the system evolves between the two measurements following an arbitrary unitary transformation.

The scalar product form of quantum correlations (Eq. 90) allows for the violation of the temporal Bell's inequality and the maximal value of the left-hand side of (Eq. 89) is achieved for the choice of the measurement settings: $\mathbf{a}_1 = \frac{1}{\sqrt{2}}(\mathbf{b}_1 - \mathbf{b}_2)$, $\mathbf{a}_2 = \frac{1}{\sqrt{2}}(\mathbf{b}_1 + \mathbf{b}_2)$ and is equal to $2 + \sqrt{2}$.

8.1 Quantum Random Access Codes

Random access code is a communication task for two parties, say again Alice and Bob. Alice receives some classical n -bit string known only to her (her local input). She is allowed

to send just a one-bit message, m , to Bob. Bob is asked to tell the value of the b th bit of Alice, $b = 1, 2, \dots, n$. However b is known only to him (this is his local input data). The goal is to construct a protocol enabling Bob to tell the value of the b th bit of Alice, with as high average probability of success as possible, for a uniformly random distribution of Alice's bit-strings, and a uniform distribution of b 's. Note that Alice does not know in advance which bit Bob is to recover. Thus, she has no option to send just this required bit.

If they share a quantum channel, then one speaks about a quantum version of the previous problem. Alice is asked to encode her classical n -bit message into 1 qubit (quantum bit) and send it to Bob. He performs some measurement on the received qubit to extract the required bit. In general, the measurement that he uses will depend on which bit he wants to reveal. The idea behind these so-called quantum random access codes already appeared in a paper written circa 1970, and published in 1983, by Wiesner (1983).

We illustrate the concept of random access code with the simplest scheme, in which in a classical framework Alice needs to encode a two-bit string $b_0 b_1$ into a single bit, or into a single qubit in a quantum framework.

In the classical case, Alice and Bob need to decide on a protocol defining which bit-valued message is to be sent by Alice, for each of the four possible values of her two-bit string $b_0 b_1$. There are only $2^4 = 16$ different deterministic protocols, thus the probability of success can be evaluated in a straightforward way. The optimal deterministic classical protocols can then be shown to have a probability of success $P_C = 3/4$. For example, if Alice sends one of the two bits, then Bob will reveal this bit with certainty and have probability of 1/2 to reveal the other one. Since any probabilistic protocol can be represented as a convex combination of the 16 deterministic protocols, the corresponding probability of success for any such probabilistic protocol will be given by the weighted sum of the probabilities of success of the individual deterministic protocols. This implies that the optimal probabilistic protocols can at best be as efficient as the optimal deterministic protocol, which is 3/4.

Ambainis et al. (1999) showed that there is a quantum solution of the random access code with probability of success $P_Q = \cos^2(\pi/8) \approx 0.85$. It is realized as follows: depending on her two-bit string $b_0 b_1$, Alice prepares one of the four states $|\psi_{b_0 b_1}\rangle$. These states are chosen to be on the equator of the Bloch sphere, separated by equal angles of $\pi/2$ radians (see Fig. 3). Using the Bloch sphere parametrization $|\psi(\theta, \phi)\rangle = \cos(\theta/2)|0\rangle + \exp(i\phi)\sin(\theta/2)|1\rangle$, the four encoding states are represented as:

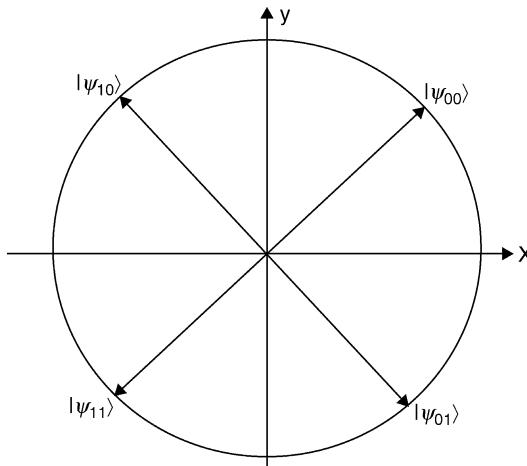

$$\begin{aligned} |\psi_{00}\rangle &= |\psi(\pi/2, \pi/4)\rangle \\ |\psi_{01}\rangle &= |\psi(\pi/2, 7\pi/4)\rangle \\ |\psi_{10}\rangle &= |\psi(\pi/2, 3\pi/4)\rangle \\ |\psi_{11}\rangle &= |\psi(\pi/2, 5\pi/4)\rangle \end{aligned} \tag{91}$$

Bob's measurements, which he uses to guess the bits, will depend on which bit he wants to obtain. To guess b_0 , he projects the qubit along the x -axis in the Bloch sphere, and to decode b_1 he projects it along the y -axis. He then estimates the bit value to be 0 if the measurement outcome was along the positive direction of the axis and 1 if it was along the negative axis. It can easily be calculated that the probability of successful retrieving of the correct bit value is the same in all cases: $P_Q = \cos^2(\pi/8) \approx 0.85$, which is higher than the optimal probability of success $P_C = 0.75$ of the classical random access code using one bit of communication.

We will now introduce a hidden variable model of the quantum solution to see that the key resource in its efficiency lies in violation of temporal Bell's inequalities. Galvao (2002) was

Fig. 3

The set of encoding states and decoding measurements in quantum random access code represented in the $x - y$ plane of the Bloch sphere. Alice prepares one of the four quantum states $|\psi_{b_0 b_1}\rangle$ to encode two bits $b_0, b_1 \in \{0, 1\}$. Depending on which bit Bob wants to reveal he performs either a measurement along the x (to reveal b_0) or along the y axis (to reveal b_1).

the first to point to the relation between violation of Bell's type inequalities and quantum random access codes. See also Spekkens et al. (2009) for a relation with the parity-oblivious multiplexing.

A hidden-variable model equivalent to the quantum protocol, which best fits the temporal Bell's inequalities can be considered as a description of the following modification of the original quantum protocol. Alice prepares the initial state of her qubit as a completely random state, described by a density matrix proportional to the unit operator, σ_0 . Her parity of bit values $b_0 \oplus b_1$ defines a measurement basis, which is used by her to prepare the state to be sent to Bob. Note that the result of the dichotomic measurement in the basis defined by $b_0 \oplus b_1$ is due to the nature of the initial state, completely random and totally uncontrollable by Alice. To fix the bit value b_1 (and thus also the value b_0 , since the parity is defined by the choice of the measurement basis) on her wish, Alice either leaves the state unchanged, if the result of measurement corresponds to her wish of b_1 , or she rotates the state in the $x - y$ plane at 180° to obtain the orthogonal state, if the result corresponds to $b_1 \oplus 1$. Just a glance at the states involved in the standard quantum protocol shows the two complementary (unbiased) bases which define her measurement settings, and which resulting states are linked with which values of $b_0 b_1$. After the measurement, the resulting state is sent to Bob, while Alice is in possession of a bit pair $b_0 b_1$, which is perfectly correlated with the qubit state on the way to Bob. That is, we have exactly the same starting point as in the original quantum protocol.

Now, it is obvious that the quantum protocol violates the temporal inequalities, while any hidden variable model of the above procedure using the four assumptions (1–4) behind the temporal inequalities is not violating them. What is important is the saturation of the temporal inequalities which is equivalent to a probability of success of $3/4$.

The link with temporal Bell's inequalities points to another advantage of quantum over classical random access codes. Usually, one considers the advantage to be *resource dependent*.

With this, we mean that there is an advantage as far as one compares one classical bit with one qubit. Yet the proof given above shows that the quantum strategy has an advantage over *all* hidden variable models respecting (1–4), that is, also those where Alice and Bob use temporal classical correlations between systems of arbitrarily large number of degrees of freedom.

Let us conclude this chapter by pointing out an interesting research avenue. Here, a brief review was given on the results demonstrating that “no go theorems” for various hidden variable classes of theories are behind better-than-classical efficiency in many quantum communication protocols. It would be interesting to investigate the link between fundamental features of quantum mechanics and the power of quantum computation. We showed that temporal Bell's inequalities distinguish between classical and quantum search (Grover) algorithms (Morikoshi 2006). Also cluster states – entangled states on which the logic gates are applied as sequences of only single-qubit measurements – are known to violate Bell's inequalities (Scarani et al. 2005; Tóth et al. 2006). These results point to the aforementioned link but we are still far away from understanding what the key non-classical ingredients are that give rise to the enhanced quantum computational power. The question gets even more fascinating after realizing that not only too little (Van den Nest et al. 2006; Brennen and Miyake 2008; Anders and Browne 2009; Vidal 2007; Markov and Shi 2008; Fannes et al. 1992) but also too much entanglement does not allow powerful quantum computation (Gross et al. 2008; Bremner et al. 2008).

Abstract

This chapter surveys the field of quantum computer algorithms. It gives a taste of both the breadth and the depth of the known algorithms for quantum computers, focusing on some of the more recent results. It begins with a brief review of quantum Fourier transform-based algorithms, followed by quantum searching and some of its early generalizations. It continues with a more in-depth description of two more recent developments: algorithms developed in the quantum walk paradigm, followed by tensor network evaluation algorithms (which include approximating the Tutte polynomial).

1 Introduction

Quantum computing is a new computational paradigm created by reformulating information and computation in a quantum mechanical framework (Feynman 1982; Deutsch 1985). Since the laws of physics appear to be quantum mechanical, this is the most relevant framework to consider when considering the fundamental limitations of information processing. Furthermore, in recent decades a major shift from just observing quantum phenomena to actually controlling quantum mechanical systems has been seen. The communication of quantum information over long distances, the “teleportation” of quantum information, and the encoding and manipulation of quantum information in many different physical media were also observed. We still appear to be a long way from the implementation of a large-scale quantum computer; however, it is a serious goal of many of the world’s leading physicists, and progress continues at a fast pace.

In parallel with the broad and aggressive program to control quantum mechanical systems with increased precision, and to control and interact a larger number of subsystems, researchers have also been aggressively pushing the boundaries of what useful tasks one could perform with quantum mechanical devices. These include improved metrology, quantum communication and cryptography, and the implementation of large-scale quantum algorithms.

It was known very early on (Deutsch 1985) that quantum algorithms cannot compute functions that are not computable by classical computers, however they might be able to efficiently compute functions that are not efficiently computable on a classical computer. Or, at the very least, quantum algorithms might be able to provide some sort of speed-up over the best possible or best-known classical algorithms for a specific problem.

The purpose of this chapter is to survey the field of quantum algorithms, which has grown tremendously since Shor’s breakthrough algorithms (Shor 1994, 1997) over 15 years ago. Much of the work in quantum algorithms is now textbook material (e.g., Nielsen and Chuang (2000); Hirvensalo (2001); Kitaev et al. (2002); Kaye et al. (2007); Mermin (2007)), and these examples will only be briefly mentioned in order to provide a broad overview. Other parts of this chapter, in particular, [Sects. 4](#) and [5](#), give a more detailed description of some more recent work.

We organized this chapter according to underlying tools or approaches taken, and we include some basic applications and specific examples, and relevant comparisons with classical algorithms.

In [Sect. 2](#) we begin with algorithms one can naturally consider to be based on a quantum Fourier transform, which includes the famous factoring and discrete logarithm algorithms of Peter Shor (1994, 1997). Since this topic is covered in several textbooks and recent surveys, this topic will only be briefly surveyed. Several other sections could have been added on algorithms

for generalizations of these problems, including several cases of the non-Abelian hidden subgroup problem, and hidden lattice problems over the reals (which have important applications in number theory); however, these are covered in a recent survey (Mosca 2009) and in substantial detail in Childs and van Dam (2010).

☞ [Section 3](#) continues with a brief review of classic results on quantum searching and counting, and more generally amplitude amplification and amplitude estimation.

In ☞ [Sect. 4](#), algorithms based on quantum walks are discussed. The related topic of adiabatic algorithms, which was briefly summarized in Mosca (2009) will not be covered here; a broader survey of this and related techniques (“quantum annealing”) can be found in Das and Chakrabarti (2008).

☞ [Section 5](#) concludes with algorithms based on the evaluation of the trace of an operator, also referred to as the evaluation of a tensor network, and which has applications such as the approximation of the Tutte polynomial.

The field of quantum algorithms has grown tremendously since the seminal work in the mid-1990s, and a full detailed survey would simply be infeasible for one chapter. Several other sections could have been added. One major omission is the development of algorithms for simulating quantum mechanical systems, which was Feynman’s original motivation for proposing a quantum computer. This field was briefly surveyed in Mosca (2009), with emphasis on the recent results in Berry et al. (2007) (more recent developments can be found in Wiebe et al. (2008)). This remains an area worthy of a comprehensive survey; like many other areas that researchers have tried to survey, it is difficult because it is still an active area of research. It is also an especially important area because these algorithms tend to offer a fully exponential speed-up over classical algorithms, and thus are likely to be among the first quantum algorithms to be implemented that will offer a speed-up over the fastest-available classical computers.

Finally, one could also write a survey of quantum algorithms for intrinsically quantum information problems, such as entanglement concentration, or quantum data compression. This topic is not covered in this chapter, though there is a very brief survey in Mosca (2009).

One can find a rather comprehensive list of the known quantum algorithms (up to mid-2008) in Stephen Jordan’s PhD thesis (Jordan 2008). It is hoped that this chapter complements some of the other recent surveys in providing a reasonably detailed overview of the state of the art in quantum algorithms.

2 Algorithms Based on the Quantum Fourier Transform

The early line of quantum algorithms was developed in the “black-box” or “oracle” framework. In this framework, part of the input is a black box that implements a function $f(x)$, and the only way to extract information about f is to evaluate it on inputs x . These early algorithms used a special case of quantum Fourier transform, the Hadamard gate, in order to solve the given problem with fewer black-box evaluations of f than a classical algorithm would require.

Deutsch (1985) formulated the problem of deciding whether a function $f: \{0, 1\} \rightarrow \{0, 1\}$ was constant or not. Suppose one has access to a black box that implements f reversibly by mapping $x, 0 \mapsto x, f(x)$; one can further assume that the black box in fact implements a unitary transformation U_f that maps $|x\rangle |0\rangle \mapsto |x\rangle |f(x)\rangle$. Deutsch’s problem is to output “constant” if $f(0) = f(1)$ and to output “balanced” if $f(0) \neq f(1)$, given a black box for evaluating f . In other words determine $f(0) \oplus f(1)$ (where \oplus denotes addition modulo 2). Outcome “0” means f is constant and “1” means f is not constant.

A classical algorithm would need to evaluate f twice in order to solve this problem. A quantum algorithm can apply U_f only once to create

$$\frac{1}{\sqrt{2}}|0\rangle|f(0)\rangle + \frac{1}{\sqrt{2}}|1\rangle|f(1)\rangle$$

Note that if $f(0) = f(1)$, then applying the Hadamard gate to the first register yields $|0\rangle$ with probability 1, and if $f(0) \neq f(1)$, then applying the Hadamard gate to the first register and ignoring the second register leaves the first register in the state $|1\rangle$ with probability $\frac{1}{2}$; thus a result of $|1\rangle$ could only occur if $f(0) \neq f(1)$.

As an aside, one can note that in general, given

$$\frac{1}{\sqrt{2}}|0\rangle|\psi_0\rangle + \frac{1}{\sqrt{2}}|1\rangle|\psi_1\rangle$$

applying the Hadamard gate to the first qubit and measuring it will yield “0” with probability $\frac{1}{2} + \text{Re}(\langle\psi_0|\psi_1\rangle)$; this “Hadamard test” is discussed in more detail in [Sect. 5](#).

In Deutsch's case, measuring a “1” meant $f(0) \neq f(1)$ with certainty, and a “0” was an inconclusive result. Even though it was not perfect, it still was something that could not be done with a classical algorithm. The algorithm can be made exact (Cleve et al. 1998) (i.e., one that outputs the correct answer with probability 1) if one assumes further that U_f maps $|x\rangle|b\rangle \mapsto |x\rangle|b \oplus f(x)\rangle$, for $b \in \{0, 1\}$, and one sets the second qubit to $\frac{1}{\sqrt{2}}|0\rangle - \frac{1}{\sqrt{2}}|1\rangle$. Then U_f maps

$$\left(\frac{|0\rangle + |1\rangle}{\sqrt{2}}\right) \left(\frac{|0\rangle - |1\rangle}{\sqrt{2}}\right) \mapsto (-1)^{f(0)} \left(\frac{|0\rangle + (-1)^{f(0) \oplus f(1)}|1\rangle}{\sqrt{2}}\right) \left(\frac{|0\rangle - |1\rangle}{\sqrt{2}}\right)$$

Thus, a Hadamard gate on the first qubit yields the result

$$(-1)^{f(0)}|f(0) \oplus f(1)\rangle \left(\frac{|0\rangle - |1\rangle}{\sqrt{2}}\right)$$

and measuring the first register yields the correct answer with certainty.

The general idea behind the early quantum algorithms was to compute a black-box function f on a superposition of inputs, and then extract a global property of f by applying a quantum transformation to the input register before measuring it. It is usually assumed that we have access to a black box that implements

$$U_f : |\mathbf{x}\rangle|\mathbf{b}\rangle \mapsto |\mathbf{x}\rangle|\mathbf{b} \oplus f(\mathbf{x})\rangle$$

or in some other form where the input value \mathbf{x} is kept intact and the second register is shifted by $f(\mathbf{x})$ in some reversible way.

Deutsch and Jozsa (1992) used this approach to get an exact algorithm that decides whether $f : \{0, 1\}^n \mapsto \{0, 1\}$ is constant or “balanced” (i.e., $|f^{-1}(0)| = |f^{-1}(1)|$), with a promise that one of these two cases holds. Their algorithm evaluated f only twice, while classically any exact algorithm would require $2^{n-1} + 1$ queries in the worst case. Bernstein and Vazirani (1997) defined a specific class of such functions $f_{\mathbf{a}}$: $\mathbf{x} \mapsto \mathbf{a} \cdot \mathbf{x}$, for any $\mathbf{a} \in \{0, 1\}^n$, and showed how the same algorithm that solves the Deutsch–Jozsa problem allows one to determine \mathbf{a} with two evaluations of $f_{\mathbf{a}}$ while a classical algorithm requires n evaluations. (Both of these algorithms can be done with one query if we have $|\mathbf{x}\rangle|b\rangle \mapsto |\mathbf{x}\rangle|b \oplus f(\mathbf{x})\rangle$.) They further showed how a related “recursive Fourier sampling” problem could be solved super-polynomially faster on a quantum computer. Simon (1994) later built on these tools to

develop a black-box quantum algorithm that was exponentially faster than any classical algorithm for finding a hidden string $\mathbf{s} \in \{0, 1\}^n$ that is encoded in a function $f: \{0, 1\}^n \rightarrow \{0, 1\}^n$ with the property that $f(\mathbf{x}) = f(\mathbf{y})$ if and only if $\mathbf{x} = \mathbf{y} \oplus \mathbf{s}$.

Shor (1994, 1997) built on these black-box results to find an efficient algorithm for finding the order of an element in the multiplicative group of integers modulo N (which implies an efficient classical algorithm for factoring N) and for solving the discrete logarithm problem in the multiplicative group of integers modulo a large prime p . Since the most widely used public key cryptography schemes at the time relied on the difficulty of integer factorization, and others relied on the difficulty of the discrete logarithm problem, these results had very serious practical implications. Shor's algorithms straightforwardly apply to black-box groups, and thus permit finding orders and discrete logarithms in any group that is reasonably presented, including the additive group of points on elliptic curves, which is currently one of the most widely used public key cryptography schemes (see e.g., Menezes et al. (1996)).

Researchers tried to understand the full implications and applications of Shor's technique, and a number of generalizations were soon formulated (e.g., Boneh and Lipton 1995; Grigoriev 1997). One can phrase Simon's algorithm, Shor's algorithm, and the various generalizations that soon followed as special cases of the *hidden subgroup problem*. Consider a finitely generated Abelian group G , and a hidden subgroup K that is defined by a function $f: G \rightarrow X$ (for some finite set X) with the property that $f(x) = f(y)$ if and only if $x - y \in K$ (we use additive notation, without loss of generality). In other words, f is constant on cosets of K and distinct on different cosets of G . In the case of Simon's algorithm, $G = \mathbb{Z}_2^n$ and $K = \{\mathbf{0}, \mathbf{s}\}$. In the case of Shor's order-finding algorithm, $G = \mathbb{Z}$ and $K = r\mathbb{Z}$ where r is the unknown order of the element. Other examples and how they fit in the hidden subgroup paradigm are given in Mosca (2008).

Soon after, Kitaev (Kitaev 1995) solved a problem he called the *Abelian stabilizer problem* using an approach that seemed different from Shor's algorithm, one based in eigenvalue estimation. Eigenvalue estimation is in fact an algorithm of independent interest for the purpose of studying quantum mechanical systems. The Abelian stabilizer problem is also a special case of the hidden subgroup problem. Kitaev's idea was to turn the problem into one of estimating eigenvalues of unitary operators. In the language of the hidden subgroup problem, the unitary operators were shift operators of the form $f(x) \mapsto f(x + y)$. By encoding the eigenvalues as relative phase shifts, he turned the problem into a phase estimation problem.

The Simon/Shor approach for solving the hidden subgroup problem is to first compute $\sum_x |x\rangle |f(x)\rangle$. In the case of finite groups G , one can sum over all the elements of G , otherwise one can sum over a sufficiently large subset of G . For example, if $G = \mathbb{Z}$, and $f(x) = a^x \bmod N$ for some large integer N , we first compute $\sum_{x=0}^{2^n-1} |x\rangle |a^x\rangle$, where $2^n > N^2$ (we omit the “mod N ” for simplicity). If r is the order of a (i.e., r is the smallest positive integer such that $a^r \equiv 1$) then every value x of the form $x = y + kr$ gets mapped to a^y . Thus, we can rewrite the above state as

$$\sum_{x=0}^{2^n-1} |x\rangle |a^x\rangle = \sum_{y=0}^{r-1} \left(\sum_j |y + jr\rangle \right) |a^y\rangle \quad (1)$$

where each value of a^y in this range is distinct. Tracing out the second register one is thus left with a state of the form

$$\sum_j |y + jr\rangle$$

for a random y and where j goes from 0 to $\lfloor(2^n - 1)/r\rfloor$. We loosely refer to this state as a “periodic” state with period r . We can use the inverse of the quantum Fourier transform (or the quantum Fourier transform) to map this state to a state of the form $\sum_x \alpha_x |x\rangle$, where the amplitudes are biased toward values of x such that $x/2^n \approx k/r$. With probability at least $4/\pi^2$ we obtain an x such that $|x/2^n - k/r| \leq 1/2^{n+1}$. One can then use the continued fractions algorithm to find k/r (in lowest terms) and thus find r with high probability. It is important to note that the continued fractions algorithm is not needed for many of the other cases of the Abelian hidden subgroup considered, such as Simon’s algorithm or the discrete logarithm algorithm when the order of the group is already known.

In contrast, Kitaev’s approach for this special case was to consider the map $U_a: |b\rangle \mapsto |ba^x\rangle$. It has eigenvalues of the form $e^{2\pi i k/r}$, and the state $|1\rangle$ satisfies

$$|1\rangle = \frac{1}{\sqrt{r}} \sum_{k=0}^{r-1} |\psi_k\rangle$$

where $|\psi_k\rangle$ is an eigenvector with eigenvalue $e^{2\pi i k/r}$:

$$U_a: |\psi_k\rangle \mapsto e^{2\pi i k x/r} |\psi_k\rangle$$

If one considers the controlled- U_a , denoted $c - U_a$, which maps $|0\rangle |b\rangle \mapsto |0\rangle |b\rangle$ and $|1\rangle |b\rangle \mapsto |1\rangle |ba\rangle$, and if one applies it to the state $(|0\rangle + |1\rangle)|\psi_k\rangle$ one gets

$$(|0\rangle + |1\rangle)|\psi_k\rangle \mapsto (|0\rangle + e^{2\pi i k/r}|1\rangle)|\psi_k\rangle$$

In other words, the eigenvalue becomes a relative phase, and thus one can reduce eigenvalue estimation to phase estimation. Furthermore, since one can efficiently compute a^j by performing j multiplications modulo N , one can also efficiently implement $c - U_{a^j}$ and thus easily obtain the qubit $|0\rangle + e^{2\pi i 2^j(k/r)}|1\rangle$ for integer values of j without performing $c - U_a$ a total of 2^j times. Kitaev developed an efficient ad hoc phase estimation scheme in order to estimate k/r to high precision, and this phase estimation scheme could be optimized further (Cleve et al. 1998). In particular, one can create the state

$$(|0\rangle + |1\rangle)^n |1\rangle = \sum_{x=0}^{2^n-1} |x\rangle |1\rangle = \sum_{k=0}^{r-1} \sum_{x=0}^{2^n-1} |x\rangle |\psi_k\rangle$$

(we use the standard binary encoding of the integers $x \in \{0, 1, \dots, 2^n - 1\}$ as bit strings of length n) to apply the $c - U_{a^j}$ using the $(n-j)$ th bit as the control bit, and using the second register (initialized in $|1\rangle = \sum_k |\psi_k\rangle$) as the target register, for $j = 0, 1, 2, \dots, n-1$, to create

$$\sum_k (|0\rangle + e^{2\pi i 2^{n-1} k} |1\rangle) \cdots (|0\rangle + e^{2\pi i 2^1 k} |1\rangle) (|0\rangle + e^{2\pi i k} |1\rangle) |\psi_k\rangle \quad (2)$$

$$= \sum_{x=0}^{2^n-1} |x\rangle |a^x\rangle = \sum_{k=0}^{r-1} \sum_{x=0}^{2^n-1} e^{2\pi i x k} |x\rangle |\psi_k\rangle \quad (3)$$

If the second register is ignored or discarded, one is left with a state of the form $\sum_{x=0}^{2^n-1} e^{2\pi i x k/r} |x\rangle$ for a random value of $k \in \{0, 1, \dots, r-1\}$. The inverse quantum Fourier transformation maps this state to a state $\sum_y \alpha_y |y\rangle$ where most of the weight of the amplitudes is near values of y such that $y/2^n \approx k/r$ for some integer k . More specifically $|y/2^n - k/r| \leq 1/2^{n+1}$ with probability at least $4/\pi^2$; furthermore $|y/2^n - k/r| \leq 1/2^n$ with probability at least $8/\pi^2$. As in the case of Shor’s algorithm, one can use the continued fractions algorithm to determine k/r (in lowest terms) and thus determine r with high probability.

It was noted (Cleve et al. 1998) that this modified eigenvalue estimation algorithm for order-finding was essentially equivalent to Shor’s period-finding algorithm for order-finding. This can be seen by noting that we have the same state in [Eqs. 1](#) and [2](#), and in both cases, we discard the second register and apply an inverse Fourier transform to the first register. The only difference is the basis in which the second register is mathematically analyzed.

The most obvious direction in which to try to generalize the Abelian hidden subgroup algorithm is to solve instances of the hidden subgroup problem for non-Abelian groups. This includes, for example, the graph automorphism problem (which corresponds to finding a hidden subgroup of the symmetric group). There has been nontrivial, but limited, progress in this direction, using a variety of algorithmic tools, such as sieving, “pretty good measurements,” and other group theoretic approaches. Other generalizations include the hidden shift problem and its generalizations, hidden lattice problems on real lattices (which has important applications in computational number theory and computationally secure cryptography), and hidden nonlinear structures. These topics and techniques would take several dozen pages just to summarize, so the reader can refer to Mosca (2009) or Childs and van Dam (2010) so that more room is left to summarize other important topics.

3 Amplitude Amplification and Estimation

A very general problem for which quantum algorithms offer an improvement is that of searching for a solution to a computational problem in the case that a solution x can be easily verified. One can phrase such a general problem as finding a solution x to the equation $f(x) = 1$, given a means for evaluating the function f . One can further assume that $f: \{0, 1\}^n \mapsto \{0, 1\}$.

The problems from [Sect. 2](#) can be rephrased in this form (or a small number of instances of problems of this form), and the quantum algorithms for these problems exploit some nontrivial algebraic structure in the function f in order to solve the problems superpolynomially faster than the best possible or best-known classical algorithms. Quantum computers also allow a more modest speed-up (up to quadratic) for searching for a solution to a function f without any particular structure. This includes, for example, searching for solutions to NP -complete problems.

Note that classically, given a means for guessing a solution x with probability p , one could amplify this success probability by repeating many times, and after a number of guesses in $O(1/p)$, the probability of finding a solution is in $\Omega(1)$. Note that the quantum implementation of an algorithm that produces a solution with probability p will produce a solution with probability amplitude \sqrt{p} . The idea behind quantum searching is to somehow amplify this probability to be close to 1 using only $O(1/\sqrt{p})$ guesses and other steps.

Lov Grover (1996) found precisely such an algorithm, and this algorithm was analyzed in detail and generalized (Boyer et al. 1998; Brassard and Høyer 1997; Grover 1998; Brassard et al. 2002) to what is known as “amplitude amplification.” Any procedure for guessing a solution with probability p can be (with modest overhead) turned into a unitary operator A that maps $|0\rangle \mapsto \sqrt{p}|\psi_1\rangle + \sqrt{1-p}|\psi_0\rangle$, where $0 = 00\dots 0$, $|\psi_1\rangle$ is a superposition of states encoding solutions x to $f(x) = 1$ (the states could in general encode x followed by other “junk” information) and $|\psi_0\rangle$ is a superposition of states encoding values of x that are not solutions.

One can then define the quantum search iterate (or “Grover iterate”) to be

$$Q = -AU_0A^{-1}U_f$$

where $U_f: |\mathbf{x}\rangle \mapsto (-1)^{f(\mathbf{x})}|\mathbf{x}\rangle$, and $U_0 = I - 2|\mathbf{0}\rangle\langle\mathbf{0}|$ (in other words, maps $|\mathbf{0}\rangle \mapsto -|\mathbf{0}\rangle$ and $|\mathbf{x}\rangle \mapsto |\mathbf{x}\rangle$ for any $\mathbf{x} \neq \mathbf{0}$). Here, for simplicity, it is assumed that there are no “junk” bits in the unitary computation of f by A . Any such junk information can either be “uncomputed” and reset to all 0s, or even ignored (letting U_f act only on the bits encoding \mathbf{x} and applying the identity to the junk bits).

This algorithm is analyzed thoroughly in the literature and in textbooks, so the main results and ideas are only summarized here to help the reader understand the later sections on searching via quantum walk.

If one applies Q a total of k times to the input state $A|00\dots0\rangle = \sin(\theta)|\psi_1\rangle + \cos(\theta)|\psi_0\rangle$, where $\sqrt{p} = \sin(\theta)$, then one obtains

$$Q^k A|00\dots0\rangle = \sin((2k+1)\theta)|\psi_1\rangle + \cos((2k+1)\theta)|\psi_0\rangle$$

This implies that with $k \approx \frac{\pi}{4\sqrt{p}}$ one obtains $|\psi_1\rangle$ with probability amplitude close to 1, and thus measuring the register will yield a solution to $f(\mathbf{x}) = 1$ with high probability. This is quadratically better than what could be achieved by preparing and measuring $A|\mathbf{0}\rangle$ until a solution is found.

One application of such a generic amplitude amplification method is for searching. One can also apply this technique to approximately count (Brassard et al. 1997) the number of solutions to $f(\mathbf{x}) = 1$, and more generally to estimate the amplitude (Brassard et al. 2002) with which a general operator A produces a solution to $f(\mathbf{x}) = 1$ (in other words, the transition amplitude from one recognizable subspace to another).

There are a variety of other applications of amplitude amplification that cleverly incorporate amplitude amplification in an unobvious way into a larger algorithm. Some of these examples are discussed in Mosca (2009) and most are summarized in Jordan (2008).

Since there are some connections to some of the more recent tools developed in quantum algorithms, we will briefly explain how amplitude estimation works.

Consider any unitary operator A that maps some known input state, say $|\mathbf{0}\rangle = |00\dots0\rangle$, to a superposition $\sin(\theta)|\psi_1\rangle + \cos(\theta)|\psi_0\rangle$, $0 \leq \theta \leq \pi/2$, where $|\psi_1\rangle$ is a normalized superposition of “good” states \mathbf{x} satisfying $f(\mathbf{x}) = 1$ and $|\psi_0\rangle$ is a normalized superposition of “bad” states \mathbf{x} satisfying $f(\mathbf{x}) = 0$ (again, for simplicity, one can ignore extra junk bits). If we measure $A|\mathbf{0}\rangle$, we would measure a “good” \mathbf{x} with probability $\sin^2(\theta)$. The goal of amplitude estimation is to approximate the amplitude $\sin(\theta)$. One can assume for convenience that there are $t > 0$ good states and $n - t > 0$ bad states, and that $0 < \sin(\theta) < \pi/2$.

It can be noted that the quantum search iterate $Q = -AU_0A^{-1}U_f$ has eigenvalues $|\psi_+\rangle = \frac{1}{\sqrt{2}}(|\psi_0\rangle + i|\psi_1\rangle)$ and $|\psi_-\rangle = \frac{1}{\sqrt{2}}(|\psi_0\rangle - i|\psi_1\rangle)$ with respective eigenvalues $e^{i2\theta}$ and $e^{-i2\theta}$. It also has $2^n - 2$ other eigenvectors; $t - 1$ of them have eigenvalue +1 and are the states orthogonal to $|\psi_1\rangle$ that have support on the states $|\mathbf{x}\rangle$ where $f(\mathbf{x}) = 1$, and $n - t - 1$ of them have eigenvalue -1 and are the states orthogonal to $|\psi_0\rangle$ that have support on the states $|\mathbf{x}\rangle$ where $f(\mathbf{x}) = 0$. It is important to note that $A|\psi\rangle = \frac{e^{i\theta}}{\sqrt{2}}|\psi_+\rangle + \frac{e^{-i\theta}}{\sqrt{2}}|\psi_-\rangle$ has its full support on the two-dimensional subspace spanned by $|\psi_+\rangle$ and $|\psi_-\rangle$.

It is worth noting that the quantum search iterate $Q = AU_0A^{-1}U_f$ can also be thought of as two reflections

$$-U_{A|\mathbf{0}\rangle}U_f = (2A|\mathbf{0}\rangle\langle\mathbf{0}|A^\dagger - I)(I - 2\sum_{\mathbf{x}|f(\mathbf{x})=1}|\mathbf{x}\rangle\langle\mathbf{x}|)$$

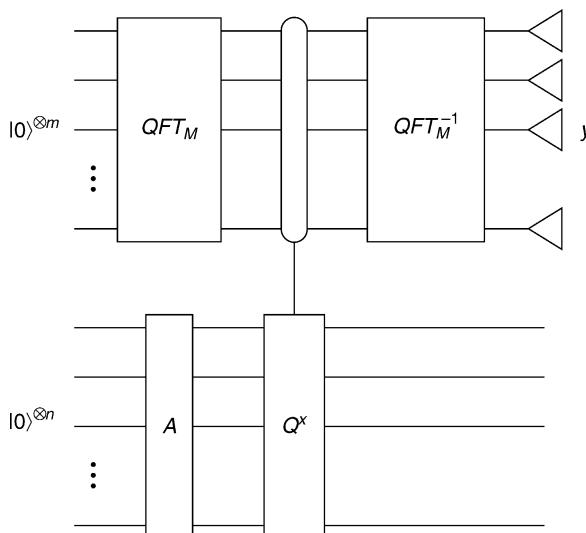

one that flags the “good” subspace with a -1 phase shift, and then one that flags the subspace orthogonal to $A|0\rangle$ with a -1 phase shift. In the two-dimensional subspace spanned by $A|0\rangle$ and $U_f A|0\rangle$, these two reflections correspond to a rotation by angle 2θ . Thus, it should not be surprising to find eigenvalues $e^{\pm 2\pi i \theta}$ for states in this two-dimensional subspace. (In [Sect. 4](#), a more general situation where we have an operator Q with many nontrivial eigenspaces and eigenvalues will be considered.)

Thus, one can approximate $\sin(\theta)$ by estimating the eigenvalue of either $|\psi_+\rangle$ or $|\psi_-\rangle$. Performing the standard eigenvalue estimation algorithm on Q with input $A|0\rangle$ (as illustrated in [Fig. 1](#)) gives a quadratic speed-up for estimating $\sin^2(\theta)$ versus simply repeatedly measuring $A|0\rangle$ and counting the frequency of 1s. In particular, we can obtain an estimate $\tilde{\theta}$ of θ such that $|\tilde{\theta} - \theta| < \varepsilon$ with high (constant) probability using $O(1/\varepsilon)$ repetitions of Q , and thus $O(1/\varepsilon)$ repetitions of $U_f A$ and A^{-1} . For fixed p , this implies that $\tilde{p} = \sin^2(\tilde{\theta})$ satisfies $|\tilde{p} - p| \in O(\varepsilon)$ with high probability. Classical sampling requires $O(1/\varepsilon^2)$ samples for the same precision. One application is speeding up the efficiency of the “Hadamard” test mentioned in [Sect. 5.2.3](#).

Another interesting observation is that increasingly precise eigenvalue estimation of Q on input $A|0\rangle$ leaves the eigenvector register in a state that gets closer and closer to the mixture

Fig. 1

The circuit estimates the amplitude with which the unitary operator A maps $|0\rangle$ to the subspace of solutions to $f(x) = 1$. One uses $m \in \Omega(\log(1/\varepsilon))$ qubits in the top register, and prepares it in a uniform superposition of the strings y representing the integers $0, 1, 2, \dots, 2^m - 1$ (one can in fact optimize the amplitudes of each y to achieve a slightly better estimate (D’Ariano et al. 2007)). The controlled- Q^y circuit applies Q^y to the bottom register when the value y is encoded in the top qubits. If $A|0\rangle = \sin(\theta)|\psi_1\rangle + \cos(\theta)|\psi_0\rangle$, where $|\psi_1\rangle$ is a superposition of solutions x to $f(x) = 1$, and $|\psi_0\rangle$ is a superposition of values x with $f(x) = 0$, then the value $y = y_1 y_2 \dots y_m$ measured in the top register corresponds to the phase estimate $2\pi y / 2^m$, which is likely to be within $\frac{2\pi}{2^m}$ (modulo 2π) of either 2θ or -2θ . Thus, the value of $\sin^2 \pi y / 2^m$ is likely to satisfy $|\sin^2 \pi y / 2^m - \sin^2 \theta| \in O(\varepsilon)$.

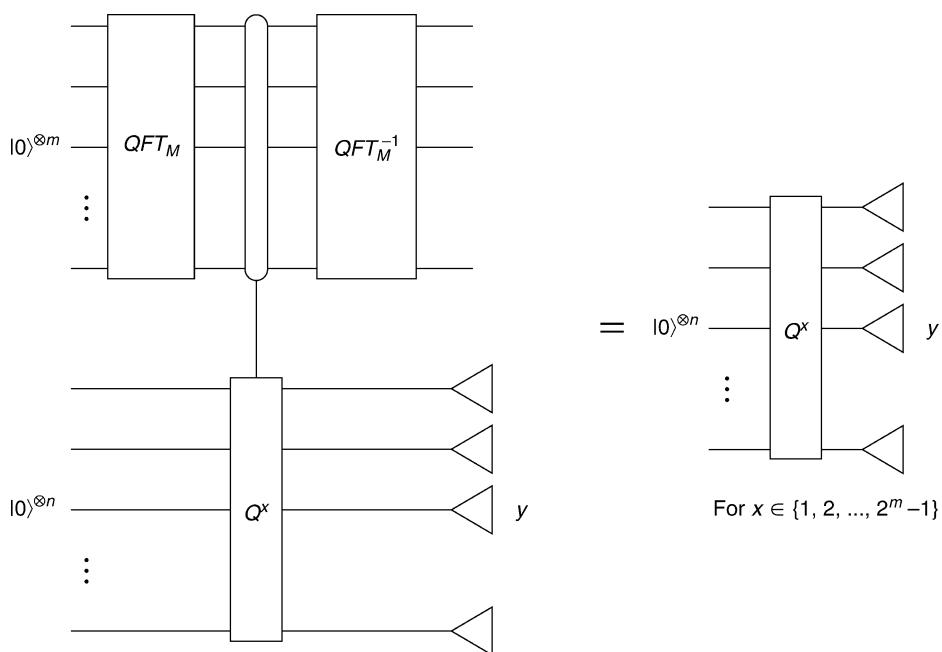

$\frac{1}{2}|\psi_+\rangle\langle\psi_+| + \frac{1}{2}|\psi_-\rangle\langle\psi_-|$ that equals $\frac{1}{2}|\psi_1\rangle\langle\psi_1| + \frac{1}{2}|\psi_0\rangle\langle\psi_0|$. Thus, eigenvalue estimation will leave the eigenvector register in a state that contains a solution to $f(\mathbf{x}) = 1$ with probability approaching $\frac{1}{2}$. One can in fact, using this entire algorithm as subroutine in another quantum search algorithm, obtain an algorithm with success probability approaching 1 (Mosca 2001; Kaye et al. 2007), and the convergence rate can be improved further (Tulsi et al. 2006). Another important observation is that for the purpose of searching, the eigenvalue estimate register is never used except in order to determine a random number of times in which to apply Q to the second register. This in fact gives the quantum searching algorithm of Boyer et al. (1998). In other words, applying Q a random number of times decoheres or approximately projects the eigenvector register in the eigenbasis, which gives a solution with high probability (Fig. 2). The method of approximating projections by using randomized evolutions was recently refined, generalized, and applied in Boixo et al. (2009).

Quantum searching as discussed in this section has been further generalized in the quantum walk paradigm, which is the topic of the next section.

Fig. 2

The amplitude estimation circuit can also be used for searching for a solution to $f(\mathbf{x}) = 1$, as illustrated in the figure on the left. The second register starts off in the state $|0\rangle^{\otimes m}$, and after a sufficiently precise eigenvalue estimation of the quantum search iterate Q , the second register is approximately projected in the eigenbasis. The idea projection would yield the mixed state $\frac{1}{2}|\psi_+\rangle\langle\psi_+| + \frac{1}{2}|\psi_-\rangle\langle\psi_-| = \frac{1}{2}|\psi_1\rangle\langle\psi_1| + \frac{1}{2}|\psi_0\rangle\langle\psi_0|$, and thus yields a solution to $f(\mathbf{x}) = 1$ with probability approaching $\frac{1}{2}$ as m gets large (the probability is in $\Omega(1)$ once $m \in \Omega(1/\sqrt{p})$). The same algorithm can in fact be achieved by discarding the top register and instead randomly picking a value $y \in \{0, 1, \dots, 2^m - 1\}$ and applying Q^y to $|0\rangle^{\otimes n}$, as illustrated on the right.

4 Quantum Walks

Random walks are a common tool throughout classical computer science. Their applications include the simulation of biological, physical, and social systems, as well as probabilistic algorithms such as Monte Carlo methods and the Metropolis algorithm. A classical random walk is described by a $n \times n$ matrix P , where the entry $P_{u,v}$ is the probability of a transition from a vertex v to an adjacent vertex u in a graph G . In order to preserve normalization, it is required that P is *stochastic* – that is, the entries in each column must sum to 1. We denote the initial probability distribution on the vertices of G by the column vector q . After n steps of the random walk, the distribution is given by $P^n q$.

Quantum walks were developed in analogy to classical random walks, but it was not initially obvious how to do this. Most generally, a quantum walk could begin in an initial state $\rho_0 = |\psi_0\rangle\langle\psi_0|$ and evolve according to any completely positive map \mathcal{E} such that, after t time steps, the system is in state $\rho(t) = \mathcal{E}^t(\rho_0)$. Such a quantum walk is simultaneously using classical randomness and quantum superposition. We can focus on the power of quantum mechanics by restricting to unitary walk operations, which maintain the system in a coherent quantum state. So, the state at time t can be described by $|\psi(t)\rangle = U^t|\psi_0\rangle$, for some unitary operator U . However, it is not initially obvious how to define such a unitary operation. A natural idea is to define the state space A with basis $\{|v\rangle : v \in V(G)\}$ and walk operator \tilde{P} defined by $\tilde{P}_{u,v} = \sqrt{P_{u,v}}$. However, this will not generally yield a unitary operator \tilde{P} , and a more complex approach is required. Some of the earliest formulations of unitary quantum walks appear in papers by Nayak and Vishwanath (2000), Ambainis et al. (2001), Kempe (2003), and Aharonov et al. (2001). These early works focused mainly on quantum walks on the line or a cycle. In order to allow unitary evolution, the state space consisted of the vertex set of the graph, along with an extra “coin register.” The state of the coin register is a superposition of $|\text{LEFT}\rangle$ and $|\text{RIGHT}\rangle$. The walk then proceeds by alternately taking a step in the direction dictated by the coin register and applying a unitary “coin tossing operator” to the coin register. The coin tossing operator is often chosen to be the Hadamard gate. It was shown in Aharonov et al. (2001), Ambainis (2003), Ambainis et al. (2001), Kempe (2003), and Nayak and Vishwanath (2000) that the mixing and propagation behavior of these quantum walks was significantly different from their classical counterparts. These early constructions developed into the more general concept of a discrete time quantum walk, which will be defined in detail.

Two methods will be described for defining a unitary walk operator. In a *discrete time* quantum walk, the state space has basis vectors $\{|u\rangle \otimes |v\rangle : u, v \in V\}$. Roughly speaking, the walk operator alternately takes steps in the first and second registers. This is often described as a walk on the edges of the graph. In a *continuous time* quantum walk, the attention will be restricted to symmetric transition matrices P . We take P to be the Hamiltonian for the system. Applying Schrödinger’s equation, this will define continuous time unitary evolution in the state space spanned by $\{|u\rangle : u \in V\}$. Interestingly, these two types of walk are not known to be equivalent. An overview of both types of walk as well as some of the algorithms that apply them will be given.

4.1 Discrete Time Quantum Walks

Let P be a stochastic matrix describing a classical random walk on a graph G . We would like the quantum walk to respect the structure of the graph G , and take into account the

transition probabilities $P_{u,v}$. The quantum walk should be governed by a unitary operation, and is therefore reversible. However, a classical random walk is not, in general, a reversible process. Therefore, the quantum walk will necessarily behave differently than the classical walk. While the state space of the classical walk is V , the state quantum walk takes place in the space spanned by $\{|u, v\rangle : u, v \in V\}$. One can think of the first register as the current location of the walk, and the second register as a record of the previous location. To facilitate the quantum walk from a state $|u, v\rangle$, one can first mix the second register over the neighbors of u , and then swap the two registers. The method by which one mixes over the neighbors of u must be chosen carefully to ensure that it is unitary. To describe this formally, one can define the following states for each $u \in V$:

$$|\psi_u\rangle = |u\rangle \otimes \sum_{v \in V} \sqrt{P_{vu}} |v\rangle \quad (4)$$

$$|\psi_u^*\rangle = \sum_{v \in V} \sqrt{P_{vu}} |v\rangle \otimes |u\rangle \quad (5)$$

Furthermore, define the projections onto the space spanned by these states:

$$\Pi = \sum_{u \in V} |\psi_u\rangle \langle \psi_u| \quad (6)$$

$$\Pi^* = \sum_{u \in V} |\psi_u^*\rangle \langle \psi_u^*| \quad (7)$$

In order to mix the second register, we perform the reflection $(2\Pi - I)$. Letting S denote the swap operation, this process can be written as

$$S(2\Pi - I) \quad (8)$$

It turns out that we will get a more elegant expression for a single step of the quantum walk if we define the walk operator W to be two iterations of this process:

$$W = S(2\Pi - I)S(2\Pi - I) \quad (9)$$

$$= (2(S\Pi S) - I)(2\Pi - I) \quad (10)$$

$$= (2\Pi^* - I)(2\Pi - I) \quad (11)$$

So, the walk operator W is equivalent to performing two reflections.

Many of the useful properties of quantum walks can be understood in terms of the spectrum of the operator W . We define D , the $n \times n$ matrix with entries $D_{u,v} = \sqrt{P_{u,v}P_{v,u}}$. This is called the *discriminant matrix*, and has eigenvalues in the interval $[0, 1]$. In the theorem that follows, the eigenvalues of D that lie in the interval $(0, 1)$ will be expressed as $\cos(\theta_1), \dots, \cos(\theta_k)$. Let $|\theta_1\rangle, \dots, |\theta_k\rangle$ be the corresponding eigenvectors of D . Now, define the subspaces

$$A = \text{span}\{|\psi_u\rangle\} \quad (12)$$

$$B = \text{span}\{|\psi_u^*\rangle\} \quad (13)$$

Finally, define the operator

$$Q = \sum_{v \in V} |\psi_v\rangle \langle v| \quad (14)$$

and

$$|\phi_j\rangle = Q|\theta_j\rangle \quad (15)$$

The following spectral theorem for quantum walks can be now stated:

Theorem 1 (Szegedy 2004) *The eigenvalues of W acting on the space $A + B$ can be described as follows:*

1. *The eigenvalues of W with non-zero imaginary part are $e^{\pm 2i\theta_1}, e^{\pm 2i\theta_2}, \dots, e^{\pm 2i\theta_k}$ where $\cos(\theta_1), \dots, \cos(\theta_k)$ are the eigenvalues of D in the interval $(0, 1)$. The corresponding (un-normalized) eigenvectors of $W(P)$ can be written as $|\phi_j\rangle - e^{\pm 2i\theta_j} S |\phi_j\rangle$ for $j = 1, \dots, k$.*
2. *$A \cap B$ and $A^\perp \cap B^\perp$ span the $+1$ eigenspace of W . There is a direct correspondence between this space and the $+1$ eigenspace of D . In particular, the $+1$ eigenspace of W has the same degeneracy as the $+1$ eigenspace of D .*
3. *$A \cap B^\perp$ and $A^\perp \cap B$ span the -1 eigenspace of W .*

We say that P is *symmetric* if $P^T = P$ and *ergodic* if it is aperiodic. Note that if P is symmetric, then the eigenvalues of D are just the absolute values of the eigenvalues of P . It is well-known that if P is ergodic, then it has exactly one stationary distribution (i.e., a unique $+1$ eigenvalue). Combining this fact with theorem (1) gives the following corollary.

Corollary 1 *If P is ergodic and symmetric, then the corresponding walk operator W has a unique $+1$ eigenvector in $\text{span}(A, B)$:*

$$|\psi\rangle = \frac{1}{\sqrt{n}} \sum_{v \in V} |\psi_v\rangle = \frac{1}{\sqrt{n}} \sum_{v \in V} |\psi_v^*\rangle \quad (16)$$

Moreover, if we measure the first register of $|\psi\rangle$, we get a state corresponding to vertex u with probability

$$\Pr(u) = \frac{1}{n} \sum_{v \in V} P_{u,v} = \frac{1}{n} \quad (17)$$

This is the uniform distribution, which is the unique stationary distribution for the classical random walk.

4.1.1 The Phase Gap and the Detection Problem

In this section, an example of a quadratic speedup will be given for the problem of detecting whether there are any “marked” vertices in the graph G . First, the following are defined:

Definition 1 The *phase gap* of a quantum walk is defined as the smallest positive value 2θ such that $e^{\pm 2i\theta}$ are eigenvalues of the quantum walk operator. It is denoted by $\Delta(P)$.

Definition 2 Let $M \subseteq V$ be a set of marked vertices. In the *detection problem*, one is asked to decide whether M is empty.

Let P be ergodic and reversible, with positive eigenvalues. We define the following modified walk P' :

$$P'_{uv} = \begin{cases} P_{uv} & v \notin M \\ 0 & u \neq v, v \in M \\ 1 & u = v, v \in M \end{cases} \quad (18)$$

This walk resembles P , except that it acts as the identity on the set M . That is, if the walk reaches a marked vertex, it stays there. Let P_M denote the operator P' restricted to $V \setminus M$. Then, arranging the rows and columns of P' , we can write

$$P' = \begin{pmatrix} P_M & 0 \\ P'' & I \end{pmatrix} \quad (19)$$

By Theorem 1, if $M = \emptyset$, then $P_M = P' = P$ and $\|P_M\| = 1$. Otherwise, we have the strict inequality $\|P_M\| < 1$. The following theorem bounds $\|P_M\|$ away from 1:

Theorem 2 *If $(1 - \delta)$ is the absolute value of the eigenvalue of P with second largest magnitude, and $|M| \geq |\varepsilon|V$, then $\|P_M\| \leq 1 - \frac{\delta\varepsilon}{2}$.*

It will be now shown that the detection problem can be solved using eigenvalue estimation. \blacklozenge Theorem 2 will allow us to bound the running time of this method. First, we describe the discriminant matrix for P' :

$$D(P')_{uv} = \begin{cases} P_{uv} & u, v \notin M \\ 1 & u = v, v \in M \\ 0 & \text{otherwise} \end{cases} \quad (20)$$

Now, beginning with the state

$$|\psi\rangle = \frac{1}{\sqrt{n}} \sum_{v \in V} |\psi_v\rangle = \frac{1}{\sqrt{n}} \sum_{v \in V} \sqrt{P_{v,u}} |u\rangle |\nu\rangle \quad (21)$$

we measure whether or not we have a marked vertex; if so, we are done. Otherwise, we have the state

$$|\psi_M\rangle = \frac{1}{\sqrt{|V \setminus M|}} \sum_{u, v \in V \setminus M} \sqrt{P_{vu}} |u\rangle |\nu\rangle \quad (22)$$

If $M = \emptyset$, then this is the state $|\psi\rangle$ defined in \blacklozenge Eq. 16, and is the +1 eigenvector of $W(P)$. Otherwise, by Theorem 1, this state lies entirely in the space spanned by eigenvectors with values of the form $e^{\pm 2i\theta_j}$, where θ_j is an eigenvalue of P_M . Applying \blacklozenge Theorem 2, we know that

$$\theta \geq \cos^{-1} \left(1 - \frac{\delta\varepsilon}{2} \right) \geq \sqrt{\frac{\delta\varepsilon}{2}} \quad (23)$$

So, the task of distinguishing between M being empty or nonempty is equivalent to that of distinguishing between a phase parameter of 0 and a phase parameter of at least $\sqrt{\frac{\delta\varepsilon}{2}}$. Therefore, applying phase estimation to $W(P')$ on state $|\psi_M\rangle$ with precision $O(\sqrt{\delta\varepsilon})$ will decide whether M is empty with constant probability. This requires time $O\left(\frac{1}{\sqrt{\delta\varepsilon}}\right)$.

By considering the modified walk operator P' , it can be shown that the detection problem requires $O\left(\frac{1}{\delta\varepsilon}\right)$ time in the classical setting. Therefore, the quantum algorithm provides a quadratic speedup over the classical one for the detection problem.

4.1.2 Quantum Hitting Time

Classically, the first hitting time is denoted $H(\rho, M)$. For a walk defined by P , starting from the probability distribution ρ on V , $H(\rho, M)$ is the smallest value n such that the walk reaches a marked vertex $v \in M$ at some time $t \in \{0, \dots, n\}$ with constant probability. This idea is captured by applying the modified operator P' and some n times, and then considering the probability that the walk is in some marked state $v \in M$. Let ρ_M be any initial distribution restricted to the vertices $V \setminus M$. Then, at time t , the probability that the walk is in an unmarked state is $\|P_M^t \rho_M\|_1$, where $\|\cdot\|_1$ denotes the L_1 norm. Assuming that M is nonempty, we can see that $\|P_M\| < 1$. So, as $t \rightarrow \infty$, we have $\|P_M^t \rho_M\|_1 \rightarrow 0$. So, as $t \rightarrow \infty$, the walk defined by P' is in a marked state with probability 1. As a result, if we begin in the uniform distribution π on V , and run the walk for some time t , we will “skew” the distribution toward M , and thus away from the unmarked vertices. So, we define the classical hitting time to be the minimum t such that

$$\|P_M^t \rho_M\|_1 < \varepsilon \quad (24)$$

for any constant ε of our choosing. Since the quantum walk is governed by a unitary operator, it does not converge to a particular distribution the way that the classical walk does. We cannot simply wait an adequate number of time steps and then measure the state of the walk; the walk might have already been in a state with high overlap on the marked vertices and then evolved away from this state! Quantum searching has the same problem when the number of solutions is unknown. We can get around this in a similar way by considering an expected value over a sufficiently long period of time. This will form the basis of the definition of hitting time. Define

$$|\pi\rangle = \frac{1}{\sqrt{|V \setminus M|}} \sum_{v \in V \setminus M} |\psi_v\rangle \quad (25)$$

Then, if M is empty, $|\pi\rangle$ is a $+1$ eigenvector of W , and $W^t|\pi\rangle = |\pi\rangle$ for all t . However, if M is nonempty, then the spectral theorem tells that $|\pi\rangle$ lies in the space spanned by eigenvectors with eigenvalues $e^{\pm 2i\theta_j}$ for nonzero θ_j . As a result, it can be shown that, for some values of t , the state $W^t|\pi\rangle$ is “far” from the initial distribution $|\pi\rangle$. The quantum hitting is defined in the same way as Szegedy (2004). The hitting time $H_Q(W)$ as the minimum value T such that

$$\frac{1}{T+1} \sum_{t=0}^T \|W^t|\pi\rangle - |\pi\rangle\|^2 \geq 1 - \frac{|M|}{|V|} \quad (26)$$

This leads to Szegedy’s hitting time theorem (2004).

Theorem 3 *The quantum hitting time $H_Q(W)$ is*

$$O\left(\frac{1}{\sqrt{1 - \|P_M\|}}\right)$$

Corollary 2 *Applying \bullet Theorem 2, if the second largest eigenvalue of P has magnitude $(1 - \delta)$ and $|M|/|V| \geq \varepsilon$, then $H_Q(W) \in O\left(\frac{1}{\sqrt{\delta\varepsilon}}\right)$.*

Notice that this corresponds to the running time for the algorithm for the detection problem, as described above. Similarly, the classical hitting time is in $O\left(\frac{1}{\delta\varepsilon}\right)$, corresponding to the best classical algorithm for the detection problem.

It is also worth noting that, if there are no marked elements, then the system remains in the state $|\pi\rangle$, and the algorithm never “hits.” This gives an alternative way to approach the detection problem. We run the algorithm for a randomly selected number of steps $t \in \{0, \dots, T\}$ with T of size $O(\sqrt{1/\delta\varepsilon})$, and then measure whether the system is still in the state $|\pi\rangle$; if there are any marked elements, then we can expect to find some other state with constant probability.

4.1.3 The Element Distinctness Problem

In the element distinctness problem, a black box is given that computes the function

$$f: \{1, \dots, n\} \rightarrow S \quad (27)$$

and we are asked to determine whether there exist $x, y \in \{1, \dots, n\}$ with $x \neq y$ and $f(x) = f(y)$. We would like to minimize the number of queries made to the black box. There is a lower bound of $\Omega(n^{2/3})$ on the number of queries, due indirectly to Aaronson and Shi (2004). The algorithm of Ambainis (2004) proves that this bound is tight. The algorithm uses a quantum walk on the Johnson graph $J(n, p)$ has vertex set consisting of all subsets of $\{1, \dots, n\}$ of size p . Let S_1 and S_2 be p -subsets of $\{1, \dots, n\}$. Then, S_1 is adjacent to S_2 if and only if $|S_1 \cap S_2| = p - 1$. The Johnson graph $J(n, p)$ therefore has $\binom{n}{p}$ vertices, each with degree $p(n - p)$. The state corresponding to a vertex S of the Johnson graph will not only record which subset $\{s_1, \dots, s_p\} \subseteq \{1, \dots, n\}$ it represents, but the function values of those elements. That is,

$$|V\rangle = |s_1, s_2, \dots, s_p; f(s_1), f(s_2), \dots, f(s_p)\rangle \quad (28)$$

Setting up such a state requires p queries to the black box.

The walk then proceeds for t iteration, where t is chosen from the uniform distribution on $\{0, \dots, T\}$ and $T \in O(1/\sqrt{\delta\varepsilon})$. Each iteration has two parts to it. First, one needs to check if there are distinct s_i, s_j with $f(s_i) = f(s_j)$ – that is, whether the vertex S is marked. This requires no calls to the black box, since the function values are stored in the state itself. Second, if the state is unmarked, one needs to take a step of the walk. This involves replacing, say, s_i with s'_i , requiring one query to erase $f(s_i)$ and another to insert the value $f(s'_i)$. So, each iteration requires a total of 2 queries. ε and δ will be bounded now. If only one pair x, y exists with $f(x) = f(y)$, then there are $\binom{n-2}{p-2}$ marked vertices. This tells that, if there are any such pairs at all, epsilon is $\Omega(p^2/n^2)$. Johnson graphs are very well understood in graph theory. It is a well-known result that the eigenvalues for the associated walk operator are given by

$$\lambda_j = 1 - \frac{j(n+1-j)}{p(n-p)} \quad (29)$$

for $0 \leq j \leq p$. For a proof, see Brouwer (1989). This gives $\delta = \frac{n}{p(n-p)}$. Putting this together, we find that $\sqrt{1/\delta\varepsilon}$ is $O\left(\frac{n}{\sqrt{p}}\right)$. So, the number of queries required is $O\left(p + \frac{n}{\sqrt{p}}\right)$. In order to minimize this quantity, we choose p to be of size $\Theta(n^{2/3})$. The query complexity of this algorithm is $O(n^{2/3})$, matching the lower bound of Aaronson and Shi (2004).

4.1.4 Unstructured Search as a Discrete Time Quantum Walk

Unstructured search in terms of quantum walks will be considered now. For unstructured search, we are required to identify a marked element from a set of size n . Let M denote the set

of marked elements, and U denote the set of unmarked elements. Furthermore, let $m = |M|$ and $q = |U|$. It is assumed that the number of marked elements, m , is very small in relation to the total number of elements n . If this were not the case, we could efficiently find a marked element with high probability by simply checking a randomly chosen set of vertices. Since the set lacks any structure or ordering, the corresponding walk takes place on the complete graph on n vertices. One can define the following three states:

$$|UU\rangle = \frac{1}{q} \sum_{u,v \in U} |u, v\rangle \quad (30)$$

$$|UM\rangle = \frac{1}{\sqrt{nq}} \sum_{\substack{u \in U \\ v \in M}} |u, v\rangle \quad (31)$$

$$|MU\rangle = \frac{1}{\sqrt{nq}} \sum_{\substack{u \in M \\ v \in U}} |u, v\rangle \quad (32)$$

Noting that $\{|UU\rangle, |UM\rangle, |MU\rangle\}$ is an orthonormal set, the action of the walk operator on the three-dimensional space will be considered

$$\Gamma = \text{span}\{|UU\rangle, |UM\rangle, |MU\rangle\} \quad (33)$$

In order to do this, we will express the spaces A and B , defined in [Eqs. 12](#) and [13](#) in terms of a different basis. First we can label the unmarked vertices:

$$U = \{u_0, \dots, u_{q-1}\} \quad (34)$$

Then, we can define

$$|\gamma_k\rangle = \frac{1}{\sqrt{q}} \sum_{j=0}^{q-1} e^{\frac{2\pi i j k}{q}} |\psi_{u_j}\rangle \quad (35)$$

and

$$|\gamma_k^*\rangle = \frac{1}{\sqrt{q}} \sum_{j=0}^{q-1} e^{-\frac{2\pi i j k}{q}} |\psi_{u_j}^*\rangle \quad (36)$$

with k ranging from 0 to $q - 1$. Note that $|\gamma_0\rangle$ corresponds to the definition of $|\pi\rangle$ in [Eq. 25](#). We can then rewrite A and B :

$$A = \text{span} \{|\gamma_k\rangle\} \quad (37)$$

$$B = \text{span} \{|\gamma_k^*\rangle\} \quad (38)$$

Now, note that for $k \neq 0$, the space Γ is orthogonal to $|\gamma_k\rangle$ and $|\gamma_k^*\rangle$. Furthermore,

$$|\gamma_0\rangle = \frac{1}{\sqrt{n}} (\sqrt{m}|UM\rangle + \sqrt{q}|UU\rangle) \quad (39)$$

and

$$|\gamma_0^*\rangle = \frac{1}{\sqrt{n}} (\sqrt{m}|MU\rangle + \sqrt{q}|UU\rangle) \quad (40)$$

Therefore, the walk operator

$$W = (2\Pi^* - I)(2\Pi - I) \quad (41)$$

when restricted to Γ is simply

$$W' = \left(2|\gamma_0^*\rangle\langle\gamma_0^*| - I\right)\left(2|\gamma_0\rangle\langle\gamma_0| - I\right) \quad (42)$$

► *Figure 3* illustrates the space Γ that contains the vectors $|\gamma_0\rangle$ and $|\gamma_k^*\rangle$.

At this point, it is interesting to compare this algorithm to Grover's search algorithm. It can be defined that

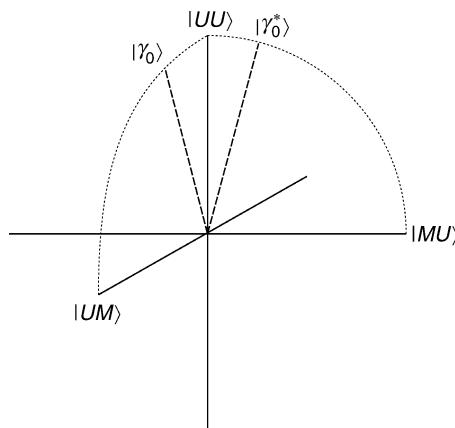

$$|\rho_t\rangle = W^t|UU\rangle. \quad (43)$$

Now, define $|\rho_t^1\rangle$ and $|\rho_t^2\rangle$ to be the projection of $|\rho_t\rangle$ onto $\text{span}\{|UU\rangle, |UM\rangle\}$ and $\text{span}\{|UU\rangle, |MU\rangle\}$, respectively. We can think of these as the “shadow” cast by the vector $|\rho_t\rangle$ on two-dimensional planes within the space Γ . Note that $|\gamma_0\rangle$ lies in the $\text{span}\{|UU\rangle, |UM\rangle\}$ and its projection onto $\text{span}\{|UU\rangle, |MU\rangle\}$ is $\sqrt{q/n}|UU\rangle$. So, the walk operator acts on $|\rho_t\rangle$ by reflecting it around the vector γ_0 and then around $\sqrt{q/n}|UU\rangle$. This is very similar to Grover search, except for the fact that the walk operator in this case does not preserve the magnitude of $|\rho_t^1\rangle$. So, with each application of the walk operator, $|\rho_t^1\rangle$ is rotated by 2θ , where $\theta = \tan^{-1}(\sqrt{m/q})$ is the angle between $|UU\rangle$ and $|\gamma_0\rangle$. The case for $|\rho_t^2\rangle$ is exactly analogous, with the rotation taking place in the plane $\text{span}\{|UU\rangle, |MU\rangle\}$. So, we can think of the quantum walk as Grover search taking place simultaneously in two intersecting planes. It should not come as a surprise, then, that we can achieve a quadratic speedup similar to that of Grover search.

A slightly modified definition of hitting time will be now used to show that the walk can indeed be used to find a marked vertex in $O(\sqrt{n})$ time. Rather than using the hitting time as defined in ◉ Sect. 4.1.2, the state $|\pi\rangle = |\gamma_0\rangle$ will be replaced with $|UU\rangle$. Note that we can create $|UU\rangle$ from $|\pi\rangle$ by simply measuring whether the second register contains a marked vertex. This is only a small adjustment, since $|\gamma_0\rangle$ is close to $|UU\rangle$. Furthermore, both lie in the space Γ , and the action of the walk operator is essentially identical for both starting states.

■ **Fig. 3**

The three-dimensional space Γ . The walk operator acts on this space by alternately performing reflections in the vector $|\gamma_0\rangle$ and $|\gamma_k^*\rangle$.

It should not be surprising to the reader that the results of [Sect. 4.1.2](#) apply to this modified definition as well.

In this case, the operator P is defined by

$$P_{uv} = \begin{cases} 0 & \text{if } u = v \\ \frac{1}{n-1} & \text{if } u \neq v \end{cases} \quad (44)$$

Let v_0, \dots, v_{n-1} be a labeling of the vertices of G . Let x^0, \dots, x^{n-1} denote the eigenvectors of P , with $x_{v_j}^k$ denoting the amplitude on v_j in x^k . Then, the eigenvalues of P are as follows:

$$x_{v_j}^k = \frac{1}{n} \cdot e^{\frac{2\pi i j k}{n}} \quad (45)$$

Then, x^0 has eigenvalue 1, and is the stationary distribution. All the other x^k have eigenvalue $-1/(n-1)$, giving a spectral gap of $\delta = \frac{n-2}{n-1}$. Applying corollary 2 gives the quantum hitting time for the corresponding quantum walk operator W

$$H_Q(W) \leq \sqrt{\frac{(n-1)n}{n-2}} = O(\sqrt{n}) \quad (46)$$

So, we run the walk for some randomly selected time $t \in \{0, \dots, T-1\}$ with T of size $O(\sqrt{n})$, then measure whether either the first or second register contains a marked vertex. Applying Theorem 3, the probability that neither contains a marked vertex is

$$\begin{aligned} \frac{1}{T} \sum_{t=0}^{T-1} |\langle \rho_t | UU \rangle|^2 &\leq \frac{1}{T} \sum_{t=0}^{T-1} |\langle \rho_t | UU \rangle| \\ &= 1 - \frac{1}{2T} \sum_{t=0}^{T-1} \| |\rho_t\rangle - |UU\rangle \|^2 \\ &\leq 1 - \frac{|M|}{2|V|} \end{aligned}$$

Assuming that $|M|$ is small compared to $|V|$, we find a marked vertex in either the first or second register with high probability. Repeating this procedure a constant number of times, the success probability can be forced arbitrarily close to 1.

4.1.5 The MNRS Algorithm

Magniez et al. (2007) developed an algorithm that generalizes the search algorithm described above to any graph. A brief overview of this algorithm and others is also given in the survey paper by Santha (2008). The MNRS algorithm employs similar principles to Grover's algorithm; we apply a reflection in M , the space of unmarked states, followed by a reflection in $|\pi\rangle$, a superposition of marked and unmarked states. This facilitates a rotation through an angle related to the number of marked states. In the general case considered by Magniez et al., $|\pi\rangle$ is the stationary distribution of the walk operator. It turns out to be quite difficult to implement a reflection in $|\pi\rangle$ exactly. Rather, the MNRS algorithm employs an approximate version of this reflection. This algorithm requires $O\left(\frac{1}{\sqrt{\delta\epsilon}}\right)$ applications of the walk operator, where δ is the eigenvalue gap of the operator P , and ϵ is the proportion vertices that are marked. In his survey paper, Santha (2008) outlines some applications of the MNRS algorithm, including a version of the element distinctness problem where we are asked to find elements x and y such that $f(x) = f(y)$.

4.2 Continuous Time Quantum Walks

To define a classical continuous time random walk for a graph with no loops, we define a matrix similar to the adjacency matrix of G , called the *Laplacian*:

$$L_{uv} = \begin{cases} 0 & u \neq v, uv \notin E \\ 1 & u \neq v, uv \in E \\ -\deg(v) & u = v \end{cases} \quad (47)$$

Then, given a probability distribution $p(t)$ on the vertices of G , the walk is defined by

$$\frac{d}{dt} p(t) = Lp(t) \quad (48)$$

Using the Laplacian rather than the adjacency matrix ensures that $p(t)$ remains normalized. A continuous time quantum walk is defined in a similar way. For simplicity, it will be assumed that the Laplacian is symmetric, although it is still possible to define the walk in the asymmetric case. Then, since the Laplacian is Hermitian, we can simply take it to be the Hamiltonian of our system. Letting $|\rho(t)\rangle$ be a normalized vector in \mathbb{C}^V , Schrödinger's equation gives

$$i \frac{d}{dt} |\rho(t)\rangle = L|\rho(t)\rangle \quad (49)$$

Solving this equation, we get an explicit expression for $\rho(t)$:

$$|\rho(t)\rangle = e^{-itL} |\rho(0)\rangle \quad (50)$$

Let $\{|\lambda_1\rangle \dots |\lambda_n\rangle\}$ be the eigenvectors of L with corresponding values $\{\lambda_1, \dots, \lambda_n\}$. We can rewrite the expression for $\rho(t)$ in terms of this basis as follows:

$$|\rho(t)\rangle = \sum_{j=1}^n e^{-i\lambda_j t} \langle \lambda_j | \rho_0 \rangle |\lambda_j\rangle \quad (51)$$

Clearly, the behavior of a continuous time quantum walk is very closely related to the eigenvectors and spectrum of the Laplacian.

Note that we are not required to take the Laplacian as the Hamiltonian for the walk. We could take any Hermitian matrix we like including the adjacency matrix, or the transition matrix of a (symmetric) Markov chain.

4.2.1 A Continuous Time Walk for Unstructured Search

For unstructured search, the walk takes place on a complete graph. First, the following two states are defined:

$$|V\rangle = \frac{1}{\sqrt{|V|}} \sum_{v \in V} |v\rangle \quad (52)$$

$$|M\rangle = \frac{1}{\sqrt{|M|}} \sum_{v \in M} |v\rangle \quad (53)$$

The Hamiltonian that will be used is a slightly modified version of the Laplacian for the complete graph, with an extra “marking term” added:

$$H = |V\rangle\langle V| + |M\rangle\langle M| \quad (54)$$

It is convenient to consider the action of this Hamiltonian in terms of the vectors $|M\rangle$ and $|M^\perp\rangle$, where

$$|M^\perp\rangle = \frac{1}{\sqrt{|V \setminus M|}} \sum_{v \in V \setminus M} |v\rangle = \frac{1}{\sqrt{1 - \langle M|V\rangle^2}} (|V\rangle - |M\rangle\langle M|V\rangle) \quad (55)$$

As outlined in Childs (2008), we let $\alpha = \langle M|V\rangle$. We can then rewrite the Hamiltonian in terms of the basis $\{|M\rangle, |M^\perp\rangle\}$:

$$H = \begin{pmatrix} \alpha^2 & \alpha\sqrt{1-\alpha^2} \\ \alpha\sqrt{1-\alpha^2} & 1-\alpha^2 \end{pmatrix} + \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \quad (56)$$

$$= \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + \alpha^2 \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} + \alpha\sqrt{1-\alpha^2} \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \quad (57)$$

$$= I + \alpha^2 \sigma_Z + \alpha\sqrt{1-\alpha^2} \sigma_X \quad (58)$$

$$= I + \alpha(\alpha\sigma_Z + \sqrt{1-\alpha^2}\sigma_X) \quad (59)$$

where σ_X and σ_Z are the Pauli X and Z operators. Note that the identity term in the sum simply introduces a global phase, and can be ignored. Note that the operator

$$A = \alpha\sigma_Z + \sqrt{1-\alpha^2}\sigma_X \quad (60)$$

has eigenvalues ± 1 , and is therefore Hermitian and unitary. Therefore, we can write

$$e^{-iHt} = e^{-iAt} = \cos(\alpha t)I - i\sin(\alpha t)A \quad (61)$$

Also note that

$$A|V\rangle = (\alpha\sigma_Z + \sqrt{1-\alpha^2}\sigma_X)(\alpha|M\rangle + \sqrt{1-\alpha^2}|M^\perp\rangle) \quad (62)$$

$$= |M\rangle \quad (63)$$

If we start with the state $|V\rangle$, we can now calculate the state of the system at time t :

$$|\rho(t)\rangle = \cos(\alpha t)|V\rangle - i\sin(\alpha t)A|V\rangle \quad (64)$$

$$= \cos(\alpha t)|V\rangle - i\sin(\alpha t)|M\rangle \quad (65)$$

So, at time t , the probability of finding the system in a state corresponding to a marked vertex is

$$\sum_{v \in M} |\langle v|\rho(t)\rangle|^2 = |M| \left(\frac{\cos^2(\alpha t)}{|V|} + \frac{\sin^2(\alpha t)}{|M|} \right) \quad (66)$$

$$= \alpha^2 \cos^2(\alpha t) + \sin^2(\alpha t) \quad (67)$$

At time $t = 0$, this is the same as sampling from the uniform distribution, as we would expect. However, at time $t = \pi/2\alpha = \pi/2 \cdot \sqrt{N/M}$, we observe a marked vertex with probability 1. Therefore, this search algorithm runs in time $O(\sqrt{N/M})$, which coincides with the running time of Grover's search algorithm and the related discrete time quantum walk algorithm.

4.2.2 Mixing in Quantum Walks and the Glued Tree Traversal Problem

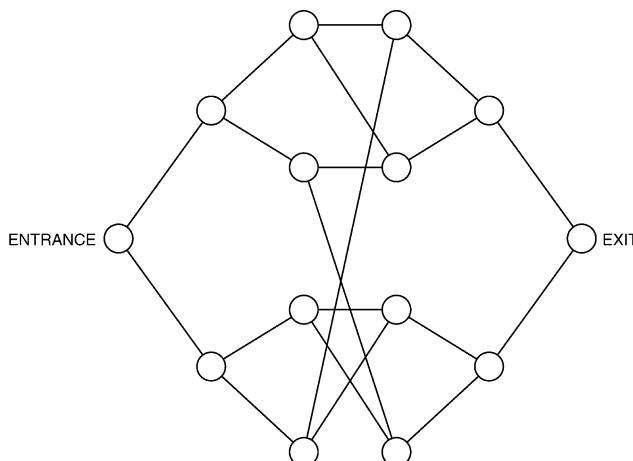

While continuous time quantum walks give a generic quadratic speedup over their classical counterparts, there are some graphs on which the quantum walk gives exponential speedup. One such example is the “glued trees” of Childs et al. (2003). In this example, the walk takes place on the following graph, obtained by taking two identical binary trees of depth d and joining their leaves using a random cycle, as illustrated in Fig. 4. Beginning at the vertex ENTRANCE, we would like to know how long we need to run the algorithm to reach EXIT. It is straightforward to show that classically this will take time exponential in d , the depth of the tree. Intuitively, this is because there are so many vertices and edges in the “middle” of the graph, that there is small probability of a classical walk “escaping” to the exit. It will then be proved that a continuous time quantum walk can achieve an overlap of $\Omega(P(d))$ with the EXIT vertex in time $O\left(\frac{1}{Q(d)}\right)$, where Q and P are polynomials.

Let V_s denote the set of vertices at depth s , so that $V_0 = \{\text{ENTRANCE}\}$ and $V_{2d+1} = \{\text{EXIT}\}$. Taking the adjacency matrix to be the Hamiltonian, the operator $U(t) = e^{-iHt}$ acts identically on the vertices in V_s for any s . Therefore, the states

$$|s\rangle = \frac{1}{\sqrt{|V_s|}} \sum_{v \in V_s} |v\rangle \quad (68)$$

Fig. 4

A small glued tree graph.

form a convenient basis. We can therefore think of the walk on G as a walk on the states $\{|s\rangle : 0 \leq s \leq 2d + 1\}$. We also note that, if A is the adjacency matrix of G ,

$$A|s\rangle = \begin{cases} \sqrt{2}|s+1\rangle & s = 0 \\ \sqrt{2}|s-1\rangle & s = 2d + 1 \\ \sqrt{2}|s-1\rangle + 2|s+1\rangle & s = d \\ \sqrt{2}|s+1\rangle + 2|s-1\rangle & s = d + 1 \\ \sqrt{2}|s+1\rangle + \sqrt{2}|s-1\rangle & \text{otherwise} \end{cases} \quad (69)$$

Aside from the exceptions at ENTRANCE, EXIT, and the vertices in the center, this walk looks exactly like the walk on a line with uniform transition probabilities.

Continuous time classical random walks will eventually converge to a limiting distribution. The time that it takes for the classical random walk to get “close” to this distribution is called the *mixing time*. More formally, we can take some small constant γ , and take the mixing time to be the amount of time it takes to come within γ of the stationary distribution, according to some metric. In general, we express the mixing time in terms of $1/\gamma$ and n , the number of vertices in the graph.

Since quantum walks are governed by a unitary operator, the same convergent behavior cannot be expected. However, the limiting behavior of quantum walks can be defined by taking an average over time. In order to do this, we define $\Pr(u,v,T)$. If we select $t \in [0, T]$ uniformly at random and run the walk for time t , beginning at vertex u , then $\Pr(u,v,T)$ is the probability that we find the system in state v . Formally, this can be written as

$$\Pr(u,v,T) = \frac{1}{T} \int_0^T |\langle v | e^{-iAt} | u \rangle|^2 dt \quad (70)$$

where A is the adjacency matrix of the graph. Now, if $\{|\lambda\rangle\}$ is taken to be the set of eigenvectors of A with corresponding eigenvalues $\{\lambda\}$, then $\Pr(u,v,T)$ can be rewritten as follows:

$$\Pr(u,v,T) = \frac{1}{T} \int_0^T \left| \sum_{\lambda} e^{-i\lambda t} \langle v | \lambda \rangle \langle \lambda | u \rangle \right|^2 dt \quad (71)$$

$$= \frac{1}{T} \int_0^T \sum_{\lambda, \lambda'} \left(e^{-i(\lambda - \lambda')t} \langle v | \lambda \rangle \langle \lambda | u \rangle \langle v | \lambda' \rangle \langle \lambda' | u \rangle \right) dt \quad (72)$$

$$= \sum_{\lambda} |\langle v | \lambda \rangle \langle \lambda | u \rangle|^2 \quad (73)$$

$$+ \frac{1}{T} \sum_{\lambda \neq \lambda'} \langle v | \lambda \rangle \langle \lambda | u \rangle \langle v | \lambda' \rangle \langle \lambda' | u \rangle \int_0^T e^{-i(\lambda - \lambda')t} dt \quad (74)$$

$$= \sum_{\lambda} |\langle v | \lambda \rangle \langle \lambda | u \rangle|^2 \quad (75)$$

$$+ \sum_{\lambda \neq \lambda'} \langle v | \lambda \rangle \langle \lambda | u \rangle \langle v | \lambda' \rangle \langle \lambda' | u \rangle \frac{1 - e^{-i(\lambda - \lambda')T}}{i(\lambda - \lambda')T} \quad (76)$$

In particular, we have

$$\lim_{T \rightarrow \infty} \Pr(u, v, T) = \sum_{\lambda} |\langle v | \lambda \rangle \langle \lambda | u \rangle|^2 \quad (77)$$

This value will be denoted by $\Pr(u, v, \infty)$. This is the quantum analogue of the limiting distribution for a classical random walk. We would now like to apply this to the specific case of the glued tree traversal problem. First, we will lower bound $\Pr(\text{ENTRANCE}, \text{EXIT}, \infty)$. It will be then shown that $\Pr(\text{ENTRANCE}, \text{EXIT}, T)$ approaches this value rapidly as T is increased, implying that we can traverse the glued tree structure efficiently using a quantum walk.

Define the reflection operator Θ by

$$\Theta|j\rangle = |2d - 1 - j\rangle \quad (78)$$

This operator commutes with the adjacency matrix, and hence the walk operator because of the symmetry of the glued trees. This implies that Θ can be diagonalized in the eigenbasis of the walk operator e^{-iAt} for any t . What is more, the eigenvalues of Θ are ± 1 . As a result, if $|\lambda\rangle$ is an eigenvalue of e^{-iAt} , then

$$\langle \lambda | \text{ENTRANCE} \rangle = \pm \langle \lambda | \text{EXIT} \rangle \quad (79)$$

This can be applied to [Eq. 77](#), yielding

$$\Pr(\text{ENTRANCE}, \text{EXIT}, \infty) = \sum_{\lambda} |\langle \text{ENTRANCE} | \lambda \rangle|^4 \quad (80)$$

$$\geq \frac{1}{2d+2} \sum_{\lambda} |\langle \text{ENTRANCE} | \lambda \rangle|^2 \quad (81)$$

$$= \frac{1}{2d+2} \quad (82)$$

Now, we need to determine how quickly $\Pr(\text{ENTRANCE}, \text{EXIT}, T)$ approaches $\Pr(\text{ENTRANCE}, \text{EXIT}, \infty)$ as we increase T :

$$|\Pr(\text{ENTRANCE}, \text{EXIT}, T) - \Pr(\text{ENTRANCE}, \text{EXIT}, \infty)| \quad (83)$$

$$= \left| \sum_{\lambda \neq \lambda'} \langle \text{EXIT} | \lambda \rangle \langle \lambda | \text{ENTRANCE} \rangle \langle \text{EXIT} | \lambda' \rangle \langle \lambda' | \text{ENTRANCE} \rangle \frac{1 - e^{-i(\lambda-\lambda')T}}{i(\lambda - \lambda')T} \right| \quad (84)$$

$$\leq \sum_{\lambda \neq \lambda'} |\langle \lambda | \text{ENTRANCE} \rangle|^2 |\langle \lambda' | \text{ENTRANCE} \rangle|^2 \frac{1 - e^{-i(\lambda-\lambda')T}}{i(\lambda - \lambda')T} \quad (85)$$

$$\leq \frac{2}{T\delta} \quad (86)$$

where δ is the difference between the smallest gap between any two distinct eigenvalues of A . As a result, we get

$$\Pr(\text{ENTRANCE}, \text{EXIT}, T) \geq \frac{1}{2d-1} - \frac{2}{T\delta} \quad (87)$$

Childs et al. (2003) show that δ is $\Omega(1/d^3)$. Therefore, if we take T of size $O(d^4)$, we get success probability $O(1/d)$. Repeating this process, we can achieve an arbitrarily high probability of success in time polynomial in d – an exponential speedup over the classical random walk.

4.2.3 AND-OR Tree Evaluation

AND-OR trees arise naturally when evaluating the value of a two player combinatorial game. The players will be called P_0 and P_1 . The positions in this game are represented by nodes on a tree. The game begins at the root, and players alternate, moving from the root toward the leaves of the tree. For simplicity, we assume that a binary tree is being dealt with; that is, for each move, the players have exactly two moves. While the algorithm can be generalized to any approximately balanced tree, but the binary case is considered for simplicity. We also assume that every game lasts some fixed number of turns d , where a turn consists of one player making a move. The total number of leaf nodes is denoted by $n = 2^d$. We can label the leaf nodes according to which player wins if the game reaches each node; they are labeled with a 0 if P_0 wins, and a 1 if P_1 wins. We can then label each node in the graph by considering its children. If a node corresponds to P_0 's turn, we take the AND of the children. For P_1 's move, we take the OR of the children. The value at the root node tells which player has a winning strategy, assuming perfect play.

Now, since

$$\text{AND}(x_1, \dots, x_k) = \text{NAND}(\text{NAND}(x_1, \dots, x_k)) \quad (88)$$

$$\text{OR}(x_1, \dots, x_k) = \text{NAND}(\text{NAND}(x_1), \dots, \text{NAND}(x_k)) \quad (89)$$

we can rewrite the AND-OR tree using only NAND operations. Furthermore, since

$$\text{NOT}(x_1) = \text{NAND}(x_1) \quad (90)$$

rather than label leaves with a 1, we can insert an extra node below the leaf and label it 0. Also, consecutive NAND operations cancel out, and will be removed. This is illustrated in [Fig. 5](#). Note that the top-most node will be omitted from now on, and the shaded node will be referred to as the ROOT node. Now, the entire AND-OR tree is encoded in the structure of the NAND tree. We will write $\text{NAND}(v)$ to denote the NAND of the value obtained by evaluating the tree up to a vertex v . The value of the tree is therefore $\text{NAND}(\text{ROOT})$.

The idea of the algorithm is to use the adjacency matrix of the NAND tree as the Hamiltonian for a continuous time quantum walk. It will be shown that the eigenspectrum of this walk operator is related to the value of $\text{NAND}(\text{ROOT})$. This idea first appeared in a paper of Farhi et al. (2007), and was later refined by Ambainis et al. (2007). We will begin with the following lemma:

Lemma 1 *Let $|\lambda\rangle$ be an eigenvector of A with value λ . Then, if v is a node in the NAND tree with parent node p and children C ,*

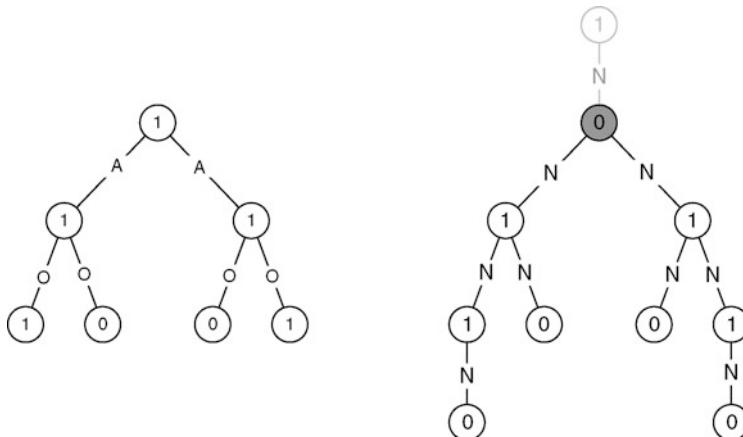

$$\langle p|\lambda\rangle = -\lambda\langle v|\lambda\rangle + \sum_{c \in C} \langle c|\lambda\rangle \quad (91)$$

Therefore, if A has an eigenvector with value 0, then

$$\langle p|\lambda_0\rangle = \sum_{c \in C} \langle c|\lambda_0\rangle \quad (92)$$

Fig. 5

An AND-OR tree and the equivalent NAND tree, with example values. Note that the top-most node will be omitted from now on, and the shaded node in the NAND tree will be referred to as the **ROOT node**.

Using this fact and some inductive arguments, Ambainis et al. (2007) prove the following theorem:

Theorem 4 *If $\text{NAND}(\text{ROOT}) = 0$, then there exists an eigenvector $|\lambda_0\rangle$ of A with eigenvalue 0 such that $|\langle \text{ROOT} | \lambda_0 \rangle| \geq \frac{1}{\sqrt{2}}$. Otherwise, if $\text{NAND}(\text{ROOT}) = 1$, then for any eigenvector $|\lambda\rangle$ of A with $\langle \lambda | A | \lambda \rangle < \frac{1}{2\sqrt{n}}$, we have $\langle \text{ROOT} | \lambda_0 \rangle = 0$.*

This result immediately leads to an algorithm. We perform phase estimation with precision $O(1/\sqrt{n})$ on the quantum walk, beginning in the state $|\text{ROOT}\rangle$. If $\text{NAND}(\text{ROOT}) = 0$, get a phase of 0 with probability $\geq \frac{1}{2}$. If $\text{NAND}(\text{ROOT}) = 1$, we will never get a phase of 0. This gives a running time of $O(\sqrt{n})$. While attention has been restricted to binary trees here, this result can be generalized to any m -ary tree.

It is worth noting that unstructured search is equivalent to taking the OR of n variables. This is an AND-OR tree of depth 1, and n leaves. The $O(\sqrt{n})$ running time of Grover's algorithm corresponds to the running time for the quantum walk algorithm.

Classically, the running time depends not just on the number of leaves, but on the structure of the tree. If it is a balanced m -ary tree of depth d , then the running time is

$$O\left(\left(\frac{(m-1 + \sqrt{m^2 + 14m + 1})}{4}\right)^d\right) \quad (93)$$

In fact, the quantum speedup is maximal when we have an n -ary tree of depth 1. This is just unstructured search, and requires $\Omega(n)$ time classically.

Reichardt and Spalek (2008) generalize the AND-OR tree problem to the evaluation of a broader class of logical formulas. Their approach uses *span programs*. A span program P consists of a set of target vector t , and a set of input vectors $\{v_1^0, v_1^1, \dots, v_n^0, v_n^1\}$ corresponding

to logical literals $\{x_1, \bar{x}_1, \dots, x_n, \bar{x}_n\}$. The program corresponds to a Boolean function $f_P: \{0, 1\}^n \rightarrow \{0, 1\}$ such that, for $\sigma \in \{0, 1\}^n$, $f(\sigma) = 1$ if and only if (Karchmer and Wigderson 1993)

$$\sum_{j=1}^n v_j^{\sigma_j} = t$$

Reichardt and Spalek outline the connection between span programs and the evaluation of logical formulas. They show that finding $\sigma \in f^{-1}(1)$ is equivalent to finding a zero eigenvector for a graph G_P corresponding to the span program P . In this sense, the span program approach is similar to the quantum walk approach of Childs et al. – both methods evaluate a formula by finding a zero eigenvector of a corresponding graph.

5 Tensor Networks and Their Applications

A tensor network consists of an underlying graph G , with an algebraic object called a *tensor* assigned to each vertex of G . The value of the tensor network is calculated by performing a series of operations on the associated tensors. The nature of these operations is dictated by the structure of G . At their simplest, tensor networks capture basic algebraic operations, such as matrix multiplication and the scalar product of vectors. However, their underlying graph structure makes them powerful tools for describing combinatorial problems as well. Two such examples will be explored – the Tutte polynomial of a planar graph, and the partition function of a statistical mechanical model defined on a graph. As a result, the approximation algorithm that will be described below for the value of a tensor network is implicitly an algorithm for approximating the Tutte polynomial, as well as the partition function for these statistical mechanics models. We begin by defining the notion of a tensor. We then outline how these tensors and tensor operations are associated with an underlying graph structure. For a more detailed account of this algorithm, the reader is referred to Arad and Landau (2008). Finally, we will describe the quantum approximation algorithm for the value of a tensor network, as well as the applications mentioned above.

5.1 Tensors: Basic Definitions

Tensors are formally defined as follows:

Definition 3 A tensor M of rank m and dimension q is an element of \mathbf{C}^{q^m} . Its entries are denoted by M_{j_1, j_2, \dots, j_m} , where $0 \leq j_k \leq q - 1$ for all j_k .

Based on this definition, a vector is simply a tensor of rank 1, while a square matrix is a tensor of rank 2. Several operations on tensors, which will generalize many familiar operations from linear algebra, will be now defined.

Definition 4 Let M and N be two tensors of dimension q and rank m and n , respectively. Then, their product, denoted $M \otimes N$, is a rank $m + n$ tensor with entries

$$(M \otimes N)_{j_1, \dots, j_m, k_1, \dots, k_n} = M_{j_1, \dots, j_m} \cdot N_{k_1, \dots, k_n} \quad (94)$$

This operation is simply the familiar tensor product. While the way that the entries are indexed is different, the resulting entries are the same.

Definition 5 Let M be a tensor of rank m and dimension q . Now, take a and b with $1 \leq a < b \leq m$. The contraction of M with respect to a and b is a rank $m - 2$ tensor N defined as follows:

$$N_{j_1, \dots, j_{a-1}, j_a+1, \dots, j_{b-1}, j_b+1, \dots, j_m} = \sum_{k=0}^{q-1} M_{j_1, \dots, j_{a-1}, k, j_{a+1}, \dots, j_{b-1}, k, j_{b+1}, \dots, j_m} \quad (95)$$

One way of describing this operation is that each entry in the contracted tensor is given by summing along the “diagonal” defined by a and b . This operation generalizes the partial trace of a density operator. The density operator of two-qubit system can be thought of as a rank 4 tensor of dimension two. Tracing out the second qubit is then just taking a contraction with respect to 3 and 4. It is also useful to consider the combination of these two operations.

Definition 6 If M and N are two tensors of dimension q and rank m and n , then for a and b with $1 \leq a \leq m$ and $1 \leq b \leq n$, the contraction of M and N is the result of contracting the product $M \otimes N$ with respect to a and $m + b$.

We now have the tools to describe a number of familiar operations in terms of tensor operations. For example, the inner product of two vectors can be expressed as the contraction of two rank 1 tensors. Matrix multiplication is just the contraction of 2 rank 2 tensors M and N with respect to the second index of M and the first index of N . Finally, if a Hilbert space $H = \mathbb{C}^q$ is taken, then we can identify a tensor M of dimension q and rank m with a linear operator $M^{s,t} : H^{\otimes t} \rightarrow H^{\otimes s}$ where $s + t = m$:

$$M^{s,t} = \sum_{j_1, \dots, j_m} M_{j_1, \dots, j_m} |j_1\rangle \otimes \dots \otimes |j_s\rangle \langle j_{s+1}| \otimes \dots \otimes \langle j_m| \quad (96)$$

This correspondence with linear operators is essential to understanding tensor networks and their evaluation.

5.2 The Tensor Network Representation

A tensor network $T(G, \mathbf{M})$ consists of a graph $G = (V, E)$ and a set of tensors $\mathbf{M} = \{M[v] : v \in V\}$. A tensor is assigned to each vertex, and the structure of the graph G encodes the operations to be performed on the tensors. It can be said that the *value* of a tensor network is the tensor that results from applying the operations encoded by G to the set of tensors \mathbf{M} . When the context is clear, we will let $T(G, \mathbf{M})$ denote the value of the network. In addition to the typical features of a graph, G is allowed to have *free edges* – edges that are incident with a vertex on one end, but are unattached at the other. For simplicity, it will be assumed that all of the tensors in \mathbf{M} have the same dimension q . It is also required that $\deg(v)$, the degree of vertex v , is equal to the rank of the associated tensor $M[v]$. If G consists of a single vertex v with m free edges, then $T(G, \mathbf{M})$ represents a single tensor of rank m . Each index of M is associated with a particular edge. It will often be convenient to refer to the edge associated with an index a as e_a . A set of rules that will

allow us to construct a tensor network corresponding to any sequence of tensor operations will be defined now:

- If M and N are the value of two tensor networks $T(G, \mathbf{M})$ and $T(H, \mathbf{N})$, then taking the product $M \otimes N$ is equivalent to taking the disjoint union of the two tensor networks, $T(G \cup H, \mathbf{M} \cup \mathbf{N})$.
- If M is the value of a tensor network $T(G, \mathbf{M})$, then contracting M with respect to a and b is equivalent to joining the free edges e_a and e_b in G .
- As a result, taking the contraction of M and N with respect to a and b corresponds to joining the associated edge e_a from $T(G, \mathbf{M})$ and e_b from $T(H, \mathbf{N})$.

Some examples are illustrated in Fig. 6. Applying these simple operations iteratively allows one to construct a network corresponding to any series of products and contractions of tensors. Note that the number of free edges in $T(G, \mathbf{M})$ is always equal to the rank of the corresponding tensor M . Tensor networks that have no free edges, and whose value is therefore a scalar, will be of particular interest.

The tensor network interpretation of a linear operator $M^{s,t}$ defined in Eq. 96 can now be considered. $M^{s,t}$ is associated with a rank $m = s + t$ tensor M . An equivalent tensor network could consist of a single vertex with m free edges (e_1, \dots, e_m) . The operator $M^{s,t}$ acts on elements of $(\mathbb{C}^q)^{\otimes t}$, which are rank t tensors, and can therefore be represented by a single vertex with t free edges (e'_1, \dots, e'_t) . The action of $M^{s,t}$ on an element $N \in (\mathbb{C}^q)^{\otimes t}$ is therefore represented by connecting e'_k to e_{s+k} for $k = 1, \dots, t$. Fig. 7 illustrates the operator $M^{2,2}$ acting on a rank 2 tensor. Note that the resulting network has two free edges, corresponding to the rank of the resulting tensor.

Fig. 6

The network representation of a tensor M of rank 4, and the contraction of two rank 4 tensors, M and N .

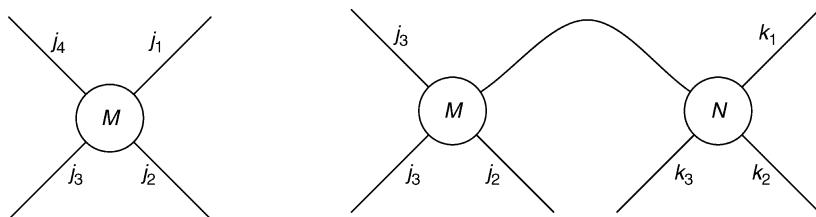

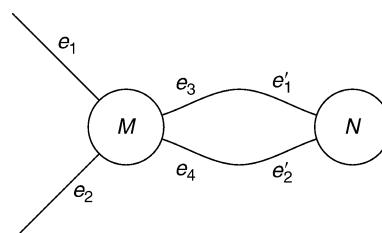

Fig. 7

The network corresponding to the operator $M^{2,2}$ acting on a rank 2 tensor N .

Now, the tensor networks that are of most interest – those with no free edges – will be reconsidered. We first consider the example of an inner product of two rank 1 tensors. This corresponds to a graph consisting of two vertices u and v joined by a single edge. The value of the tensor is then

$$T(G, \mathbf{M}) = \sum_{j=0}^q (M[u])_j \cdot (M[v])_j \quad (97)$$

That is, it is a sum of q terms, each of which corresponds to the assignment of an element of $\{0, \dots, q-1\}$ to the edge (u, v) . We can refer to this assignment as an q -edge coloring of the graph. In the same way, the value of a more complex tensor network is given by a sum whose terms correspond to q -edge colorings of G . Given a coloring of G , let $M[v]^\gamma = (M[v])_{i_1, \dots, i_m}$ where i_1, \dots, i_m are the values assigned by γ to the edges incident at v . That is, a q -edge coloring specifies a particular entry of each tensor in the network. Then, we can rewrite the value of $T(G, \mathbf{M})$ as follows:

$$T(G, \mathbf{M}) = \sum_{\gamma} \left(\prod_{v \in V} M[v]^\gamma \right) \quad (98)$$

where γ runs over all q -edge colorings of G . Thinking of the value of a tensor network as a sum over all q -edge colorings of G will prove useful when we consider applications of tensor networks to statistical mechanics models.

5.3 Evaluating Tensor Networks: the Algorithm

In this section, we will first show how to interpret a tensor network as a series of linear operators. We will then show how to apply these operators using a quantum circuit. Finally, we will see how to approximate the value of the tensor network using the Hadamard test.

5.3.1 Overview

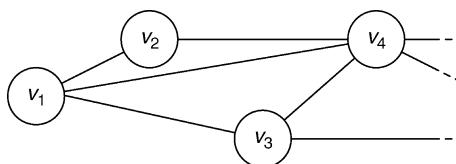

In order to evaluate a tensor network $T(G, \mathbf{M})$, some structure is first given to it, by imposing an ordering on the vertices of G ,

$$V(G) = \{v_1, \dots, v_n\}$$

The sets $S_j = \{v_1, \dots, v_j\}$ are further defined. This gives a natural way to depict the tensor network, which is shown in Fig. 8. The evaluation algorithm will “move” from left to right, applying linear operators corresponding to the tensors M_{v_i} . One can think of the edges in

Fig. 8

Part of the graph G , with an ordering on $V(G)$.

analogy to the “wires” of a quantum circuit diagram. To make this more precise, let v_i be a vertex of degree d . Let t be the number of vertices connecting v_i to S_{i-1} and s be the number of edges connecting v_i to $V(G) \setminus S_i$. Then, the operator that is applied at v_i is $M_{v_i}^{s,t}$. Letting j be the number of edges from S_{i-1} to $V(G) \setminus S_i$, we apply the identity operator I_j on the j indices that correspond to edges not incident at v_i . Combining these, we get an operator

$$N_i = M_{v_i}^{s,t} \otimes I_j \quad (99)$$

Note that, taking the product of these operators, $\prod_{i=1}^n N_i$, gives the value of $T(G, \mathbf{M})$. However, there are a few significant details remaining. Most notably, the operators N_i are not, in general, unitary. In fact, they may not even correspond to square matrices. A method for converting the N_i into equivalent unitary operators will be now outlined.

5.3.2 Creating Unitary Operators

The first task is to convert the operators N_i into “square” operators – that is, operators whose domain and range have the same dimension. Referring to [Eq. 99](#), the identity I_j is already square, so we need only modify $M_{v_i}^{s,t}$. In order to do this, some extra qubits will be added in the $|0\rangle$ state. We consider three cases:

1. If $s = t$, we define $\widetilde{M}_{v_i}^{s,t} = M_{v_i}^{s,t}$
2. If $s > t$, then we add $s - t$ extra qubits in the $|0\rangle$ state, and define $\widetilde{M}_{v_i}^{s,t}$ such that

$$\widetilde{M}_{v_i}^{s,t}(|\psi\rangle \otimes |0\rangle^{\otimes(s-t)}) = M_{v_i}^{s,t}|\psi\rangle \quad (100)$$

For completeness, we say that if the last $s - t$ qubits are not in the $|0\rangle$ state, $\widetilde{M}_{v_i}^{s,t}$ takes them to the 0 vector.

3. If $s < t$, then we define

$$\widetilde{M}_{v_i}^{s,t}|\psi\rangle = (M_{v_i}^{s,t}|\psi\rangle) \otimes |0\rangle^{\otimes(t-s)} \quad (101)$$

Finally, we define

$$\widetilde{N}_i = \widetilde{M}_{v_i}^{s,t} \otimes I_j \quad (102)$$

which is a square operator. Now, to derive corresponding unitary operators, we make use of the following lemma:

Lemma 2 *Let M be a linear map $A: H^{\otimes t} \rightarrow H^{\otimes t}$, where H is a Hilbert space $H = \mathbb{C}^q$. Furthermore, let $G = \mathbb{C}^2$ be a spanned by $\{|0\rangle, |1\rangle\}$. Then, there exists a unitary operator $U_M: (H^{\otimes t} \otimes G) \rightarrow (H^{\otimes t} \otimes G)$ such that*

$$U_M(|\psi\rangle \otimes |0\rangle) = \frac{1}{\|M\|} M|\psi\rangle \otimes |0\rangle + |\phi\rangle \otimes |1\rangle \quad (103)$$

U_M can be implemented on a quantum computer in $\text{poly}(q^t)$ time.

A proof can be found in Arad and Landau ([2008](#)) as well as Aharonov et al. ([2007](#)). Applying this lemma, we can create n unitary operators $U_{\widetilde{N}_j}$ for $1 \leq j \leq n$, and define

$$U = \prod_{j=1}^n U_{\widetilde{N}_j} \quad (104)$$

It is easily verified that

$$\langle 0|^{\otimes r} U | 0 \rangle^{\otimes r} = \frac{T(G, \mathbf{M})}{\prod_j \| M_{v_j}^{s,t} \|} \quad (105)$$

where r is dependent on the number of vertices n as well as the structure of G and the ordering of the vertices v_1, \dots, v_n .

5.3.3 The Hadamard Test

In order to approximate $\langle 0|^{\otimes r} U | 0 \rangle^{\otimes r}$, most authors suggest the *Hadamard test* – a well-known method for approximating the weighted trace of a unitary operator. First, we add an ancillary qubit that will act as a control register. We then apply the circuit outlined below, and measure the ancillary qubit in the computational basis.

It is not difficult to show that we measure

$$\begin{aligned} |0\rangle &\text{ with probability } \frac{1}{2}(1 + \operatorname{Re}\langle \psi | U | \psi \rangle) \\ |1\rangle &\text{ with probability } \frac{1}{2}(1 - \operatorname{Re}\langle \psi | U | \psi \rangle) \end{aligned}$$

So, if one assigns a random variable X such that $X = 1$ when one measures $|0\rangle$ and $X = -1$ when one measures $|1\rangle$, then X has expected value $\operatorname{Re}\langle \psi | U | \psi \rangle$. So, in order to approximate $\operatorname{Re}\langle \psi | U | \psi \rangle$ to a precision of ε with constant probability $p > 1/2$, one requires $O(\varepsilon^{-2})$ repetitions of this protocol. In order to calculate the imaginary portion, we apply the gate

$$R = \begin{pmatrix} 1 & 0 \\ 0 & -i \end{pmatrix}$$

to the ancillary qubit, right after the first Hadamard gate. It is important to note that the Hadamard test gives an *additive approximation* of $\langle 0|^{\otimes r} U | 0 \rangle^{\otimes r}$. Additive approximations will be examined in [Sect. 5.3.5](#).

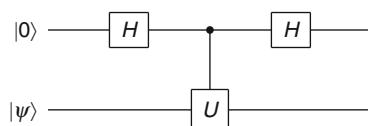

5.3.4 Approximating $\langle 0|^{\otimes r} U | 0 \rangle^{\otimes r}$ Using Amplitude Estimation

In order to estimate $\langle 0|^{\otimes r} U | 0 \rangle^{\otimes r}$, most of the literature applies the Hadamard test ([Fig. 9](#)). However, it is worth noting that we can improve the running time by using the process of *amplitude estimation*, as outlined in [Sect. 3](#). Using the notation from [Sect. 3](#), we have $U_f = U_0$ and $A = U$, the unitary corresponding to the tensor network $T(G, \mathbf{M})$. We begin in the state $U|0\rangle^{\otimes r}$, and the search iterate is

$$Q = -UU_0U^{-1}U_0 \quad (106)$$

Fig. 9

The quantum circuit for the Hadamard test.

In order to approximate $\langle 0 |^{\otimes r} U | 0 \rangle^{\otimes r}$ to a precision of ε , the running time is in $O(1/\varepsilon)$, a quadratic improvement over the Hadamard test.

5.3.5 Additive Approximation

Let $f: S \rightarrow \mathbb{C}$ be a function that we would like to evaluate. Then, an *additive approximation* A with approximation scale $\Delta: S \rightarrow \mathbb{R}$ is an algorithm that, on input $x \in S$ and parameter $\varepsilon > 0$, outputs $A(x)$ such that

$$\Pr(|A(x) - f(x)| \geq \varepsilon \Delta(x)) \leq c \quad (107)$$

for some constant c with $0 \leq c < 1/2$. If $\Delta(x)$ is $O(f(x))$, then A is a *fully polynomial randomized approximation scheme*, or FPRAS.

The approximation scale for the algorithm outlined above will be now determined. Using amplitude estimation, we estimate

$$\langle 0 |^{\otimes r} U | 0 \rangle^{\otimes r} = \frac{T(G, \mathbf{M})}{\prod_j \|M_{v_j}^{s,t}\|} \quad (108)$$

to within ε with time requirement in $O(1/\varepsilon)$. However, the quantity we actually want to evaluate is $T(G, \mathbf{M})$, so we must multiply by $\prod_j \|M_{v_j}^{s,t}\|$. Therefore, the algorithm has approximation scale

$$\Delta(G, \mathbf{M}) = \prod_j \|M_{v_j}^{s,t}\| \quad (109)$$

We apply [Lemma 2](#) to each vertex in G , and require $O(1/\varepsilon)$ repetitions of the algorithm to approximate $T(G, \mathbf{M})$ with the desired accuracy using amplitude estimation. This gives an overall running time

$$O\left(\text{poly}(q^{D(G)}) \cdot |V(G)| \cdot \varepsilon^{-1}\right) \quad (110)$$

where $D(G)$ is the maximum degree of any vertex in G . The algorithm is, therefore, an additive approximation of $T(G, \mathbf{M})$.

5.4 Approximating the Tutte Polynomial for Planar Graphs Using Tensor Networks

In 2000, Kitaev, Freedman, Larsen, and Wang (Freedman et al. 2000, 2001) demonstrated an efficient quantum simulation for topological quantum field theories. In doing so, they implied that the Jones polynomial can be efficiently approximated at $e^{2\pi i/5}$. This suggests that efficient quantum approximation algorithms might exist for a wider range of knot invariants and values. Aharonov et al. (2008) developed such a Jones polynomial for any complex value. Yard and Wocjan (2006) developed a related algorithm for approximating the HOMFLYPT polynomial of a braid closure. Both of these knot invariants are special cases of the Tutte polynomial. While the tensor network algorithm in [Sect. 3.2](#) follows directly from a later paper of Aharonov et al. (2007), it owes a good deal to these earlier results for knot invariants.

A definition of the Tutte polynomial, as well as an overview of its relationship to tensor networks and the resulting approximation algorithm, will be given.

5.4.1 The Tutte Polynomial

The multivariate Tutte Polynomial is defined for a graph $G = (V, E)$ with edge weights $\mathbf{w} = \{w_e\}$ and variable q as follows:

$$Z_G(q, \mathbf{w}) = \sum_{A \subseteq E} q^{k(A)} \prod_{e \in A} w_e \quad (111)$$

where $k(A)$ denotes the number of connected components in the graph induced by A . The power of the Tutte polynomial arises from the fact that it captures nearly all functions on graphs defined by a *skein relation*. A skein relation is of the form

$$f(G) = x \cdot f(G/e) + y \cdot f(G \setminus e) \quad (112)$$

where G/e is created by contracting an edge e and $G \setminus e$ is created by deleting e . Oxley and Welsh (Welsh 1993) show that, with a few additional restrictions on f , if f is defined by a skein relation, then computing f can be reduced to computing Z_G . It turns out that many functions can be defined in terms of a skein relation, including

1. The partition functions of the Ising and Potts models from statistical physics
2. The chromatic and flow polynomials of a graph G
3. The Jones Polynomial of an alternating link

The exact evaluation of the Tutte polynomial, even when restricted to planar graphs, turns out to be $\#P$ -hard for all but a handful of values of q and \mathbf{w} . While FPRAS seems very unlikely for the Tutte polynomial of a general graph and any parameters q and \mathbf{w} . The interesting question seems to be *which* graphs and parameters admit an efficient and accurate approximation. By describing the Tutte polynomial as the evaluation of a Tensor network, an additive approximation algorithm for the Tutte polynomial is immediately produced. However, we do not have a complete characterization of the graphs and parameters for which this approximation is nontrivial.

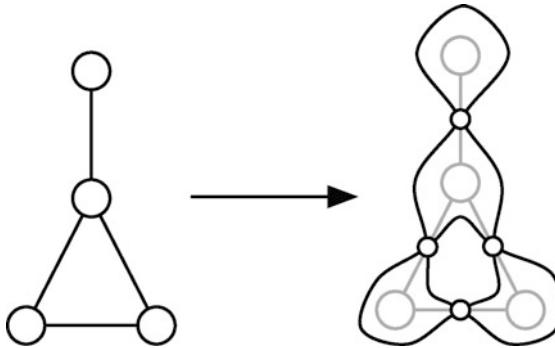

5.4.2 The Tutte Polynomial as a Tensor Network

Given a planar graph G , and an embedding of G in the plane, we define the *medial graph* L_G . The vertices of L_G are placed on the edges of G . Two vertices of L_G are joined by an edge if they are adjacent on the boundary of a face of G . If G contains vertices of degree 2, then L_G will have multiple edges between some pair of vertices. Also note that L_G is a regular graph with valency 4. An example of a graph and its associated medial graph is depicted in [Fig. 10](#).

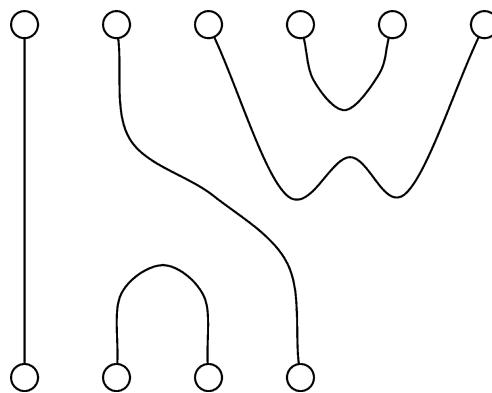

In order to describe the Tutte polynomial in terms of a tensor network, we make use of the *generalized Temperley–Lieb algebra*, as defined in Aharonov et al. (2007). The basis elements of the Temperley–Lieb algebra $GTL(d)$ can be thought of as diagrams in which m upper pegs are joined to n lower pegs by a series of strands. The diagram must contain no crossings or loops. See [Fig. 11](#) for an example of such an element. Two basis elements are considered equivalent if they are isotopic to each other or if one can be obtained from the other by “padding” it on the right with a series of vertical strands. The algebra consists of all complex weighted sums of these basis elements. Given two elements of the algebra T_1 and T_2 , we can take their product $T_2 \cdot T_1$ by simply placing T_2 on top of T_1 and joining the strands. Note that if the number of strands do not match, we can simply pad the appropriate element

Fig. 10

A graph G and the resulting medial graph L_G .

**Fig. 11**

An element of the Temperley–Lieb algebra with six upper pegs and four lower pegs.

with some number of vertical strands. As a consequence, the identity element consists of any number of vertical strands. In composing two elements in this way, a loop may be created. Let us say that $T_1 \cdot T_2$ contains one loop. Then, if T_3 is the element created by removing the loop, we define $T_1 \cdot T_2 = dT_3$, where d is the complex parameter of $GTL(d)$.

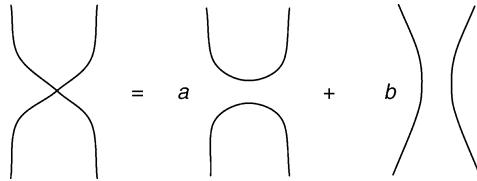

We would also like this algebra to accommodate drawings with crossings. Let T_1 be such a diagram, and T_2 and T_3 be the diagrams resulting from “opening” the crossing in the two ways indicated in Fig. 12. Then, we define $T_1 = aT_2 + bT_3$, for appropriately defined a and b .

If we think of L_G as the projection of a knot onto the plane, where the vertices of L_G are the crossings of the knot, we see that L_G can be expressed in terms of the generalized Temperley–Lieb algebra. We would like to take advantage of this in order to map L_G to a series of tensors that will allow us to approximate the Tutte polynomial of G . Aharonov et al. define such a representation ρ of the Temperley–Lieb algebra. If $T \in GTL(d)$ is a basis element with m lower pegs and n upper pegs, then ρ is a linear operator such that

$$\rho(T) : H^{\otimes m+1} \rightarrow H^{\otimes n+1} \quad (113)$$

Fig. 12

An element that contains a crossing is equated to a weighted sum of the elements obtained by “opening” the crossing.

where $H = \mathbf{C}^k$ for some k , which depends on the particular embedding of G , such that

1. ρ preserves multiplicative structure. That is, if T_1 has m upper pegs and T_2 has m lower pegs, then

$$\rho(T_2 \cdot T_1) = \rho(T_2) \cdot \rho(T_1) \quad (114)$$

2. ρ is linear. That is,

$$\rho(\alpha T_1 + \beta T_2) = \alpha \rho(T_1) + \beta \rho(T_2) \quad (115)$$

For these purposes, k can be upper bounded by the number of edges $|E(L_G)| = 2|E(G)|$, and corresponds to the value r in [Eq. 105](#). To represent L_G , each crossing (vertex) of L_G is associated with a weighted sum of two basis elements, and therefore is represented by a weighted sum of the corresponding linear operators, $\rho(T_1) = a\rho(T_2) + b\rho(T_3)$. The minima and maxima of L_G are also basis elements of $GTL(d)$, and can be represented as well. Finally, since L_G is a closed loop, and has no “loose ends”, $\rho(L_G)$ must be a scalar multiple of the identity operator on $H = \mathbf{C}^k$. This relates well to our notion that the value of a tensor network with no loose ends is just a scalar.

We would like this scalar to be the Tutte polynomial of the graph G . In order to do this, we need to choose the correct values for a , b , and d . Aharonov et al. show how to choose these values so that the scalar is a graph invariant called the Kauffman bracket, from which we can calculate the Tutte polynomial for planar graphs. So, we can construct a tensor network whose value is the Kauffman bracket of L_G , and this gives the Tutte polynomial of G by the following procedure:

1. Construct the medial graph L_G and embed it in the plane.
2. Let L'_G be constructed by adding a vertex at each local minimum and maximum of L_G . These vertices are required in order to assign the linear operator associated with each minimum/maximum with a vertex in the tensor network.
3. Each vertex v of L'_G has a Temperley–Lieb element T_v associated with it. For some vertices, this is a crossing; for others, it is a local minimum or maximum. Assign the tensor $M[v] = \rho(T_v)$ to the vertex v .

The tensor network we are interested in is then $T(L'_G, \mathbf{M})$, where $\mathbf{M} = \{M[v] : v \in V(L'_G)\}$. Approximating the value of this tensor network gives an approximation of the Kauffman bracket of L_G , and therefore of the Tutte polynomial of G . Furthermore, it is known that L'_G has maximum degree 4. Finally, we will assume that $|E(G)| \geq |V(G)|$ giving a running time of

$$O(\text{poly}(q^4) \cdot |E(G)| \cdot \varepsilon^{-1}) \quad (116)$$

In this case, q depends on the particular embedding $f: L_G$, but can be upper bounded by $|E|$. For more details on the representation ρ and quantum approximations of the Tutte polynomial as well as the related Jones polynomial, the reader is referred to the work of Aharonov et al., in particular Aharonov and Arad (2006) and Aharonov et al. (2007).

5.5 Tensor Networks and Statistical Mechanics Models

Many models from statistical physics describe how simple local interactions between microscopic particles give rise to macroscopic behavior. See Beaudin et al. (2008) for an excellent introduction to the combinatorial aspects of these models. The models that we are concerned with here are described by a weighted graph $G = (V, E)$. In this graph, the vertices represent particles, while edges represent an interaction between particles. A configuration σ of a q -state model is an assignment of a value from the set $\{0, \dots, q - 1\}$ to each vertex of G . We denote the value assigned to v by σ_v . For each edge $e = (u, v)$, we define a local Hamiltonian $h_e(\sigma_u, \sigma_v) \in \mathbb{C}$. The Hamiltonian for the entire system is then given taking the sum:

$$H(\sigma) = \sum_{e=(u,v)} h_e(\sigma_u, \sigma_v) \quad (117)$$

The sum runs over all the edges of G . The *partition function* is then defined as

$$Z_G(\beta) = \sum_{\sigma} e^{-\beta H(\sigma)} \quad (118)$$

where $\beta = 1/kT$ is referred to as the *inverse temperature* and k is Boltzmann's constant. The partition function is critical to understanding the behavior of the system. First, the partition function allows one to determine the probability of finding the system in a particular configuration, given an inverse temperature β :

$$\Pr(\sigma') = \frac{e^{-\beta H(\sigma')}}{Z_G(\beta)} \quad (119)$$

This probability distribution is known as the Boltzmann distribution. Calculating the partition function also allows us to derive other properties of the system, such as entropy and free energy. An excellent discussion of the partition function from a combinatorial perspective can be found in Welsh (1993).

A tensor network whose value is the partition function Z_G will be now constructed. Given the graph G , we define the vertices of $G' = (V', E')$ as follows:

$$V' = V \cup \{v_e : e \in E\} \quad (120)$$

We are simply adding a vertex for each edge e of G , and identifying it by v_e . We then define the edge set of G' :

$$E' = \{(x, v_e), (v_e, y) : (x, y) \in E\} \quad (121)$$

So, the end product G' resembles the original graph; vertices in the middle of each edge of the original graph have been simply added. The tensors that will be identified with each vertex will be defined separately for the vertex set V of the original graph and the set $V_E = \{v_e\}$ of vertices that are added to define G' . In each case, they will be dimension q tensors for a q -state model. For $v \in V$, $M[v]$ is an “identity” operator; that is, it takes on the value 1 when all indices are

equal, and 0 otherwise:

$$(M[v])_{i_1, \dots, i_m} = \begin{cases} 1 & \text{if } i_1 = i_2 = \dots = i_m \\ 0 & \text{otherwise} \end{cases} \quad (122)$$

The vertices in V_E encode the actual interactions between neighboring particles. The tensor associated with v_e is

$$(M_{v_e})_{s,t} = e^{-\beta h_e(s,t)} \quad (123)$$

Now, one can consider the value of the tensor network in terms of q -edge colorings of G :

$$T(G', \mathbf{M}) = \sum_{\gamma} \left(\prod_{v \in V'} M[v]^{\gamma} \right) \quad (124)$$

where γ runs over all q -edge colorings of G' . Based on the definitions of the tensors $M[v]$ for $v \in V$, we see that $\prod_{v \in V'} M[v]^{\gamma}$ is nonzero only when the edges incident at each vertex are all colored identically. This restriction ensures that each nonzero term of the sum (❷ Eq. 124) corresponds to a configuration σ of the q -state model. That is, a configuration σ corresponds to a q -edge coloring γ of G' where each $\gamma(e) = \sigma_v$ whenever e is incident with $v \in V$. This gives the following equality:

$$\begin{aligned} T(G', \mathbf{M}) &= \sum_{\gamma} \left(\prod_{v \in V'} M[v]^{\gamma} \right) \\ &= \sum_{\sigma} \prod_{e=(u,v)} e^{-\beta h_e(\sigma_u, \sigma_v)} \\ &= \sum_{\sigma} e^{-\beta H(\sigma)} \\ &= Z_G(\beta) \end{aligned}$$

The time required to approximate the value of this tensor network will be now considered. Recall that the running time is given by

$$O\left(\text{poly}(q^{D(G')}) \cdot |V(G')| \cdot \varepsilon^{-1}\right) \quad (125)$$

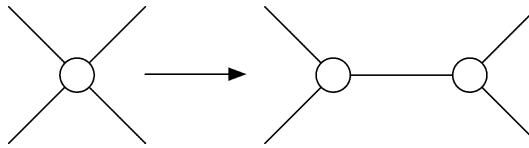

First, it is observed that, if one assumes that G is connected, then $|V(G')|$ is $O(|E|)$. Restrictions are not placed on the maximum degree $D(G')$. The vertices of G' of high degree must be in V , since all vertices in V_E have degree 2. Now, the tensors assigned to vertices of V are just identity operators; they ensure that the terms of the sum from ❷ Eq. 124 are nonzero only when all the edges incident at v are colored identically. As a result, one can replace each vertex $v \in V$ with $\deg(v) > 3$ by $(\deg(v) - 2)$ vertices, each of degree 3. See ❷ Fig. 13 for an example. The tensor assigned to each of these new vertices is the identity operator of rank 3. It is not difficult to show that this replacement does not affect the value of the tensor network. It does, however, affect the number of vertices in the graph, adding a multiplicative factor to the running time, which can now be written

$$O\left(\text{poly}(q) \cdot d(G) \cdot |E| \cdot \varepsilon^{-1}\right) \quad (126)$$

For more details on the approximation scale of this algorithm, the reader is referred to Arad and Landau (2008).

Fig. 13

Replacing a vertex v by $(\deg(v) - 2)$ vertices.

Arad and Landau also discuss a useful restriction of q -state models called *difference models*. In these models, the local Hamiltonians h_e depend only on the difference between the states of the vertices incident with e . That is, $h_e(\sigma_u, \sigma_v)$ is replaced by $h_e(|\sigma_u - \sigma_v|)$, where $|\sigma_u - \sigma_v|$ is calculated modulo q . Difference models include the well-known Potts, Ising and Clock models. Arad and Landau show that the approximation scale can be improved when attention is restricted to difference models.

Van den Nest et al. (Cuevas et al. 2008; Hübener et al. 2008) show that the partition function for difference models can be described as the overlap between two quantum states

$$Z_G = \langle \psi_G | \left(\bigotimes_{e \in E(G)} |\alpha_e\rangle \right) \quad (127)$$

Van den Nest uses the state $|\psi_G\rangle$ to encode the structure of the graph, while each state $|\alpha_e\rangle$ encodes the strength of the local interaction at e . The actual computation of this overlap is best described as a tensor network. While this description does not yield a computational speedup over the direct method described above, it is an instructive way to deconstruct the problem. In the case of planar graphs, it also relates the partition function of a graph G and its planar dual.

Geraci and Lidar (Geraci 2008; Geraci and Lidar 2008) show that the Potts partition may be efficiently and exactly evaluated for a class of graphs related to irreducible cyclic cocycle codes. While their algorithm does not employ tensor networks, it is interesting to consider the implications of their results in the context of tensor networks. Is there a class of tensor networks whose value can be efficiently and exactly calculated using similar techniques?

6 Conclusion

In this chapter, we reviewed quantum algorithms of several types: those based on the quantum Fourier transform, amplitude amplification, quantum walks, and evaluating tensor networks. This is by no means a complete survey of quantum algorithms; most notably absent are algorithms for simulating quantum systems. This is a particularly natural application of quantum computers, and these algorithms often achieve an exponential speedup over their classical counterparts.

Algorithms based on the quantum Fourier transform, as reviewed in [Sect. 2](#), include some of the earliest quantum algorithms that give a demonstrable speedup over classical algorithms, such as the algorithms for Deutsch's problem and Simon's problem. Many problems in this area can be described as hidden subgroup problems. Although problems of this type have been well-studied, many questions remain open. For example, there is no efficient quantum algorithm known for most examples of non-Abelian groups. In particular, the quantum complexity of the graph isomorphism problem remains unknown.

Similarly, the family of algorithms based on amplitude amplification and estimation has a relatively long history. While Grover's original searching algorithm is the best-known example, this approach has been greatly generalized. For example, in Brassard et al. (2002) it is shown how the same principles applied by Grover to searching can be used to perform amplitude estimation and quantum counting. Amplitude amplification and estimation have become ubiquitous tools in quantum information processing, and are often employed as critical subroutines in other quantum algorithms.

Quantum walks provide an interesting analogue to classical random walks. While they are inspired by classical walks, quantum walks have many properties that set them apart. Some applications of quantum walks are natural and somewhat unsurprising; using a walk to search for a marked element is an intuitive idea. Others, such as evaluating AND-OR trees are much more surprising. Quantum walks remain an active area of research, with many open questions. For example, the relative computational capabilities of discrete and continuous time quantum walks are still not fully understood.

The approximation algorithm for tensor networks as described in this chapter (Arad and Landau 2008) is relatively new. However, it is inspired by the earlier work of Aharonov et al. (2008), as well as Wocjan and Yard (2006). The tensor network framework allows us to capture a wide range of problems, particularly problems of a combinatorial nature. Indeed, many $\#P$ -hard problems, such as evaluating the Tutte polynomial, can be captured as tensor networks. The difficulty arises from the additive nature of the approximation. One of the most important questions in this area is when this approximation is useful, and when the size of the approximation window renders the approximation trivial.

Numerous other families of new quantum algorithms that are not elaborated in this chapter have also been briefly mentioned, and many others unfortunately go unmentioned. We tried to balance an overview of some of the classic techniques with a more in-depth treatment of some of the more recent and novel approaches to finding new quantum algorithms.

We expect and hope to see many more exciting developments in the coming years: novel applications of existing tools and techniques, new tools and techniques in the current paradigms, as well as new algorithmic paradigms.

Abstract

The development of large-scale quantum computing started rapidly in 1994 after the presentation of the factoring algorithm by Peter Shor. In this review, the basic requirements for the successful implementation of quantum algorithms on physical systems are first discussed and then a few basic concepts in actual information processing are presented. After that, the current situation is evaluated, concentrating on the most promising methods for which actual experimental progress has taken place. Among these are trapped ions, nuclear spins, and various solid-state structures such as quantum dots and Josephson junctions.

1 Introduction

The term “quantum computing” was perhaps first expressed by Richard Feynman (1982), when he suggested that one might optimize the simulation of quantum systems with computers that are based on the principles of quantum mechanics. Such quantum simulators are now studied both theoretically and experimentally. A good example is provided by cold neutral atoms that are trapped into optical lattices formed by laser beams (Bloch 2005). As the atomic interactions can be tuned with magnetic fields, and quantum statistics plays a definite role in the system dynamics, one can hope to simulate nontrivial models for many-body dynamics in lattices, including quantum phase transitions (Sachdev 1999).

The modern view on quantum computing, however, leans toward an analogy with digital computers, in the sense that the framework consists of binary numbers (registers), logical operations (gates), and networks (circuits) (Steane 1998; Nielsen and Chuang 2000; Stenholm and Suominen 2005; Mermin 2007). Rather than solving problems in physics, the aim is to solve mathematical problems. Appropriate examples are the famous factoring algorithm of Shor (1994), or the search algorithm of Grover (1997). These algorithms use some of the special properties of quantum mechanics such as superpositions and entanglement, to achieve a computational speedup that has a more fortuitous scaling with the proportion of the problem than the corresponding classical approaches. Part of the wide attention given to quantum computing is based on the special role that the factoring of large integers has in the security of the public key cryptosystems (Mollin 2002). Apart from these two algorithms, the apparent benefits of quantum computers are still unclear.

The basic element in quantum computing is the physical representation of the quantum bit, also called a qubit. For quantum communication and quantum measurement purposes, it is quite meaningful to study systems consisting only of a few qubits; this is the limit that some of the experimentally studied systems have already reached. The number of qubits needed for solving nontrivial mathematical problems, however, is on the order of a hundred in the ideal case, closer to a thousand or more with error correction included (currently the best figure is on the order of ten qubits, with liquid nuclear magnetic resonance (NMR) systems (Negrevergne et al. 2006)). This defines the concept of large-scale quantum computing, which in practice usually means that one needs to construct a mesoscopic or even a macroscopic quantum system. There are many detailed studies of physical implementation of quantum computing, such as Chen et al. (2007); Nakahara and Ohmi (2008); Stolze et al. (2008). The purpose of this review is to provide a short overview of the topic.

2 DiVincenzo Criteria

The general conditions for building a successfully working quantum computer are rather obvious, and the best known formulation for them was given by DiVincenzo (2000) (he was also the first to make careful comparison of various physical systems suitable for quantum computing; see, for example, DiVincenzo (1995)). The five items in his famous “checklist” can be formulated roughly as

1. *A scalable set of well-defined and individually identifiable two-state quantum systems that can act as qubits and which relate as a whole to a well-defined and finite state space.*

To represent binary numbers, we need to give each qubit a label. Scalability means that we should be able to increase the number of qubits without limit (at least in theory). Combined with the other items below, this can prove to be a hard demand.

2. *Physical preparation of single qubits or groups of qubits into pure states in the state space.*

This often reduces to the possibility of preparing the fiducial state where all qubits are firmly set to the state representing the number 0. Any other state can be then obtained if the next item on the checklist is available.

3. *Implementation of unitary operations that involve one or two qubits.*

Since it is expected that all algorithms can be mapped into networks of single qubit operations and two-qubit conditional logic, this is sufficient. Furthermore, any network can be realized with single qubit operations and control-NOT operations, and the latter in turn can be constructed from simple conditional phase flips. This last stage is important because it opens the possibility for adiabatic operations and the use of geometric phases.

Physically, the requirement for conditional logic maps usually into controlling the interaction between two arbitrary qubits. In experimental realizations we can use the fact that as the computational power scales exponentially with the number of qubits, we nevertheless need to implement only a polynomially increasing number of SWAP gates to reduce the condition of interactions between arbitrary two qubits into nearest-neighbor operations only. This greatly helps in finding eligible physical implementations.

It should be noted that in optimizing networks, it may be helpful to allow other operations such as the three-qubit control-NOT operation either with two control bits and one target bit (Toffoli gate) or one control bit and two target bits with conditional mutual swapping (Fredkin gate).

4. *Performance of all required unitary operations at a time scale that is faster than any physical mechanism that causes the quantum system to decohere.*

Unfortunately, this requirement clashes often with the scalability requirement in item 1, and it is sometimes considered as a fundamental obstacle to quantum computing (Haroche and Raimond 1996). At worst, the decoherence times for quantum registers scale exponentially with the number of qubits (Unruh 1995). In fact, decoherence times for registers made of qubits can be much faster than the decoherence time for a single qubit times the number of qubits (Palma et al. 1996). In addition, for typical algorithms, the number of necessary basic operations can also increase rapidly with the number of qubits (at least polynomially as in the quantum Fourier transform (Coppersmith 1994; Barenco et al. 1996) needed in Shor’s factoring algorithm).

Although this requirement sets in principle the upper bound to the number of available qubits, it does not necessarily prevent one from reaching computationally useful numbers of qubits. Also, error correction (usually by redundancy) or the use of decoherence-free subspaces are among the tools used to further evade the effects of decoherence.

5. *The possibility to physically read the state of each qubit once the computation has been performed.*

This requirement is often fulfilled if one can satisfy items 1–3 as well and it could be combined with item 2. In actual proof-of-principle demonstrations, one often performs full quantum tomography on the final state, and uses the fidelity of the experimental state with the expected ideal result as the figure of merit.

For quantum communication purposes, these five requirements have been augmented by two additional ones (DiVincenzo 2000):

6. *The ability to interconvert stationary and flying qubits.*
7. *The ability to faithfully transmit qubits between specified locations.*

These additions also apply to quantum computing if we consider grid-like quantum computing, in which single qubits or collections of qubits form the nodes of a metacomputer; see, for example, the ion trap proposal in Kielpinski et al. (2000). If realizable, such an approach provides an option to circumvent the scalability requirement in item 1. Recently quantum teleportation has become a viable tool for satisfying items 6 and 7, and a suitable method to access quantum memories, for example.

These stringent requirements usually mean that we need to have a mesoscopic quantum system and the ability to control its dynamics with high accuracy. Several suggestions for physical implementation of quantum computing have appeared since 1994. Although many of them might have a chance of experimental realization at least on the level of a few qubits, very few have been selected as targets for serious studies. For few-qubit applications, their intended use in, for example, quantum communication sets other requirements such as the possibility of transmission or interaction with information carriers such as photons(items 6 and 7 in the list above). The purpose of this review is to discuss those realizations that are now studied by several groups of experimentalists, with some initial success, for the purpose of large-scale quantum computing (at least in principle). Before that, it is advantageous to provide a short representation of some of the concepts that were briefly mentioned above.

3 Elements of Quantum Computation

The purpose of a quantum computer is to solve problems following an algorithm. The implementation of an algorithm must be mapped into a unitary operation, and for practical purposes this operation must be factored into a series of few-qubit operations known as gates. In this sense, the quantum computer resembles its classical counterpart. For the more mathematical aspects of quantum algorithms and quantum computing, the book by Hirvensalo (2004) is suggested.

3.1 Quantum Algorithms

As mentioned above, the main existing algorithms aim at either factoring large integers (Shor) or searching databases (Grover). The factoring algorithm relies on calculating a modular function $f(x) = a^x \bmod M$, where a is an almost freely chosen integer and M is the number that we want to factor. The periodicity of this function is the key single number that one seeks.

The quantum parallelism means that for a combined set of input and output registers (both with N qubits and $2^N \simeq M^2$), the initial state can be written as

$$|\Psi_0\rangle_{2N} = |\Psi_0^{\text{input}}\rangle_N \otimes |\Psi_0^{\text{output}}\rangle_N = \left(\frac{1}{2^{N/2}} \sum_{x=0}^{2^N-1} |x\rangle_N \right) \otimes |0\rangle_N \quad (1)$$

where the input state is an equal superposition of all possible numbers and in the output register all qubits are in the 0 state.

At this point, it is convenient to introduce the standard single-qubit Hadamard operation H_{Had} , that is of the form

$$U_{\text{Had}} = \frac{1}{\sqrt{2}} [(|0\rangle + |1\rangle)\langle 0| + (|0\rangle - |1\rangle)\langle 1|] \quad (2)$$

and which clearly puts any qubit from a state 0 or 1 to their equal superposition. By applying U_{Had} to each input qubit, the above initial state for the input register is easily produced (assuming all qubits can be set first to state 0; even this is not always trivial in actual physical implementations because such resetting is not necessarily a unitary operation). An alternative representation of operations is the matrix form, where the qubit states are given as

$$|0\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \text{ and } |1\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix} \quad (3)$$

The Hadamard operation is a 2×2 matrix

$$U_{\text{Had}} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \quad (4)$$

and by applying it twice we get the identity $U_{\text{Had}}^2 = \mathbf{1}$.

Next, one applies the unitary transformation U_f corresponding to calculating $f(x)$ so that the result is stored into the output register while the input is left intact. Due to the linearity of quantum mechanics, this leads to the new two-register state

$$|\Psi_f\rangle_{2N} = \frac{1}{2^{N/2}} \sum_{x=0}^{2^N-1} |x\rangle_N |f(x)\rangle_N \quad (5)$$

This is a remarkable state as it represents entanglement between the register states so that each outcome can exist only with its corresponding input, in a total quantum correlation. As one obtains the result by applying U_f only once, this is often called quantum parallelism. As one can extract by measurements only one $(x, f(x))$ pair at a time, this approach is not useful for just calculating values of $f(x)$.

Since $f(x)$ is periodic, the amount of possible numbers in $|f(x)\rangle$ is limited, and for each result there is a periodic subset of numbers in the input register. If one performs a quantum Fourier transform (QFT) on the input register, one obtains an integer multiple of the inverse of the period. This, together with inaccuracies due to the finiteness of the registers, means that the total running time for the algorithm with the standard QFT network scales as N^3 , where N^2 is for the QFT, and additional N repetitions are needed to fix the period with sufficient accuracy. As the best known classical approach scales as $\exp(N^{1/3})$, the advantage increases nearly exponentially with increasing N .

The Shor algorithm is genuinely quantum in the sense that it utilizes the entanglement between the registers. Whether its speed is due to its quantum nature, or due to the inherent

efficiency of QFT, is an open question. Another quantum property is the superposition and, together with infinitesimal projections, it is the basic ingredient in the Grover algorithm.

For the database search, we need only one quantum register. Assuming that there is a mechanism that allows the computer to identify the desired item with a number stored in a register of N qubits, one can take as the initial state

$$|\Psi_0\rangle_N = \frac{1}{2^{N/2}} \sum_{x=0}^{2^N-1} |x\rangle_N \quad (6)$$

The search operation then recognizes a special value x_0 related to the wanted item. As a unitary operation, it changes the superposition into

$$|\Psi_1\rangle_N = \frac{1}{2^{N/2}} \left(\sum_{x=0, x \neq x_0}^{2^N-1} |x\rangle_N - |x_0\rangle \right) \quad (7)$$

The next step is to perform a specific single-qubit operation on each qubit, and then repeat the above. It can be shown that after $N_0 \simeq (\pi/4)\sqrt{N}$ repetitions of this two-step process, one gets

$$|\Psi_{N_0}\rangle_N = |x_0\rangle \quad (8)$$

and the item is then identified through x_0 . Compared to the Shor algorithm, the speed-up is not huge (classical search scales as $N/2$). For a nice description of the Grover algorithm, the book by Vedral (2006) is referred to.

A third algorithm that is often mentioned especially in few-qubit demonstrations is the Deutsch–Jozsa algorithm (Cleve et al. 1998) although in practice it serves only demonstration purposes. We assume an a priori unknown one-qubit function $f(x)$ that maps a one-digit binary number to a one-digit binary number. The question is whether the function is constant ($f(0) = f(1)$) or balanced ($f(0) \neq f(1)$). This is the Deutsch problem, and classically one solves it by calculating the function twice with different arguments (0 and 1), and comparing the result. The Deutsch–Jozsa algorithm is a generalization of this, so that the argument can be a number between 0 and 2^N-1 , while the values of the function are still limited to 0 or 1.

In brief, the operation starts by setting the state (input register with N qubits and output with 1 qubit)

$$|\Psi_0\rangle_{N+1} = \frac{1}{2^{(N+1)/2}} \sum_{x=0}^{2^N-1} |x\rangle_N \otimes (|0\rangle_1 - |1\rangle_1) \quad (9)$$

and then calculates $f(x)$ by a unitary transformation U_f , so that $f(x)$ is added to the existing value of the output bit (binary addition, so $0 + 0 = 0$, $0 + 1 = 1 + 0 = 1$, $1 + 1 = 0$):

$$|\Psi_f\rangle_{N+1} = \frac{1}{2^{(N+1)/2}} \sum_{x=0}^{2^N-1} |x\rangle_N \otimes (|f(x)\rangle_1 - |f(x) + 1\rangle_1) \quad (10)$$

This is equivalent to

$$|\Psi_f\rangle_{N+1} = \frac{1}{2^{(N+1)/2}} \sum_{x=0}^{2^N-1} (-1)^{f(x)} |x\rangle_N \otimes (|0\rangle_1 - |1\rangle_1) \quad (11)$$

Now the output register can be discarded, and one performs a Hadamard operation to each qubit of the input register. If projected to the all-zero state $|0\rangle_N$, one gets that the projection is successful with probability 1 for constant case, and with probability 0 for the balanced case.

3.2 Quantum Gates and Quantum Networks

It is tempting to consider performing simple unitary operations on large registers without problems, but in practice that involves too many degrees of freedom for simultaneous control. A general operation on an N -qubit register would correspond to a $2^N \times 2^N$ matrix. Clearly, one loses the quantum advantage if one thinks of the register as a 2^N -dimensional quantum state instead of working with N two-state systems. In practice, all computations are made in networks of quantum gates that act typically on single qubits, or on two qubits (for conditional logic). Such operations are unitary and thus also reversible. The Hadamard gate above is a typical single-qubit operation; most of these can be described as rotations in the single-qubit Hilbert space. These operations set qubits to specific superposition states and can also affect the phase relation between the probability amplitudes of single qubit states, and they were studied extensively in the early days of quantum computing, and reviewed in many textbooks, see, for example, Nielsen and Chuang (2000); Stenholm and Suominen (2005); Mermin (2007).

Of the two-qubit gates, we concentrate here only on a few essential ones, and their relationship to each other. The controlled-NOT (CNOT) gate is a standard element in conditional logic. In short, it flips the state of the target qubit if the control qubit is in state 1. Specifically, if the control qubit is in a superposition state, CNOT entangles it with the target qubit (in case they were initially in uncorrelated states). An alternative gate is the controlled phase gate, which alters the global phase of the two qubits by ϕ if they are both in state 1. Especially, if one can effect a gate with conditional phase change of π , that is, $|11\rangle \rightarrow -|11\rangle$, this conditional phase flip gate can be used to construct the CNOT gate. This is important for geometric quantum computing discussed later. CNOT gates are also needed in error correction methods for quantum computers. For demonstration purposes and for quantum communication one wants to either create highly entangled states of qubits, or to detect entangled states such as the Bell states. The CNOT gate is a very convenient tool to produce such states, or in mapping them to easily distinguishable qubit states.

The two-qubit gates are usually described as 4×4 matrices in the joint basis $\{|00\rangle, |01\rangle, |10\rangle, |11\rangle\}$. The representations for the CNOT gate, phase gate, and the phase flip gate are, respectively,

$$U_{\text{CNOT}} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}, \quad U_\phi = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & e^{i\phi} \end{pmatrix}, \quad U_{\text{ph-flip}} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix} \quad (12)$$

Another two-qubit gate is the SWAP gate that interchanges the state of two qubits:

$$U_{\text{SWAP}} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \quad U_{\text{iSWAP}} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & i & 0 \\ 0 & i & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \quad (13)$$

Here, we introduce also the iSWAP gate discussed later. Swapping is not conditional logic, but it is important because instead of moving qubits physically, one can alter their labeling instead. Thus, any two qubits can be made nearest neighbors, which enlarges the number of those physical systems that are realistic for quantum computing purposes. The swapping can be realized with a simple combination of three CNOT gates.

In general, the CNOT gate combined with a set of single-qubit operations form a universal set: all possible two-qubit operations can be realized with them. In the same manner as the CNOT can be constructed with conditional phase flips, we can find other forms of conditional operations that can be taken as a starting point for realizing actual computation (Bremner et al. 2002). Often the experimental realization of two-qubit operations determines which kind of conditional logic gate is the basic element. Earlier, the demonstration of the CNOT gate was considered as a necessary step for successful computation, but lately it has been replaced by many other alternatives such as CROT, $\sqrt{\text{SWAP}}$, and iSWAP (given above). The first two are represented by the following unitary transformations:

$$U_{\text{CROT}} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \end{pmatrix}, \quad U_{\sqrt{\text{SWAP}}} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & e^{i\pi/4} & ie^{i\pi/4} & 0 \\ 0 & ie^{i\pi/4} & e^{i\pi/4} & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \quad (14)$$

The second definition is obviously not a unique one for $\sqrt{\text{SWAP}}$ (e.g., clearly $\pi/4$ can be replaced with $3\pi/4$). The variation $\sqrt{i\text{SWAP}}$ has also been used. We can see that the variations of the SWAP gate are suitable for situations where only the states $|01\rangle$ and $|10\rangle$ can be coupled.

A quantum network consists of the gates and the information to which qubits and in which order one applies the gates. The quantum Fourier transform network for N qubits, for example, consists of N single-qubit Hadamard gates, and $N(N-1)/2$ conditional phase shifts (with qubit index-dependent values of phase shifts) (Coppersmith 2002; Barenco et al. 1996). In some special cases, one can utilize gates that operate on three qubits or more. The Toffoli gate swaps the state of the target qubit, if the two control qubits are both in state 1. This can be generalized into n control qubits, naturally. The Fredkin gate performs a SWAP gate on two target qubits if the control qubit is in state 1.

3.3 Error Correction

The sensitivity of quantum mechanical superpositions to disturbances is perhaps the most serious problem for actually realizing quantum computing. In addition to decoherence and dissipation, due to the coupling of quantum systems to their environment, small errors due to imperfections in gate operations interfere with the computing process. Although small, the cumulative effect of small errors can be devastating if they are allowed to propagate freely in the system through conditional logic. The errors can be suppressed by applying error correction. However, it requires operations that are typically subjected to the same inaccuracies as the actual computational operations. If the error correction during computation is effective, that is, it reduces errors more than it adds them, computation is regarded as *fault-tolerant*.

The standard quantum error correction relies on redundancy. For example, for one qubit in state

$$\alpha|0\rangle + \beta|1\rangle \quad (15)$$

we write the highly entangled three-qubit state

$$\alpha|000\rangle + \beta|111\rangle \quad (16)$$

This is achieved by starting with $(\alpha|0\rangle + \beta|1\rangle) \otimes |0\rangle \otimes |0\rangle$ and applying the CNOT on the last two zero qubits with the first one as the control. The use of three qubits increases the size of the qubit Hilbert space from 2 to 2^3 . If, at most, one of the spins flips, the location of the flip can be identified by projecting the state on four orthogonal states, which are

$$\begin{aligned} P_0 &= |000\rangle\langle 000| + |111\rangle\langle 111| \\ P_1 &= |100\rangle\langle 100| + |011\rangle\langle 011| \\ P_2 &= |010\rangle\langle 010| + |101\rangle\langle 101| \\ P_3 &= |001\rangle\langle 001| + |110\rangle\langle 110| \end{aligned} \quad (17)$$

The result identifies which qubit flipped (or that none flipped), and one can perform a correcting flip on that qubit. This does not perturb the actual superposition since we do not know whether 0 became 1 or 1 became 0, but only that a flip occurred.

With a slightly more complicated operation (and more qubits) one can identify and correct phase flips as well. In 1995 Peter Shor showed how such a general error correction scheme can be constructed with nine qubits (Shor 1995), but the number was reduced later to seven (Steane 1996; Calderbank and Shor 1996). Finally the sufficient number of qubits needed was found to be five (Bennett et al. 1996; Laflamme et al. 1996), leading to fault-tolerant error correction (Knill 2001). Systematic studies in the field have produced more general methods such as stabilizer codes (Gottesman 1996). For a recent detailed description of quantum error correction and fault-tolerant computation see Gaitan (2008); see also the related chapter and references therein in Nielsen and Chuang (2000).

For noisy computation and specific cases, one can also utilize optimization of algorithms. For instance, the quantum Fourier transform relies on conditional phase shifts. It can be shown that since the noise per operation severely perturbs the smallest phase shifts, it becomes advantageous to reduce the overall noise by not performing these phase shifts at all (Barenco et al. 1996). The improvement is due to the decreased total number of operations, and additional benefits can come for nearest-neighbor realizations since the size of the implemented phase shift is inversely proportional to the difference in qubit labels (typically equivalent to the physical distance between qubits as well).

3.4 Decoherence-Free Subspaces

Error correction can target both the technical problems as well as the environmental effects. Even for technically perfect qubit operations, one is still left with the coupling of a quantum system with its environment. The thermal heat bath is a typical example of a source for dissipation and decoherence. The first leads to qubit state flips, and the latter erodes the phase relations between amplitudes either within the qubits or (and more rapidly) between qubits. A prime example is the transversal and longitudinal relaxation times in NMR; it also illustrates the general feature that decoherence time scales can be much faster than dissipation time scales, and, thus, in most cases the decoherence time scale compared with the gate operation time is the key figure of merit.

The standard approach to decoherence is to suppress the interaction between the system and its environment. Cooling the computing system to low temperatures is a basic solution; in some cases, such as flux qubits (Sect. 8.2), the cooling is essential for the existence of the qubit system in the first place. Occasionally, the decoherence can actually be of advantage, as

we shall see in connection with the liquid NMR quantum computation in [Sect. 6.1](#), but such situations are exceptions with their own special difficulties.

For some systems, one can find, for some combinations of qubits, that they are more robust to decoherence than other combinations. Thus, one can select a decoherence-free subspace in this extended Hilbert space, and limit the computation there (Palma et al. 1996; Duan and Guo 1997; Zanardi and Rasetti 1997; Lidar et al. 1998).

3.5 Adiabatic and Geometric Quantum Computing

One of the very robust states, when it comes to decoherence and dissipation, is the ground state of a quantum system. In adiabatic evolution, the system remains always in the instantaneous eigenstate of the system. If the computing starts with the ground state of the computer, and one can perform the computation adiabatically (Farhi et al. 2000; Childs et al. 2001), it means that the system remains on the ground state all the time, and it is only the nature of the ground state that evolves into the final result of the computation.

One can describe the adiabatic process as a passage related to a changing parameter. If one performs a closed loop in the parameter space, one can affiliate a global geometric phase to the evolution. This global phase is the famous Berry phase, and it depends on the path that one takes in the parameter space. Later, the approach was generalized to non-closing loops as well. This provides the basis for geometrical quantum computation. An interacting combination of two quantum bits can be made to evolve along its changing ground state so that the global phase change is conditional to the values of the two qubits. It means that in practice one can realize, for example, the phase-flip operation. Another name for computations using geometric phases and closed loops in the parameter space is holonomic quantum computation. There is a nice recent review on the geometric quantum computing and its basic concepts (Sjöqvist 2008).

Recently, some interest was created by the quantum processor developed by the D-Wave company, based on superconducting flux qubits. The actual computation is taking place, assumably, through adiabatic evolution. This is still subject to much debate. One of the problems with adiabatic evolution is that although the lowest eigenstate of the system remains well-defined, it may get very close to some higher state, and nonadiabatic transitions between them can be suppressed only by an extremely slow evolution, which in turn may lead to other problems.

3.6 Cluster State Quantum Computing and Anyonic Quantum Computing

Normally, we assume that the quantum computation follows a very clear cycle. First the input is prepared, then processed, and after that the result is read out by measurement. This is “Hamiltonian computing.” In quantum mechanics, one can challenge this view. One approach is to make the whole computation proceed by measurements instead of unitary evolution. If a two- or three-dimensional lattice of qubits interacts suitably (e.g., Ising-type interaction), it can form a large cluster of entangled states (Briegel and Raussendorf 2001). Computation can then proceed in this cluster by targeted measurements on individual particles (Raussendorf and Briegel 2001). The reliance on irreversible measurements, instead of unitary operations only, has given the cluster approach the name *one-way quantum computing*.

Another idea based on a lattice of qubits with nearest neighbor interactions was proposed by Kitaev (1997). The approach is expected to be fault-tolerant by construction. Computation is performed by using an anyonic excitation of the system, where an exchange of two particles changes the global phase of their wavefunction. The approach relies especially on having non-Abelian anyons, which might be found in two-dimensional degenerate quantum gases (fractional quantum Hall effect). This topic has been recently reviewed thoroughly, see Nayak et al. (2008).

4 Cavity QED

In a confined space, the electromagnetic field modes become quantized into standing waves and form a discrete set of energy states for the field. In the quantum electrodynamical (QED) description, the energy of each mode with frequency ν is quantized into photon states, integer multiples of $\hbar\nu$ including the vacuum state of each mode (\hbar is the Planck constant). Such a cavity with well-defined modes in one direction can be built by opposing mirrors. The photon states of the modes can occur in quantum superpositions of photon numbers n . However, the temperature of the mirrors defines the temperature of the cavity, so to avoid thermal occupancy of the photon states, one must go to very low temperatures. Also, the quality of the mirrors must be high, otherwise the loss of photons broadens the energy spectrum of each mode.

The key issue is the controlled interaction between the cavity modes and the atoms that fly through the cavity or are placed there by means of some electromagnetic trapping. In an ideal case, one can describe the atoms as two-level systems, and limit the interaction to a single mode. One can then explore some key phenomena such as Rabi oscillations between atomic states (Jaynes–Cummings model) but, more importantly, with the atoms, one can manipulate the photonic state of the cavity. States with definite photon number n are actually highly nonclassical states of light, and they can be created with the help of the atoms. Alternatively, the photonic state of the cavity can be explored in a nondestructive way (QND, quantum non-demolishing) with atoms that are highly off-resonant but still coupled with the relevant cavity mode.

Such cavities have been prepared both in the optical and microwave region. It is easier to obtain high quality (high-Q) cavities in the microwave range than in the optical range. For the microwave range, the atoms are usually pumped into a high-energy Rydberg state (main quantum number ≈ 60), so that the transition energy falls into the microwave regime, and in the QND photonic state measurements one applies atom interferometry. The best demonstrations of controlled and coherent dynamics of two-state quantum systems and interactions with a quantized field have been achieved with such systems. These are essential factors in single-qubit operations, and the cavity QED terminology has been adapted for many other physical implementations when demonstrating that the state of a qubit is indeed a quantum superposition and coherence can be established between the qubit states. For example, by implementing Rabi oscillations in a qubit, one can estimate single-qubit decoherence through the damping of these oscillations (and by observing them to prove that there is some coherence to begin with; see, for example, the flux qubit example of Chiorescu et al. (2003)). The concepts of cavity QED were reviewed in detail in the textbook by Haroche and Raimond (2006). In fact, one of the first demonstrations of conditional phase shifts was performed in 1995 with an optical cavity, where photon qubits (0 or 1 photon per polarization

mode) experienced an interaction via off-resonant Cs atoms flying through the cavity (Turchette et al. 1995). See also the 2004 review in van Enk et al. (2004).

5 Physical Realization with Electromagnetically Trapped Particles

5.1 Trapped Ions

The trapping of ions with electromagnetic fields has provided much insight into quantum mechanics since the early 1980s (Horvath et al. 1997). Just the actual observation of the single ions, by detecting the light scattered by them, showed that single atoms are a meaningful concept in physics, not just an abstraction. The observed change of the quantum state of a single ion through a quantum jump in the mid-1980s demonstrated clearly the limits of ensemble quantum mechanics, and also the existence of the until-then hypothetic jumps. In 20 years, these jumps have evolved from a mystery into a practical tool in detecting the state of single ions (see item 5 on the DiVincenzo checklist); already in the first experiments, they were used to show that the scattered light actually originated from a specific integer number of ions.

Laser cooling of these ions was developed alongside the trapping methods, and gave control over the motional states of ions. Especially, it made it possible to reach situations where the motion itself becomes quantized, and in the case of more than one ion, one gets phonons. Thus, it is not perhaps surprising that very soon after the presentation of the Shor algorithm in 1994, Ignacio Cirac and Peter Zoller published their proposal for quantum computing with chains of ultracold ions (Cirac and Zoller 1995). Even now, this scheme provides the basic approach to quantum computing with trapped ions.

Trapping of charged particles by static electromagnetic fields is in principle not possible (Earnshaw theorem), but the problem can be averted by adding either a fast-oscillating electric field (Paul trap) or a static magnetic field (Penning trap). For quantum computing purposes, to obtain individual addressing and controllable interactions, the so far most suitable situation for many ions is provided by the linear ion trap, in which the trapping potential is an elongated cigar, into which the atoms at low temperatures form a chain as they are pushed toward each other by the trapping potential, but this is balanced by the Coulomb repulsion between charged ions. The quantized motion of ions is now a collective effect, and for sufficiently low temperatures any motion perpendicular to the cigar is suppressed, and along the cigar the lowest phonon modes correspond to the oscillation of the whole chain in unison, and to the breathing-like mode where each atom oscillated with a π phase shift compared to its two neighbors.

The cooling of such a chain is based on ions absorbing photons at lower energies, and then radiating them at higher energies, with the energy difference arising from a change of the motional state from a higher one to a lower one (sideband cooling). As the collective motion affects all ions of the chain, Cirac and Zoller proposed that if one codes one qubit per ion, using its internal electronic states, conditional logic can be mediated with the phonons in the chain. The scenario is simple: a change of the state of each qubit can be realized by addressing the particular qubit by laser light. Assuming that the chain is in its lowest motional state, one can address qubit 1 so that if it is in state 1, then a phonon appears in the chain (excitation to the next state of collective motion). When addressing qubit 2, one can make it conditional so that one has four possible outcomes, depending on the original state of the qubit 2, and the phonon state of the chain (and thus the state of qubit 1).

The lifetimes for excited atomic and ionic states are usually short, on the order of nanoseconds, so they are not a priori optimal states for qubit coding. The problem can be circumvented by using either the ground state and a long-living excited state that exists in most ions of alkaline-earth atoms (group II), or two Zeeman substates of the ground state, coupled then with a Raman setup instead of a single laser field. The shortlived electronic states have their purpose, however, as one can detect the state of qubits using the quantum jump approach.

Several groups have adopted the Cirac–Zoller scheme as a basis for demonstrating quantum computing. Basic problems on the road have been the elimination of fluctuations in the electromagnetic trapping fields and actual cooling of the chain of ions (Nägerl et al. 1998; Schmidt et al. 2003a). But successful demonstrations have been achieved. They can be coarsely divided into two groups: demonstration of gate operations, and preparation of specific entangled states of many qubits. Although the latter are often obtained as a result of logical operations and quantum computing, here we concentrate on the gate operations. The success of logical operations is verified by quantum tomography of the final state, and quantified by fidelity with the ideal result. In Innsbruck, in the group of Rainer Blatt, the control-NOT gate between two qubits was demonstrated in 2003 (Schmidt-Kaler et al. 2003b). Already in 1995, such a gate was demonstrated in Boulder (Monroe et al. 1995), but this was a nonscalable demonstration where the two qubits were coded in the same ion, and the Cirac–Zoller scheme was not used. Later in Innsbruck, the three-qubit Toffoli gate was demonstrated in 2009 (Monz et al. 2009). The three-qubit operation was achieved by taking advantage of the three lowest motional states, as an extension of the Cirac–Zoller scheme.

As the ionic chains become longer, their cooling is an increasing challenge. This has led to the proposals involving hot ions. Typically, the phonons are then replaced by photons for the conditional logic. Perhaps the most successful of the proposals is the Mølmer–Sørensen bichromatic gate (Sørensen and Mølmer 1999a, b). It relies on the idea of the conditional phase gate as the basic element. When two ions are simultaneously interacting with two light fields, the phase of the final state will depend on the internal states (acquires -1 if both qubits are in state 1). This scheme works seemingly independent of the motional states of the ions, but their presence is required nevertheless as they are absent only due to the use of the perturbation approach (which means that the gates are not necessarily very fast). Such a gate action was demonstrated recently in Innsbruck (Benhelm et al. 2008).

Despite the success with either cold or hot ions one can ask how scalable the ion trap computers are. Clearly, the lengthening of the chain will pose many problems, from cooling to individual addressing. The possibility to go for 2D structures (Wigner crystals) would allow better scaling, but also more complicated motional states and cooling of the structure. Another possibility is to distribute the computing between several small scale ion trap computers, using, for example, photons as mediators between the computers (and quantum teleportation as a tool for exchanging the quantum information between the ions and mediating photons). Perhaps a simpler alternative is to shuffle ions around, dividing the trap into computing and memory sections (Kielpinski et al. 2002; Schaetz et al. 2004). For qubit states involving the two Zeeman states of the ionic ground state one can utilize microwave fields. This opens the possibility to use high-quality cavities in the control of qubits. Cavity QED is a well-established field and can provide useful tools, although it applies best to transitions between atomic Rydberg states.

For further details, the reader is referred to an excellent review on ion trap quantum computing by Häffner et al. (2008).

5.2 Trapped Neutral Atoms

Trapping of neutral atoms into structures where they can be addressed one-by-one is much harder than for charged particles. There are basically two avenues for this: single atom traps or optical lattices. Light from a highly detuned laser field is unlikely to be absorbed by atoms, but they still interact in a manner that allows one to control the external degrees of freedom of the atoms. Basically, the atoms feel the spatial changes in the field as an external potential. If the light is tuned above the atomic transition (blue detuning) the field intensity maxima repel atoms, and for tuning below the transition (red detuning) the maxima are points of attraction. This is either called dipole or gradient force. In the simplest formulation, atoms are attracted by, for example, the focal point of a laser beam. If one adds some dissipative mechanism, one can confine atoms into such dipole traps (also called FORTs, i.e., far-off-resonant traps). This is one of the key points for laser cooling and trapping of atoms (Metcalf and Van der Straten 1999). If one adds the spin-induced degeneracy of the atomic states and the polarization of the light, one can additionally control the system with external magnetic fields, or use the laser field superpositions to create specific structures such as lattices with potential minima and maxima at regular intervals.

The trapping of atoms into microtraps is a challenging task. For quantum computing purposes, one would prefer a set of such traps with one atom (and only one) in each, which is not easy. The advantage of microtraps compared to optical lattices is that it is easier to address atoms individually, when the separation is in the micrometer range. Several possible setups are currently studied, including atom chip systems, where the atoms are localized very close to a solid surface, and wires on the surface provide the electromagnetic fields that confine the atoms. As the confining forces are weak, low temperatures and elimination of collisions with background atoms are required, not to mention an accurate trap-loading process. Conditional logic is also a challenge. If sufficiently close, the atoms can interact by a state-selective dipole–dipole interaction, which provides one possibility, but there are no proof-of-principle experimental demonstrations for quantum computation in such systems yet.

For optical lattices, the lattice site occupancy is low and not very well controlled with basic laser-cooling and trapping methods. However, the Bose–Einstein condensation of atoms provides a useful tool for preparing lattice occupation. The atoms are trapped and cooled so that they begin to occupy the lowest quantum state of the trap potential. If they are bosons, they undergo eventually a quantum phase transition to a condensed state, where the atoms are correlated completely and the whole sample is described by a single collective quantum wave function (and with a nonlinear Schrödinger equation where the atomic interaction appears as a mean-field potential) (Pethick and Smith 2008). In an optical lattice one can, for sufficiently high barriers between lattice sites, observe a transition to a Mott insulator, where (a) each lattice site is occupied and (b) with exactly the same number of atoms. This has already been achieved experimentally (Bloch 2005), and it opens possibilities for quantum computing, especially if single-atom addressability can be reached. But this is a future method and no demonstrations of quantum logic have been performed so far.

5.3 Trapped Single Electrons

Experimentally, the trapping of single electrons with electromagnetic fields preceded the trapping of ions. In general, many solid-state structures such as quantum dots or

superconducting islands rely on confining potentials for electrons or equivalent quasiparticles. In principle, even atoms and molecules are just traps for electrons. A common theme for many systems is that the dynamics of a complicated system depends only on a few electrons while the nuclei and the majority of the electrons only form a background. Not surprisingly, the popular alkaline atoms for neutral atom trapping and ionized alkaline-earth atoms for ion trapping are effectively hydrogen-like single-electron atoms. In fact, even the nuclei for atoms such as C, N, and F are made of several protons and neutrons, but as composite particles they only appear to one as spin-1/2 systems.

If one nevertheless persists with the concept of an electron trapped by externally generated electromagnetic fields, possibilities for quantum computing have been considered in such systems as well. An example is the proposal where the electrons are confined on the surface of liquid helium and controlled by electromagnetic fields (Platzman and Dykman 1999; Dykman and Platzman 2000). The surface potential for electrons stops them from penetrating the liquid but it is weakly attractive at short distances, so that a few bound states appear, confining the electrons as a two-dimensional gas at the surface. The bound states can be addressed with microwave fields. Due to the Coulomb interaction, the electrons repulse each other (in analogy to trapped ions) and, as their temperature is lowered, one observes a phase transition to a Wigner crystal (Grimes and Adams 1979) (see also Rousseau et al. (2009) and references therein; the Wigner crystal has been observed for trapped ions as well (see, e.g., Birk et al. 1992)).

However, one does not rely on the crystallization in qubit preparation but instead, by embedding electrodes into the liquid, one can provide the localization in the direction of the surface as well, and in addition one can induce individual (local) Stark shifts to resonance energies so that one can select the particular qubit, which is subsequently manipulated with the microwave field pulse (other qubits are off-resonant with the field).

The dipole–dipole interaction between adjacent electrons depends on the bound state because it shapes the electron wavefunction and thus the charge distribution (in very much the same manner as in the first quantum dot proposals that also used the dipole–dipole interaction for conditional logic (Barenco et al. 1995)). The read-out would be obtained by external field-assisted tunneling of the higher state electrons out of the surface potential; they would be individually detected by channel plates. It has been suggested also that the electron spin could be used to represent a qubit (Lyon 2006); the degeneracy of spin states is lifted with an external magnetic field, and the spin-dependence of the dipole–dipole interaction can be used. There is some experimental activity (see, e.g., Sabouret and Lyon 2006) in this field and also some theoretical studies have been done (see, e.g., Dykman and Platzman 2003; Dahm et al. 2003). The main decay channel would be the coupling of electrons to the liquid surface excitations (riplons), but one of the advantages of the system is that this coupling is weak, and compared to other suggestions such as nuclear spins in solid-state structures (see, e.g., [Sect. 6.2](#)) the advantage is that here the electrons are trapped practically in vacuum.

6 Nuclear Spin Computers

An obvious candidate for a quantum bit is the spin-1/2 particle, which is the standard example of many quantum mechanics textbooks and often provides for physics students the first encounter with group theory through SU(2) representations. As discussed in the previous section, although the electron is a typical example, many of the atomic nuclei are spin-1/2

systems as well. As they form the key ingredients in many molecules or solid structures, and can be manipulated and studied with radio-frequency fields, it is natural to consider them as possible basic elements for quantum computing. The nuclear systems, however, behave very differently depending on their surroundings, and this leads to the fact that the quantum computing aspects are best discussed separately for liquid and solid systems.

6.1 Molecular Spins in Liquids

Nuclear magnetic resonance (NMR) is a well-established research topic, and an important method in many fields such as chemistry and medical sciences. The broad success also brings problems: the sophisticated concepts and terminology in modern NMR are not anymore so accessible to physicists, especially to those working on quantum systems such as trapped ions and atoms or solid-state electron systems.

At first, the idea of doing quantum computing with large numbers of molecules in liquid at room temperature seems counterintuitive, especially since it seems to be completely complementary to other approaches, such as trapped ions that rely on single isolated systems at extremely low temperatures. This kind of approach is generally called ensemble quantum computing.

The basic element is a molecule consisting of several atoms, many of which have spin-1/2 nuclei. In a magnetic field, the spin-up and spin-down states obtain different energies, and the spins oscillate with their characteristic frequencies given by the energy difference. This Larmor frequency is typically on the order of 100 MHz. The local environment in the molecule for each nucleus is usually unique and gives a chemical shift to this energy/oscillation frequency, on the order of ~ 1 MHz or less. It means that in principle each spin can be detected and manipulated with a field of specific frequency. The magnetic moment of a single spin is too weak for practical use, and thus one needs macroscopic numbers.

In liquid state, these molecules can move and rotate freely. This has the additional advantage that interactions between the molecules simply average to zero. Furthermore, the same applies to the anisotropic dipolar magnetic spin–spin interaction within each molecule. Eventually, one is left only with the isotropic interaction between nuclear spins mediated by the atomic valence electrons. For two nearby spins, this gets down to a simple Hamiltonian

$$H = \hbar\omega_1 I_1^z + \hbar\omega_2 I_2^z + 2J_{12}I_1^z I_2^z \quad (18)$$

where $\omega_{1,2}$ are the characteristic frequencies, $I_{1,2}^z$ are the spin projection operators in the direction of the external field, and J_{12} quantifies the spin–spin interaction. Thus, one can address spins with different RF-pulses, and the third term in the Hamiltonian allows for conditional logic in the form of controlled phase slips.

Although the large numbers of molecules and the averaging characteristics of the thermal liquid seem to be useful for some aspects, one would also assume that they wash out any quantum coherences as well. In fact, since the thermal energy exceeds well the energy differences of spin states, the total state of the system is almost equal to a statistical mixture of equally populated spin states. The key issue is the small deviation from the mixture, which has the characteristics of a pure quantum state, with 2^N states for N spin-1/2 nuclei of a single molecule. This pseudo-pure state is often written in the form

$$\rho \simeq \frac{1}{2^N} \mathbf{1} + \alpha |\Psi\rangle\langle\Psi| \quad (19)$$

Clearly, since the spin operators are traceless, the thermal part does not contribute to any expectation values. Also, any unitary operation on this density matrix will only reproduce the thermal part, and operate on the pure part in the normal quantum fashion.

Of course, the above picture is highly simplified and in practice one performs complicated sequences of pulses, and uses spin-echo methods to control phase evolution. The advantage is that the decoherence times for nuclear spins are extremely long compared to the pulse durations. However, ensemble quantum computing is beset with several problems.

The factor α is small, typically 10^{-4} to 10^{-5} for a few spins at room temperature, and it scales in the high temperature limit as

$$\alpha \simeq \frac{N\hbar\Delta\omega}{k_B T 2^N} \quad (20)$$

where $\Delta\omega$ is the energy difference between spin-up and spin-down states, T is the temperature, and k_B is the Boltzmann factor. To maintain the signal size means exponentially increasing the number of molecules or repeated measurements, as pointed out by Jones (2000).

The increase in the number of qubits means that one needs larger molecules with identifiable spins, and this is difficult to achieve. For instance, one of the largest systems is an *l*-histidine molecule with 14 spin-1/2 nuclei, of which two hydrogen nuclei are indistinguishable (forming a spin-0 and spin-1 system), providing at maximum a 12-qubit + 1 qutrit system (Negrevergne et al. 2006). It may be extremely difficult to go beyond this.

The pulse sequences needed for computation become exceedingly numerous and also complicated to design, tending to scale exponentially with the number of qubits. Thus, the duration of computation is reaching the decoherence limits. In addition, the small errors in each pulse seem to accumulate quickly as the number of pulses increases. This brings forward the apparently still unresolved question about the “quantumness” of ensemble quantum computing: Is it basically a simulation of actual quantum computing rather than the real thing?

To initiate a computation, one needs to set the pure component to a specific state, typically a state with all qubits in zero state. This is not easy to do and several methods have been applied in practice. Similarly, one can detect the state of the system at the end of a computation, but it is not possible to make projective measurements on selected spins during the computation process (which is a basic ingredient in many error correcting schemes). All this leads to the problem that ensemble quantum computing is not a very suitable candidate, for example, for grid-like quantum computing.

Despite the problems listed above, one should not neglect the many successes of liquid NMR quantum computing in demonstrating or benchmarking the basic operations and algorithms:

- Four-item search (Grover) with chloroform (decoherence time $\simeq 0.3$ s, computation time $\simeq 0.035$ s), in 1998 (Chuang et al. 1998). The two qubits were H and C nuclei. Another demonstration at the same time used partially deuterated cytosine, with two H nuclei as qubits (Jones et al. 1998). In 2000, a three-qubit version with ^{13}C -labeled CHFBr_2 with H, C, and F nuclei as qubits was demonstrated (Vandersypen et al. 2000), and in a more flexible way in 2002 with ^{13}C -labeled alanine, with three C nuclei as spins (Kim et al. 2002).
- Factoring of the number 15 in 2001 with 7-qubit perfluorobutadienyl iron complex (2 C and 5 F nuclei) (Vandersypen et al. 2001).
- The largest known qubit number: 12, with *l*-histidine (Negrevergne et al. 2006).

In addition, the NMR approach has also given special impetus to developing the concept of adiabatic quantum computing. Many reviews on liquid NMR quantum computing have been published during the last 10 years. Among the most comprehensive is the 2004 review article by Vandersypen and Chuang (2004), who have been involved closely with the theoretical and experimental development of the field. Another source is the recent multiauthored book (Oliveira et al. 2007).

6.2 Nuclear and Electron Spins in Silicon

One of the characteristics of solid-state systems is that the electron spin can also play a role. While the nuclear spin can be addressed with the NMR methods, the electron spin-resonance (ESR) method becomes an equivalent tool for control (and not forgetting ENDOR, electron-nuclear spin double resonance). Computing with quantum dots is based only on electrons and will be discussed in [Sect. 7](#).

A much noted suggestion for using spins in solids was made by Kane (1998). His vision was a purified silicon lattice made of zero-spin ^{28}P atoms, with embedded spin $1/2$ ^{31}P atoms (donors) at regular nanoscale intervals (10–20 nm), and at an equivalent distance from the silicon surface. The hyperfine interaction couples the donor nuclear spin strongly with the donor electron. The advantage is that these spins have very long dephasing times that could, at very low temperatures, reach 10^6 s. Low temperatures are also needed to inhibit the actual ionization of the donors. This must be compared with the expected gate operation time, for which Kane estimated 10^{-5} s. Both figures are probably optimistic but clearly the numbers look a priori promising.

The surface of the silicon lattice would be covered with some barrier material such as SiO_2 (to isolate the donor electrons from the leads), and on top of that one would place the metallic leads (A), positioned above each qubit. With the localized constant magnetic field ($B \sim 2$ T) one can split the degeneracy of the hyperfine states, and then further control the hyperfine resonance frequencies of each qubit independently with a current in the A lead (Stark shift induced by the current-generated electric field). Thus, an applied oscillating field ($B_{\text{AC}} \sim 10^{-3}$ T) would create transitions only at the selected qubit since others would be off-resonant.

The large distance between the donors ensures that they can be controlled independently, and electron-mediated interaction between the donor nuclear spins does not play a role. Conditional logic is, however, achieved through this interaction. Additional leads (J) will be placed between the A leads. When charged positively, they pull donor electrons from adjacent qubits and the electron-enhanced interaction, dependent on the spin states (exchange interaction between the electron spins), is sufficiently strong for gate operations, and its duration is controlled by the J lead. This effects conditional logic in very much the same manner as with liquid NMR systems.

The method is in principle scalable, but it is also quite challenging technologically. Further problems are produced by the readout, since now one deals with single spins, so the NMR signal is not sufficiently large for detection (in liquid NMR, this was circumvented by large numbers). The original scheme by Kane was to combine tunneling with single-electron transistor detectors, but this is considered to be problematic both technologically as well as in the light of decoherence times.

An alternative approach that uses the donor electrons was proposed in 2000 (Vrijen et al. 2000). The approach relies on a layered Si–Ge structure. The important gain is the increase in

the distance between qubits by an order of magnitude, to make lithographic implementation easier. The role of the ^{31}P nuclei is now only to provide the location for the donor electrons. Si and Ge have different electronic g factors, so by moving electrons vertically between two Si–Ge layers with different Si/Ge proportion, one can modify the electron spin resonance for control with ESR (instead of NMR). Operation with electron spins alone speeds up the gate rate (75 MHz vs. 1 GHz). Conditional logic is still achieved with the increase of the electron wavefunction overlap but now this is achieved with the A gates (the possibility to achieve conditional logic with exchange interaction in general was suggested in Loss and DiVincenzo (1998) in the context of quantum dot computers; see also DiVincenzo et al. (2000)).

The measuring scheme (conversion of spin into charge) is also simplified. But many of the technological challenges remain, such as the ^{31}P implantation in regular lattices. Although some progress has been made in the fabrication of the Si:P materials (see, e.g., O'Brien et al. 2001; Jamieson et al. 2005), experimental advances in silicon-based quantum computing are still in the future. Laboratory research on the Si:P computers is nevertheless carried out vigorously; see, for example, Andresen et al. (2007), but clearly there are still many problems remaining even for a demonstration of a two-qubit action. Recently, coherent qubit state transfer between nuclear and electron spins was reported (Morton et al. 2008), though under the name of quantum memory rather than quantum computer studies.

6.3 Nitrogen Vacancies in Diamond

Although single-crystal diamond is nowadays considered an old-fashioned form of carbon, compared to fullerenes and graphene, for quantum computing purposes it has recently emerged as a lucrative system (Prawer and Greentree 2008). Impurities in diamond appear as color centers, giving the specific colors for emeralds, rubies, and sapphires. Proper diamonds are not usually completely transparent but have a yellowish shade, for which there is a rigorous classification scheme. This shade is due to nitrogen impurities in diamond.

The basic ingredient for diamond qubits is a nitrogen vacancy (NV). It means that the nitrogen atom (N) replaces one of the carbon atoms, and in addition next to it there is a vacancy (V) in the carbon lattice. Typically, vacancies move in the lattice, until they find a nitrogen impurity, with which they then form a highly stable local structure. For a production of these NV centers, one can use chemical vapor-deposition or ion-implantation. The electron structure of the NV center is a spin triplet ground state that can be optically coupled with the excited triplet state (giving the yellow color, of course). Thus, one can induce and observe quantum coherences on the level of a single system in the same manner as one would observe single ions in electromagnetic traps (Jelezko et al. 2004). Even quantum jumps have been observed with such a transition.

The triplet ground state is split by the dipolar interaction so that the $m_s = 0$ state is the lowest state, and $m_s = \pm 1$ states are degenerate. This degeneracy of the $m_s = \pm 1$ states can be lifted with an external magnetic field. The splitting of the Zeeman substates is about 2.9 GHz, and can be accessed with microwave fields. The interesting point is that optical excitation is only allowed from the $m_s = 0$ state so that it can be used to detect the occupancy on that state.

A nearby ^{13}C nuclear spin can couple with one of the NV electrons through hyperfine interaction, giving an extra 130 MHz splitting to the electronic states. Thus, one has four states involving the nondegenerate combinations of the electron and nuclear spin. Then one can use optical pumping for the preparation of the initial state, and manipulation with microwave and radio-frequency fields, and make the read-out with a laser again. With this, one can effect

conditional logic between the qubits in nuclear and electron spins (Jelezko et al. 2004). This is reminiscent of the first trapped ion two-qubit gate, where the qubits were stored in a single ion. The coherence properties of the electron spin have been determined experimentally (Childress et al. 2006), and recently a second ^{13}C atom was added to demonstrate the quantumness of the system by creation and detection of tripartite quantum entanglement (Neumann et al. 2008). In this room-temperature experiment, the weak point is the electron spin decoherence, which is a few microseconds. If one limits to entangling only the two nuclear spins, the time scale is pushed into the millisecond region.

The main issue with NV centers is obviously scalability, which cannot be achieved with the present setup. One solution could be an optical bus between, for example, different small crystals that host small numbers of qubits. But for the time being the NV centers are mainly suitable for demonstration purposes.

7 Solid-State Qubits with Quantum Dots

Quantum dots emerged as suitable candidates for quantum computing very early (Barenco et al. 1995; Loss and DiVincenzo 1998; Sherwin et al. 1999). The discrete energy states of the dots provide a tempting qubit representation, and the semiconductor technology is highly developed at nanoscale due to the continuous effort to follow Moore's law. The possibility for optical manipulation and the use of electron spin (spintronics) extend the possibilities further (see, e.g., the book Awschalom et al. 2002).

A quantum dot is usually obtained by preparing layered heterostructures, with electrons on the conduction band trapped into one of the layers (quantum wells), and the 2D confinement is augmented with trapping of electrons with fields provided by the electrodes that are etched on the surface of the structure (lateral quantum dot structure). One can obtain single-electron trapping by using the Coulomb blockade: a charge can only tunnel into a dot from the adjacent layer if no other charges are there, as they would block the tunneling by electric repulsion. This aspect can be further controlled by external electric fields that adjust the energy states of the dot in relation to the levels at adjacent layers. This is the basis for single-electron transistors and other such devices. The above is an example of laterally positioned and coupled dots, but vertical, multilayered structures are also possible (Burkard et al. 1999).

For scalable qubits, one could use the quantized motional states of the electrons, and for conditional logic the dipole–dipole interaction, which can be made to depend on the electron state by external fields that affect the electronic charge distributions (as proposed by Barenco et al. 1995). Alternatively, one can use the electron spin as a qubit, control the spin states by ESR fields, and use the spin-dependent exchange interaction for conditional logic, as proposed by Loss and DiVincenzo (1998).

The spin-based systems have been popular and extensive studies have been performed, not only on quantum computation but also on the dynamics and observation of spins in few electron quantum dots (see the recent review by Hanson et al. (2007)). Having more than one electron in a dot creates a singlet-triplet electron-spin structure that can be addressed with magnetic fields. An alternative system with a singlet-triplet structure is a double quantum dot, with a controllable interdot tunneling, see, for example, (Koppens et al. 2007). The tunneling is also controlled by a spin blockade, that is, to conserve the total spin a change between singlet and triplet states (and thus a specific tunneling event between dots) can only occur if a

spin-flip takes place as well. The observed coherence times (Koppens et al. 2006) for a single qubit are promising on the order of microseconds (at temperatures below 1 K), but further work is required to estimate the possibilities of spin-based quantum dot qubits.

Finally, electrons can be transferred from the valence band to the conduction band by optical transition; thus one obtains an exciton, that is, an electron–hole pair, that can act as a qubit (Troiani et al. 2000). One dot can possess more than one exciton. In fact, one of the first demonstrations of a quantum dot quantum gate (Li et al. 2003) took place (in analogy to the trapped ion demonstration (Monroe et al. 1995)) in a single quantum dot with such a biexciton as the two-qubit system. The gate operation relied on different light polarizations since for the qubits the value “1” corresponded to different electron spins in the two electron–hole pairs. The gate that was performed was actually the CROT gate. Earlier, entanglement between the excitons was demonstrated in such a system (Chen et al. 2000). To make the excitonic computers scalable is a challenge, though.

In general, the semiconductors provide a challenging environment for quantum phenomena. In addition to coupling with phonons, the quantum dot electrons feel the other electrons through spin–orbit coupling, and the nuclear spins of the background material via hyperfine interaction. Apparently the latter mechanism is found to be the more relevant mechanism in experiments (Koppens et al. 2005, 2006). For excitons, the recombination of electrons and holes by spontaneous emission (coupling to the electromagnetic degrees of freedom) is a serious obstacle. It is possible to reach gate times on the order of 1 ps, and recombination times on the order of hundreds of picoseconds have been obtained (see discussion in Li et al. 2003), so more than a few gate operations could be achieved. For scalability, qubits in different dots could be coupled by setting them into an optical microcavity, so that excitons at different dots couple to the same cavity mode, and even interactions mediated by intermediate excitons have been proposed; see Chapter 7 in Chen et al. (2007) and references therein.

8 Superconducting Qubits

Superconductivity is a quantum phenomenon that takes place for certain materials at low temperatures (Tinkham 2004). The electric current runs then without resistance in the material, and such currents are quite unaffected by external conditions, except for sufficiently strong magnetic fields. In the standard case of superconductivity, the electrons in the material form Cooper pairs that are the unstoppable current carriers, and the resistance can occur only by a mechanism that provides sufficient energy that breaks the pair. However, the Cooper pairs and the single-electron states are separated by a distinct pairing gap in energy, which at low temperatures exceeds the thermal energy in the system.

Thus superconductivity is a prime example of a macroscopic quantum coherent system, and one can attach to the degenerate electron gas a wavefunction-like order parameter that has a specific phase. The spatial gradient of that phase gives the superconducting current. Superfluidity of liquids and Bose–Einstein condensation of atomic or molecular gases are similar low-temperature examples with overall phase coherence. The connection between the phase and current means that since the phase change in a closed loop can only be a multiple of 2π , the flux related to it must be quantized. If the loop can shrink without limit in the material, it leads to quantized vortices, which are observed especially with rotated or stirred liquids and gases (Tilley and Tilley 1990). For superconductors, one can build circuits so that the loops

cannot shrink to zero size, and thus one can observe the quantization of the persistent superconducting current.

A superconducting current can pass through small regions of insulating material by quantum tunneling. One mechanism is by breaking the Cooper pair during the process (quasiparticle tunneling), or the Josephson tunneling of Cooper pairs. Typically, the latter effect is the more interesting one, and these junctions are often called Josephson or tunneling junctions. It is a quantum phenomena, since it is controlled by the phase difference ϕ over the junction, which means that the tunneling is a coherent process. The time derivative of ϕ gives the voltage over the junction, and the current through it is $I = I_c \sin(\phi)$, where I_c is the critical current that sets the upper limit. Interestingly, a current can exist across the junction even if the phase difference is constant and there is no voltage difference (DC Josephson effect). An externally created electric potential V across the junction gives a phase difference $\phi = 2eVt/\hbar$ and thus an alternating current (AC Josephson effect). The maximum of the current depends on the energy gap of the superconducting material and the temperature. SQUIDs (superconducting quantum interference devices) are based on the sensitivity of this current to external magnetic fields through the field-dependence of the energy gap. For actual insulating material, the barrier thickness should not exceed a few hundred nanometers, but for normal state metal one can go to the micrometer scale.

8.1 Charge Qubits

If one prepares a simple setup with one Josephson junction and two superconducting regions, coupled into a loop by a voltage source, one gets the so called Cooper pair box. Typically, one of the superconducting regions is small and is called an island. The fascinating aspect is that although we have countless Cooper pairs on the island, its electrostatic properties can be governed by a single Cooper pair. We can tune the system so that, initially, there is no net charge on the island (zero excess Cooper pairs). The junction has capacitance C , and there is another one (C_e) between the island and the external circuit. The Hamiltonian for the system is then (Nakahara and Ohmi 2008)

$$H = \frac{1}{2} E_c (n - n_e)^2 - E_J \cos \phi, \quad E_c = \frac{(2e)^2}{C + C_e}, \quad n_e = \frac{C_e V_e}{2e}, \quad E_J = \frac{I_c \hbar}{2e} \quad (21)$$

where V_e is the applied external voltage across the system and n is the Cooper pair number of the island. Note that n_e is a continuous quantity whereas n is limited to integer values.

It shows that one can have a field-induced degeneracy between n and $n + 1$ Cooper pairs on an island. At this degeneracy, tunneling is possible, and the two charge states are in fact coupled by the tunneling coupling E_J (this is not a true coupling; it appears as a frame of reference term since we write the system in terms of Cooper pairs localized on either side of the junction, which is not true because of tunneling). The charge number n and the junction phase ϕ form a conjugate pair of quantities (in analogy to x and p), and thus $\cos \phi$ can be interpreted as a term that induces $n \rightarrow n \pm 1$ transitions between the charge parabola.

One can also have a superposition of charge states, and this forms the charge qubit (Shnirman et al. 1997; Makhlin et al. 1999, 2000). By driving the system into the resonance point (changing n_e) one can observe coherent oscillations (Rabi oscillations) driven by E_J , or by traversing the degeneracy with fixed speed one obtains Landau-Zener transitions. Coherent oscillations and their decay were observed already in 1999 (Nakamura et al. 1999). Such charge

qubits can be coupled, for example, capacitatively, as demonstrated in 2003 (Pashkin et al. 2003), followed closely by a demonstration of conditional logic (Yamamoto et al. 2003). The superconducting systems are very robust to perturbations, but the electronics needed for manipulating and detecting the qubit states seem to be a sufficient source for non-negligible noise.

8.2 Flux Qubits

Parallel to the development of superconducting charge qubits, another idea emerged, namely the use of the current itself (Mooij et al. 1999; Friedman et al. 2000). The idea is to prefabricate the junction as a part of a small ring of superconducting material, so that the tunneling coupling E_J dominates over the charge state separation E_C . This is the standard RF-SQUID setup, and such a ring can then have a persistent current in it, controlled by the external magnetic field flux Φ_e . One can show that, due to the existence of quantum phase coherence in the ring, the total magnetic flux Φ through the ring must obey a quantization rule, so that $\Phi = (\phi + 2\pi n)\Phi_0/(2\pi)$, where the flux quantum is $\Phi_0 = \hbar/(2e)$ and ϕ is the phase change over the junction. It means that to satisfy this relation, a current I arises in the ring, so that $\Phi = \Phi_e + LI$, where L is the self-inductance of the ring. As described, for example, in Friedman et al. (2000), the flux can have the appearance of a position-like quantity, with kinetic energy $C\dot{\Phi}^2/2$ and potential

$$U = U_0 \left[\frac{1}{2} \left(\frac{2\pi(\Phi - \Phi_e)}{\Phi_0} \right)^2 - \beta \cos(2\pi\Phi/\Phi_0) \right] \quad (22)$$

where C is the junction capacitance, $U_0 = \Phi_0^2/(4\pi^2 L)$ and $\beta = 2\pi L I_c / \Phi_0$, with I_c again as the critical current of the junction.

The above potential is for practical purposes a double-well structure with two minima. The β term arises from the phase change over the junction. For $\Phi_e = \Phi_0/2$ one obtains a symmetric structure, and let one consider it for simplicity. The two wells correspond to flux quanta $n = 0$ and $n = 1$, and to equal currents flowing in opposite directions. These fluxes and accompanying supercurrents form the flux qubit. At the bottom of the wells and for large E_J they are quite stable and robust to perturbations. For smaller E_J , the true lowest quantum states spread over the whole double-well and are roughly the symmetric and antisymmetric superpositions of the localized states, and their degeneracy is split by the tunnel coupling. Variations in Φ_e make the potential antisymmetric, separating the left- and right-localized states in energy, and thus reducing the effect of the tunnel coupling. Such coherent superpositions were observed experimentally in 2000 (Friedman et al. 2000; van der Wal et al. 2000).

The system can be further refined by adding more junctions, such as three or four (Mooij et al. 1999); this makes the size of the setup smaller and reduces possible disturbances. This is because with one junction a large inductance L and, thus, a large size is needed to allow for the generation of the sufficiently large compensation flux; in the multijunction setup the compensation flux can be as small as $10^{-3}\Psi_0$. The double-well description is nevertheless still fine (van der Wal et al. 2000). The energy separation of the flux states is in the microwave region and one can thus perform single-qubit operations; here the disturbances in the external flux cause decoherence, and its time scale has been estimated to be around 20 ns by considering Ramsay interferometry with two $\pi/2$ pulses (Chirosescu et al. 2003).

The state of a flux qubit can be read out with various schemes, see van der Wal et al. (2000) and Chiorescu et al. (2003). The conditional logic can be obtained, for example, by circling the qubits with another superconducting ring so that a four-state system emerges, with two-qubit states that can be manipulated with microwave fields (Mooij et al. 1999; Hime et al. 2006; van der Ploeg et al. 2007). Inductive coupling can be achieved by making the superconducting boxes for two qubits share one edge (Majer et al. 2005). A promising scheme is to use the shared edge method but having an auxiliary qubit between the actual qubits with a large tunneling energy, so that it can be adiabatically eliminated. With this method, conditional logic has been demonstrated with four-junction qubits experimentally (Niskanen et al. 2007).

8.3 Phase Qubits and Circuit QED

One can also place a strong bias current $I_e \simeq I_c$ on the Josephson junction when $E_J \gg E_c$. The potential for the phase of the current becomes a washboard potential that has shallow local minima with a few bound states. A similar situation can be obtained with the RF-SQUID by setting a large Φ_e that tilts the potential strongly. The two lowest states form a phase qubit. Transitions between them can be driven with microwave fields, and detection can happen by state-dependent tunneling that can be observed as a direct current. The qubit circuits are coupled with a capacitor, and one can excite entangled states with microwave radiation; this has been demonstrated experimentally (Berkley et al. 2003; Steffen et al. 2006), but an actual demonstration of conditional logic is still missing. Decoherence times are on the order of 100 ns, compared to the duration of single qubit operations that is an order of magnitude less (Steffen et al. 2006).

In above examples, the superconducting system states were usually controlled with microwave radiation. This has also led to the idea of using microwave cavities for transferring quantum information (Blais et al. 2004) and, hence, to the concept of circuit QED. A coupling of a single charge qubit to a cavity mode has been demonstrated (Shuster et al. 2004). Recently, such a coupling of two phase qubits was demonstrated (Majer et al. 2007). The qubits consisted of two parallel junctions so that the tunneling coupling and, thus, the energy separation for the qubit states were controllable with external magnetic flux through the qubit system. Both qubits were coupled to a finite-length coplanar waveguide and separated by a distance of about 4 mm. They did not exchange actual photons with the cavity because they were off-resonant with it, but their presence induced a dispersive qubit–qubit coupling that shifted resonances for joint states, which was spectroscopically detected. Also, resonant coupling of a phase qubit to the cavity mode has been demonstrated, including the transfer of quantum information from the phase qubit to the photon (Houck et al. 2007). The actual exchange of a photon between two qubits through a resonant cavity coupling has been demonstrated as well (Sillanpää et al. 2007). Although still at a very preliminary phase, this approach is especially interesting as it opens up the possibility of well-separated qubits.

9 All-Optical Quantum Computing

Photons are the ultimate tools for quantum communication, so it is natural to ask if they can be applied in large-scale quantum computing as well. The problem with photons is that they are generated or destroyed quite easily, and are thus very different from more physical forms of

qubit systems. Also, they do not interact but require some medium for the process, so conditional logic with linear optical elements is not possible (starting with Bell state detection that would be simple if a linear optics CNOT gate was available (Lütkenhaus et al. 1999)). However, it is possible to circumvent this problem by using photodetectors and feedback loops as was shown in 2001 (Knill et al. 2001).

Demonstrations for simple operations in all-optical quantum computing have been performed (see, e.g., O'Brien et al. 2003), but it remains to be seen whether the actual large scale realization is a feasible goal. For a nice recent review, O'Brien (2007) is suggested.

10 Closing Remarks

The large-scale implementation of quantum computing is still clearly far beyond current experimental capabilities, as the examples given in this review demonstrate. Many ideas are only at a preliminary stage although vigorous work is going on. At least the large number of Science and Nature articles show that many of the proposed systems have broad interest, hopefully because they either hold great promise or are based on ingenious theoretical ideas and innovative experimental work. Both are definitely needed. It has been 15 years since the appearance of the Shor algorithm, but we are not yet even close to a working quantum computer. The future will show how well the attractive character of quantum information persists. Since all these attempts improve our understanding of quantum mechanics and its manifestations, and are usually linked with nanophysics research, it is quite possible that the most valuable outcome will eventually be something other than a working, large-scale quantum computer.

Abstract

Several results in quantum cryptography will be surveyed in this chapter. After a brief introduction to classical cryptography, we provide some cryptographic primitives from the viewpoint of quantum computational complexity theory, which are helpful to get an idea of quantum cryptographic protocols. We then examine cryptographic protocols of quantum key distribution, quantum bit commitment, quantum oblivious transfer, quantum zero-knowledge, quantum public-key encryption, quantum digital signature, and their security issues.

1 Introduction

Due to the rapid growth of electronic communication means, information security has become a crucial issue in the real world. Modern cryptography provides fundamental techniques for securing communication and information. While modern cryptography varies from encryption and digital signatures to cryptographic protocols, we can partition modern cryptography into public-key cryptography and secret-key cryptography. From the theoretical point of view, public-key cryptography has a computational complexity-theoretic flavor and secret-key cryptography has an information-theoretic flavor. Though the two disciplines of cryptography have different flavors, they are not separate from each other but rather complement each other.

The principal and classical task of cryptography is to provide confidentiality. Besides confidentiality, modern cryptography provides authentication, data integrity, and so on. Since Diffie and Hellman (1976) devised the notion of public-key cryptosystems, computational complexity theoretic approaches to cryptology have succeeded in theory and practice. The fundamental study of one-way functions and pseudorandom generators has developed computational complexity theory. Cryptographic protocols such as digital signatures, commitment schemes, oblivious transfer schemes, and zero-knowledge proof systems have contributed to building various information security systems. For each objective mentioned above, we should make models of adversaries so as to enable discussion of whether some cryptographic protocols or methods fulfill the objective. For public-key cryptography, it is typically thought that the adversary should be a probabilistic polynomial-time Turing machine or a polynomial-size circuit family. For secret-key cryptography, the adversary might be the Almighty or those who have some specific power.

It is when the adversary is physically realized that it can become a real threat. It is known that the real world behaves quantum mechanically. Thus, we may suppose that the adversary should run quantum mechanically. Shor's algorithm on quantum computers for the integer factorization problem (Shor 1997) illustrates that quantum adversaries would spoil the RSA cryptosystem (Rivest et al. 1978), which is widely used for secure communications. Shor also proposed an efficient quantum algorithm for the discrete logarithm problem. Moreover, since the security of many cryptographic protocols relies on the computational hardness of these two problems, cryptographic protocols might have to be reconstructed to maintain information security technologies in the future if the quantum adversary has a physical implementation.

The quantum mechanism also has an impact on the other discipline of cryptography, i.e., secret-key cryptography. In 1984, Bennett and Brassard (1984) proposed a quantum key

distribution scheme, which is a key agreement protocol using quantum communication. For the last two decades, so-called quantum cryptography has dramatically developed. For example, its unconditional security proofs were provided, some alternatives were proposed, and so on. We should especially mention that Mayers (1997) and Lo and Chau (1997) independently demonstrated that quantum mechanics cannot necessarily make all cryptographic schemes unconditionally secure.

As mentioned, secret-key cryptography enjoys the benefits of the quantum mechanism. On the other hand, Shor's algorithms can be regarded as a negative effect of the quantum mechanism on public-key cryptography. From the computational point of view, his algorithms illustrate that the quantum mechanism could make the computation more powerful. It is natural to consider that the power of the quantum mechanism could open up an era of neo-modern cryptography. Over the last decade, new possibilities (such as the unconditional security of the BB84 protocol) of quantum cryptography have been explored. Moreover, since the negative impact on public-key cryptography due to Shor, quantum cryptography has been also discussed and developed from the complexity-theoretic point of view. These investigations have promoted the development of quantum information theory and quantum computational complexity theory. In this chapter, we will survey what has been studied in quantum cryptography.

2 Classical Cryptography: Overview

2.1 One-Time Pad

The invention of Shannon's information theory initiated the mathematical study of communication. He also showed that the *one-time pad* has perfect secrecy and it is the only way to achieve perfect secrecy.

Here, a basic definition of classical cryptosystems will be given. A *symmetric-key cryptosystem* is a quintuple $(\mathcal{K}, \mathcal{P}, \mathcal{C}, \mathcal{E}, \mathcal{D})$, where

- \mathcal{K} is a finite set of possible *keys*, which must be shared with legitimate users.
- \mathcal{P} is a finite set of possible *plaintexts*.
- \mathcal{C} is a finite set of possible *ciphertexts*.
- For each k , there is an *encryption rule* $e_k \in \mathcal{E}$ and the corresponding *decryption rule* $d_k \in \mathcal{D}$, where $e_k: \mathcal{P} \rightarrow \mathcal{C}$ and $d_k: \mathcal{C} \rightarrow \mathcal{P}$ must satisfy $d_k(e_k(m)) = m$ for each $m \in \mathcal{P}$. Typically, \mathcal{E} and \mathcal{D} can be considered as the *encryption algorithm* and *decryption algorithm*, respectively. Namely, \mathcal{E} takes a key k and a plaintext m as input and computes $e_k(m)$. Similarly, \mathcal{D} takes a key k and a ciphertext c as input and computes $d_k(c)$.

In the basic scenario, there are two parties who wish to communicate with each other over an insecure channel. These parties are usually referred to as Alice and Bob. The insecurity of the channel means that an eavesdropper, called Eve, may wiretap the messages that are sent over this channel. Alice and Bob can make use of a cryptosystem to keep their information secret in spite of the existence of the eavesdropper, by agreeing with each other on a secret key k via another secure communication method.

In order for Alice to send her secret message m , she uses the key k to compute the ciphertext $c = e_k(m)$, and she sends Bob the ciphertext c over the insecure channel. Since Bob also knows the key k , he can decrypt the ciphertext by using the decryption algorithm and

obtain $d_k(c) = d_k(e_k(m)) = m$. On the other hand, since Eve wiretaps the ciphertext c but she does not know the key k , there is no easy way to obtain the original message m .

The *one-time pad* is the symmetric-key cryptosystem that achieves perfect secrecy. Suppose that $\mathcal{P} = \mathcal{C} = \mathcal{K} = \{0, 1\}^n$, $e_k(m) = m \oplus k$ and $d_k(c) = c \oplus k$, where \oplus is a bitwise XOR operation.

Let \mathbf{P} be a random variable over \mathcal{P} and \mathbf{K} a random variable over \mathcal{K} . A cryptosystem is said to have *perfect secrecy* if and only if for every $m \in \mathcal{P}$ and for every $c \in \mathcal{C}$, $\Pr[\mathbf{P} = m | \mathbf{C} = c] = \Pr[\mathbf{P} = m]$. That is, knowing the ciphertext c is not advantageous to the prediction of the original plaintext m . Shannon showed that for every perfectly secure cryptosystem the entropy of the key is at least as large as the entropy of the plaintext. This says that Alice cannot securely send her secret message of n -bits by using a key of length less than n bits.

Moreover, we have a characterization of perfect secrecy that is referred to as Shannon's Theorem. It states that the cryptosystem with $\mathcal{P} = \mathcal{C} = \mathcal{K}$ and $\text{supp}(\mathbf{P}) = \mathcal{P}$ has perfect secrecy if and only if \mathbf{K} is the uniform distribution over \mathcal{K} and there exists a unique key k such that $e_k(m) = c$ for every $m \in \mathcal{P}$ and for every $c \in \mathcal{C}$. By using Shannon's Theorem, it is not hard to see that the one-time pad has perfect secrecy.

2.2 Message Authentication

Confidentiality may be the prime function of cryptographic systems. Besides confidentiality, *authenticity* is another function of cryptographic systems. As a tool to provide message authentication, the universal hash function family (due to Carter and Wegman (1979) and Wegman and Carter (1981)) is well known. \mathcal{H} is a *universal hash function family* if the following holds.

- Each $h \in \mathcal{H}$ is a function from X to Y . Namely, the domain X and the range Y depend only on \mathcal{H} .
- For distinct $x, x' \in X$,

$$\Pr[h(x) = h(x')] = \frac{1}{|Y|}$$

where the probability is taken over the uniform distribution on \mathcal{H} .

If for distinct $x_1, x_2 \in X$ and for $y_1, y_2 \in Y$

$$\Pr[h(x_1) = y_1 \wedge h(x_2) = y_2] = \frac{1}{|Y|^2}$$

then \mathcal{H} is a pairwise independent (aka strongly universal) hash function family. It is easy to see that pairwise independent hash functions imply universal hash functions. For some domain X and range Y , there exists an efficient implementation of \mathcal{H} . Namely, there is an efficient algorithm that computes $h(x)$ on input x and the description of h . For example, we have an efficient implementation of the pairwise independent hash function family for $X = \{0, 1\}^n$ and $Y = \{0, 1\}^n$. Let us consider the following:

$$\mathcal{H} = \{h_{a,b}(x) = ax + b \mid a, b \in \mathbb{F}_{2^n}\}$$

where we identify the finite field \mathbb{F}_{2^n} (of order 2^n) with $\{0, 1\}^n$ by the standard encoding and the arithmetic computation is carried on \mathbb{F}_{2^n} . Since the computation over \mathbb{F}_{2^n} can be done

efficiently, \mathcal{H} has an efficient implementation. Also note that there exist efficient implementations for the pairwise independent hash function families whose domain and range are natural.

A typical application of the pairwise independent hash function is message authentication. Suppose that Alice and Bob share the hash key k and agree with the corresponding hash function h_k . The case where Alice sends a message m with $h_k(m)$ can be considered. If Bob receives (m, z) and checks if $z = h_k(m)$ and whenever the check fails, he can judge the message to be forged. On the other hand, since Eve does not know the hash key, the authentication part (i.e., z) seems to be perfectly random.

2.3 Block Ciphers and Cryptographic Hash Functions

Though the one-time pad has perfect secrecy, it is not practical since the key length must be at least as large as the message length. As a practical symmetric cryptosystem, blockwise encryption (called the *block cipher*) has been considered. Some block ciphers (e.g., data encryption standard (DES) and advanced encryption standard (AES)) can withstand some specific attacks. While several design paradigms have been developed so as to withstand known attacks, block ciphers cannot have perfect secrecy.

Universal hashing also has a desirable property. Because of its nature, the number of uses per key is limited. Instead, heuristic cryptographic hash functions such as SHA-1 are practically used.

2.4 Cryptographic Protocols

As mentioned, the era of modern cryptography started in the 1970s. The invention of the notion of one-way functions introduced a computational complexity viewpoint into cryptology. One-way functions are functions $f: \{0, 1\}^* \rightarrow \{0, 1\}^*$ such that, for each $x \in \{0, 1\}^*$, $f(x)$ is efficiently computable but $f^{-1}(y)$ is computationally tractable only for a negligible fraction of all y 's. The notion of one-way functions is one of the most fundamental in cryptology. Though the existence of one-way functions (which is related to the **P** versus **NP** problem) is unproven, modern cryptography has been established based on it. Actually, computational assumptions such as the existence of one-way functions have brought about many cryptographic protocols, such as public-key encryption schemes, digital signature schemes, commitment schemes, oblivious transfer schemes, zero-knowledge proof/argument systems, and so on.

2.4.1 Public-Key Encryption Scheme

A *public-key encryption scheme* is different to a symmetric-key encryption scheme. While the encryption key and the decryption key are the same in the case of symmetric-key encryption, the encryption key is different from the decryption key in the case of public-key encryption. This means that in cases of public-key encryption the encryption key can be publicly issued. The decryption key must be still secret.

The public-key encryption scheme is usually defined by a triple $(\mathcal{G}, \mathcal{E}, \mathcal{D})$:

- \mathcal{G} is a key generation algorithm that generates a pair of the secret key k_s and the public key k_p on input 1^n (the unary representation of the security parameter n). Here, the plaintext space \mathcal{P} and the ciphertext space \mathcal{C} are implicitly defined. \mathcal{P} and \mathcal{C} basically depend on the security parameter n . (They sometimes depend on the key pair (k_s, k_p) .)
- \mathcal{E} is an encryption algorithm that, given the public key k_p and the message m , computes the ciphertext $c = \mathcal{E}(k_p, m)$.
- \mathcal{D} is a decryption algorithm that, given the secret key k_s and the ciphertext c , computes the plaintext $m = \mathcal{D}(k_s, c)$.
- For every possible key pair (k_s, k_s) and for every message $m \in \mathcal{P}$, $\mathcal{D}(k_s, \mathcal{E}(k_p, m)) = m$.

As in the case of the one-time pad, there are two parties, Alice and Bob. In the case of public-key encryption, the roles of Alice and Bob are asymmetric and all parties including Eve are modeled by probabilistic polynomial-time algorithms. First, Bob or the trusted third party runs the key generation algorithm to obtain the key pair (k_s, k_p) . The public key k_p is published. If the trusted third party runs the algorithm, the secret key k_s must be transferred to Bob via a secure communication method. In order for Alice to send her secret message m to Bob, she obtains Bob's public key k_p , computes the ciphertext $c = \mathcal{E}(k_p, m)$ and sends Bob the ciphertext c . After Bob obtains the ciphertext c , he can compute $m = \mathcal{D}(k_s, c)$. Eve wiretaps the ciphertext c and she can also obtain the public key k_p . This means that she can choose an arbitrary message m' on her own and obtain the corresponding ciphertext $c' = \mathcal{E}(k_p, m')$. This ability is called the *chosen plaintext attack*. Thus, the security of public-key encryption must be guaranteed against the chosen plaintext attack at least. In recent theory, a more powerful attack model called the *chosen ciphertext attack* has been considered. Here, the details are not mentioned.

Besides the attack model, it is important to define the security goal. *One-wayness, semantic security* (Goldwasser and Micali 1984) and *non-malleability* (Dolev et al. 2000) are typical goals. One-wayness means that it is infeasible for Eve to recover the whole message from the target ciphertext. Semantic security means that it is infeasible for Eve to extract any partial information of the plaintext from the ciphertext. Non-malleability means that it is infeasible for Eve to obtain another ciphertext whose plaintext is related to the original plaintext of the target ciphertext. The bare RSA public-key encryption scheme (Rivest et al. 1978) cannot have semantic security. Thus, the RSA scheme should be used in a more sophisticated way, such as optimal asymmetric encryption padding (OAEP) (Bellare and Rogaway 1995). Furthermore, hybrid encryptions (e.g., Cramer and Shoup (2003)), among them public-key encryption, symmetric encryption and message authentication techniques, they have been extensively studied, because they easily provide a more practical and more secure public-key encryption scheme.

2.4.2 Digital Signature Scheme

A *digital signature scheme* is one of the most important protocols in cryptology. It is usually defined by a triple $(\mathcal{G}, \mathcal{S}, \mathcal{V})$:

- \mathcal{G} is a key generation algorithm that generates a pair of the secret key k_s and the public key k_p on input 1^n .
- \mathcal{S} is a signature algorithm that, given the secret key k_s and the message m , computes a signature $\sigma = \mathcal{S}(k_s, m)$.

- \mathcal{V} is a verification algorithm that, given the public key k_p and the signed message (m, σ) , checks the validity of σ for the message m .

In the basic scenario, there is a signer Alice who wishes to prove the authenticity of her message and a verifier Bob who verifies the validity of the signature. First, Alice or the trusted third party runs the key generation algorithm to obtain the key pair (k_s, k_p) . The public key k_p is published. If the trusted third party runs the algorithm, the secret key k_s must be transferred to Alice via a secure communication method. In order for Alice to sign her message m , she obtains her secret key k_s , computes the signature $\sigma = \mathcal{S}(k_s, m)$, and issues the signed message (m, σ) . If Bob wishes to verify the validity of the signature σ for the message m , he runs the verification algorithm \mathcal{V} with the public key k_p and checks the validity. Bob rejects the signed message if the check fails and accepts it otherwise.

The most secure notion of digital signature schemes is *existential unforgeability* against the *adaptive chosen message attack*. It means that for any message m even if Eve can adaptively obtain signed messages (m', σ') for her own choice $m' \neq m$ then she cannot forge the signature σ valid for the message m . It is known that digital signature schemes satisfying existential unforgeability against the adaptive chosen message attack are constructible from any one-way function (Naor and Yung 1989).

2.4.3 Bit Commitment Scheme

A *bit commitment* is a fundamental cryptographic protocol between two parties. The protocol consists of two phases: commit phase and reveal phase. In the commit phase, the sender Alice has a bit b in her private space and she wants to commit b to the receiver Bob. They exchange messages and at the end of the commit phase Bob gets some information that represents b . In the reveal phase, Alice confides b to Bob by exchanging messages. At the end of the reveal phase, Bob judges whether the information from the reveal phase really represents b or not. Basically, there are three requirements for secure bit commitment: correctness, the hiding property, and the binding property. Correctness guarantees that if both parties are honest then for any bit $b \in \{0, 1\}$ Alice has, Bob accepts it with certainty. The hiding property guarantees that (cheating) Bob cannot reveal the committed bit during the commit phase. The binding property guarantees that (cheating) Alice cannot commit her bit b such that Alice maliciously reveals $b \oplus 1$ as her committed bit but Bob accepts it.

In the classical case, a simple argument shows the impossibility of bit commitment with the hiding and the binding properties both statistical. Thus, either hiding or binding must be computational. A construction of the statistically binding scheme (of the round complexity $O(1)$) from any pseudorandom generator was given by Naor (1991). Since the existence of one-way functions is equivalent to that of pseudorandom generators (Håstad 1999), a statistically binding scheme can be based on any one-way function. A construction of a statistically hiding scheme from one-way permutation was given by Naor, Ostrovsky, Venkatesan and Yung (Naor et al. 1998). After that, the assumption of the existence of one-way permutation was relaxed to that of a approximable-preimage-size one-way function (Haitner et al. 2005). Finally, Haitner and Reingold (2007) showed that a statistically hiding scheme can be based on any one-way function by using the excellent techniques in Nguyen et al. (2006).

Since a statistically binding (resp., statistically hiding) bit commitment scheme is a building block for zero-knowledge proof (resp., zero-knowledge argument) systems (Goldreich et al. 1991;

Brassard et al. 1988), it is desirable to be efficient from several viewpoints (e.g., the total size of messages exchanged during the protocol, or the round number of communications in the protocol).

2.4.4 Oblivious Transfer

Oblivious transfer (OT) is also an important two-party cryptographic protocol. The first known OT system was introduced by Rabin (1981) where a message is received with probability $1/2$ and the sender cannot know whether his message reaches the receiver. Prior to this, Wiesner (1983) introduced a primitive called multiplexing, which is equivalent to the 1-out-of-2 OT (Even et al. 1985) known today, but it was then not seen as a tool in cryptography. Even et al. defined the 1-out-of-2 OT (Even et al. 1985), where the sender Alice has two secrets σ_0 and σ_1 and the receiver Bob can choose one of them in an oblivious manner. That is, Alice cannot know Bob's choice $i \in \{0, 1\}$ and Bob cannot know any information on σ_{1-i} . The former property is called *receiver's privacy* and the latter *sender's privacy*. Later, Crépeau (1988) showed that Rabin's OT and the 1-out-of-2 OT are equivalent. Furthermore, the more general 1-out-of- N OT (where the sender has N secrets) and the more specific 1-out-of-2 *bit* OT (where the secrets are one bit long) are similarly defined and the reductions among the variants of OT have been discussed in the literature, for example Brassard et al. (1996, 2003) and Crépeau and Savvides (2006).

OT protocols are fundamental building blocks of modern cryptography. Most notably, it is known that any secure function evaluation can be based on OT (Kilian 1988; Goldreich et al. 1987).

2.4.5 Zero-Knowledge Proof/Argument Systems

The notion of *zero-knowledge* was introduced by Goldwasser, Micali and Rackoff (Goldwasser et al. 1989). Roughly speaking, an interactive proof system has the zero-knowledge property if any (possibly cheating) verifier that communicates with the honest prover learns nothing through the interaction except the validity of the claimed statement. In the classical case, there are several variants of zero-knowledge corresponding to how to formally define the notion that the verifier "learns nothing." Anyway, the verifier "learns nothing" if there exists a polynomial-time simulator whose output is indistinguishable in some sense from the information the verifier would have after the interaction with the honest prover.

Goldreich, Micali and Wigderson (Goldreich et al. 1991) showed that any NP language has zero-knowledge proof by using a (nonuniform) computationally concealing statistically binding bit commitment scheme, that is, any (nonuniform) one-way function. This result can be extended for PSPACE languages. Moreover, a statistical zero-knowledge argument for any NP language is constructible from any one-way function (Nguyen et al. 2006).

3 Quantum Computational Cryptographic Primitive

Before showing several quantum cryptographic protocols, some computational primitive for quantum cryptography will be mentioned.

3.1 Quantum One-Way Permutations

In classical cryptography, some cryptographic protocols assume the existence of one-way permutation. Thus, some quantum cryptographic primitive might assume the existence of quantum one-way permutations. As will be seen, Dumais, Mayers and Salvail (Dumais et al. 2000) proposed a quantum bit commitment scheme based on the existence of quantum one-way permutations.

In the classical case, the RSA function and the discrete logarithm-based function could be candidates for one-way permutations. Unfortunately, such candidates are no longer one-way in the quantum setting because Shor's quantum algorithm (Shor 1997) solves the factorization problem and the discrete logarithm problem efficiently. Thus, it is important to consider the existence of quantum one-way permutations.

Kashefi, Nishimura and Vedral (Kashefi et al. 2002) gave a necessary and sufficient condition for the existence of *worst-case* quantum one-way permutations as follows.

Let $f: \{0, 1\}^n \rightarrow \{0, 1\}^n$ be a permutation. Then f is worst-case quantum one-way if and only if there exists a unitary operator in $\mathcal{Q} = \{Q_j(f) \mid j = 0, 1, \dots, n/2 - 1\}$ that is not efficiently computable. The reflection operators $Q_j(f)$ are defined as

$$Q_j(f) = \sum_{x \in \{0,1\}^n} |x\rangle\langle x| \otimes (2|\psi_{j,x}\rangle\langle\psi_{j,x}| - I)$$

where

$$|\psi_{j,x}\rangle = \frac{1}{\sqrt{2^{n-2j}}} \sum_{y: \text{pref}(f(y), 2j) = \text{pref}(x, 2j)} |y\rangle$$

and $\text{pref}(s, i)$ denotes the i bits-long prefix of a string s .

They also considered quantum weakly one-way permutations (i.e., in the cryptographic sense) and gave a sufficient condition on the existence. After that, Kawachi, Kobayashi, Koshiya and Putra (Kawachi et al. 2005b) gave a necessary condition and completed an algorithmic characterization of quantum weakly one-way permutations. The characterization is almost similar to the case of worst-case quantum one-way permutation except that the unitary operators in \mathcal{Q} permit exponentially small errors. While Kawachi et al. (2005b) mentioned a characterization of quantum weakly one-way permutations only, a similar characterization holds for quantum *strongly* one-way permutations. These characterizations might be helpful either to search for candidates of quantum one-way permutations or to disprove their existence.

3.2 Quantum Hard-Core Predicates

Hard-core predicates for one-way functions are also important in computational cryptography. Goldreich and Levin (1989) showed that a hard-core predicate is constructible from any one-way function f . Let $f'(x, r) = (f(x), r)$ be a function where $x, r \in \{0, 1\}^n$. Here, it is easy to see that f' is also one-way. The predicate

$$GL(x, r) = \langle x, r \rangle = \sum_{i=1}^n x_i r_i \bmod 2$$

is a hard-core predicate for the one-way function f' . Moreover, they gave a way to construct a hard-core function of output length $O(\log n)$ for any one-way function. Adcock and

Cleve (2002) considered quantum hard-core predicates (i.e., hard-core predicates against quantum adversaries) for quantum one-way functions. They showed that for any quantum one-way function f , $GL(x, r)$ is also a quantum hard-core predicate for the quantum one-way function $f'(x, r) = (f(x), r)$. Furthermore, they proved that the reduction between quantum hard-core predicates and quantum one-way functions is simpler and tighter than the classical reduction. Actually, they showed that a lower bound on the number of oracle calls in the classical reduction is properly larger than an upper bound in the quantum reduction.

It is widely known that list decodable codes have many computational complexity theoretical applications including hard-core functions (Sudan 2000). Intuitively speaking, if we are given a corrupted codeword of a list decodable code, we may output a short list containing messages close to the correct one rather than uniquely recover it. For example, the Goldreich–Levin Theorem (Goldreich and Levin 1989) mentioned above can be regarded as an efficient list-decoding algorithm for the binary Hadamard code. Actually, for a message x , $GL(x, 0), \dots, GL(x, 2^n - 1)$ corresponds to a codeword of the binary Hadamard code. The prediction algorithm for the hard-core predicate GL also corresponds to an access to a corrupted codeword. Suppose that we could obtain a polynomially long list that contains x with high probability by accessing the corrupted codeword. It implies that inverting the one-way function f is efficiently computable. Thus, we can say that there is no efficient algorithm to predict the hard-core value of GL .

From the quantum computational point of view, a general construction of quantum hard-core functions from quantum one-way functions was obtained due by Kawachi and Yamakami (2006), utilizing a classical code that has a quantum list-decoding algorithm. Roughly speaking, they showed that any code that has an almost orthogonal structure in a sense has a quantum list-decoding algorithm. Consequently, it enables one to discover new (quantum) hard-core functions. Especially, the quantum list-decoding technique affirmatively but quantumly settled an open problem whether Damgård's generator (Damgård 1988) is cryptographically secure or not.

4 Quantum Key Distribution

Quantum key distribution (QKD) is a quantum technique to share a random string between two parties Alice and Bob. It is the most successful protocol in quantum cryptography, which strengthens symmetric-key techniques. Usually, QKD protocols assume the authentication channel. It means that Alice and Bob beforehand have to agree on the hash key for universal hash functions. Thus, QKD can be regarded as a technique for stretching shared randomness between Alice and Bob.

Known QKD protocols can be partitioned into two types. One is based on Heisenberg's uncertainty principle and the other is based on Bell's inequality.

4.1 Based on Heisenberg's Uncertainty Principle

Quantum key distribution in the early stages, such as the BB84 protocol (Bennett and Brassard 1984) and the B92 protocol (Bennett 1992), were based on Heisenberg's uncertainty principle. The principle says that two complementary quantum states cannot be simultaneously measured. If the eavesdropper Eve wiretaps the quantum channel to obtain the secret

information, then she has to measure the quantum states. However, Heisenberg's uncertainty principle says that the measurement of quantum states affects the system. Thus, we can check the presence of an eavesdropper by observing the system change.

4.1.1 The BB84 Protocol

In this protocol, we use two orthogonal bases. One is the computational basis $\{|0\rangle, |1\rangle\}$ and the other is the diagonal basis $\{|0\rangle_{\times}, |1\rangle_{\times}\}$, where

$$\begin{aligned}|0\rangle_{\times} &= \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle) \\|1\rangle_{\times} &= \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)\end{aligned}$$

We also use $\{|0\rangle_+, |1\rangle_+\}$ to denote the computational basis $\{|0\rangle, |1\rangle\}$. The protocol is as follows:

1. Alice randomly chooses $4n$ qubits, each in one of the four states $|0\rangle_+, |0\rangle_{\times}, |1\rangle_+$ or $|1\rangle_{\times}$, and sends them to Bob.
2. For each qubit that Bob receives, he chooses either the computational basis (+) or the diagonal basis (\times) and measures the qubit with respect to the basis. If the channel is not wiretapped and Alice's basis coincides with Bob's, then his is the same as the bit of Alice. If the bases differ, his measurement result is randomly distributed.
3. Alice tells Bob the basis she used for each qubit via the classical authentication channel. Bob keeps the bits where Bob's basis coincides with Alice's. This happens in about half the cases, so Bob will have about $2n$ bits left.
4. Bob randomly partitions about $2n$ bits into two groups of about n bits. They use one group to estimate the error rate. Bob tells Alice all the bits in one group. If Alice's bits are too different from Bob's bits, they abort the protocol.
5. Alice and Bob obtain a common secret key from the remaining about n bits by performing error correction and privacy amplification.

Firstly, Mayers (1996) gave a (somewhat complex) proof of the unconditional security of the BB84 protocol. After that Shor and Preskill (2000) gave a simple proof by showing that the entanglement-based version of the BB84 protocol is equivalent for Eve to the original BB84 protocol. Note that the security proof in Mayers' fashion has been simplified (see, e.g., Koashi and Preskill (2003)).

4.1.2 The B92 Protocol

This protocol is similar to the BB84 protocol. While the BB84 protocol uses four types of quantum states, the B92 protocol instead uses two non-orthogonal quantum states.

Let $|\psi_0\rangle$ and $|\psi_1\rangle$ be two non-orthogonal quantum states. Then, two projective measurements P_0 and P_1 can be defined as follows:

$$\begin{aligned}P_0 &= I - |\psi_1\rangle\langle\psi_1| \\P_1 &= I - |\psi_0\rangle\langle\psi_0|\end{aligned}$$

The point is that $P_0|\psi_1\rangle = 0$ and $P_1|\psi_0\rangle = 0$.

The sketch of the B92 protocol is as follows: (1) Alice chooses qubits, each in one of the two quantum states $|\psi_0\rangle$ and $|\psi_1\rangle$ and sends them to Bob. (2) For each qubit that Bob receives, he chooses at random one of the two measurements P_0 and P_1 and measures the qubit. He keeps it secret whether he measures something or not. (3) Bob tells Alice the measurement he uses. (4) Alice can extract bits where $|\psi_i\rangle$ matches to P_i .

4.2 Based on Bell's Inequality

Experiments in the 1970s indicated that the correlation function of the entangled quantum states cannot be expressed by classical probability and these entangled quantum states are nonlocal. Ekert (1991) exploited these properties in the QKD protocol (E91 protocol). Namely, he used the property that the entangled photons have strong correlation to yield the secret key. On the other hand, he also used the property that the entangled photons do not satisfy Bell's inequality to detect the presence of the eavesdropper. Since the E91 protocol has a bit complex structure that relates to Bell's inequality, we give the description of a similar but simpler protocol. That is the protocol of Bennett, Brassard and Mermin (Bennett et al. 1992) based on the entanglement.

4.2.1 The BBM92 Protocol

The protocol is as follows:

1. A source S emits a pair of qubits such that

$$\begin{aligned} |\psi_{AB}\rangle &= \frac{1}{\sqrt{2}}(|0\rangle_+|0\rangle_+ + |1\rangle_+|1\rangle_+) \\ &= \frac{1}{\sqrt{2}}(|0\rangle_\times|0\rangle_\times + |1\rangle_\times|1\rangle_\times) \end{aligned}$$

The first qubit is sent in opposite directions. The first qubit is received by Alice and the second by Bob.

2. Both Alice and Bob randomly and independently choose either the computational basis (+) or the diagonal basis (\times) and measure the qubit with respect to the basis.
3. Alice and Bob announce their bases via the classical channel and keep the bits where the bases coincide.

The principle is based on the fact that Alice's bits and Bob's are exactly the same only when the pure state $|\psi_{AB}\rangle$ is prepared. If Eve wants to yield the situation where Alice's bits and Bob's are exactly the same, the only thing she can do is to prepare a pure state on the system AB and send it to Alice and Bob. Thus, Eve cannot leave any correlation between her system and the measurement results by Alice and Bob.

5 Quantum Public-Key Encryption

As mentioned, public-key cryptosystems are indispensable, even in the future if quantum computers are physically realized. Unfortunately, almost all practical public-key cryptosystems are vulnerable to Shor's algorithm. On the other hand, there are public-key

cryptosystems that have not been shown to be vulnerable to quantum adversaries. Lattice-based cryptography (Micciancio and Regev 2009) is one of them. In this section, we focus on public-key cryptosystems that use quantum computation.

5.1 The OTU00 Scheme

Okamoto, Tanaka and Uchiyama (Okamoto et al. 2000) first proposed a knapsack-based cryptosystem as a quantum public-key cryptosystem. Since knapsack-based cryptosystems in the early stages used linearity in the public key, attack algorithms were developed. To avoid attack algorithms, Chor and Rivest (1988) introduced nonlinearity into the public-key generation by using an easy discrete logarithm problem and proposed yet another knapsack-based cryptosystem. The OTU00 scheme can be regarded as an extension of the Chor–Rivest cryptosystem. This is because they use general discrete logarithm problems to generate public keys with the help of quantum computation.

The original OTU00 scheme uses the algebraic number field. Here, we give a simpler description of the OTU00 scheme based on the finite field.

[Key Generation Algorithm \mathcal{G}]

1. For the security parameter n , determine the parameters k, ℓ bounded by a polynomial in n .
2. Randomly generate a prime p and a generator g of \mathbb{F}_p^* .
3. Randomly choose k relatively prime integers $p_1, \dots, p_k \in \mathbb{F}_p^*$ such that the product of any ℓ elements out of the k elements is bounded by p .
4. Run Shor's algorithm to compute a_i such that $p_i = g^{a_i} \pmod{p}$ for each i ($1 \leq i \leq k$).
5. Randomly choose $d \in \mathbb{F}_{p-1}$.
6. Compute $b_i = (a_i + d) \pmod{(p-1)}$ for each i .
7. Return the public key (ℓ, b_1, \dots, b_k) and the secret key $(g, d, p, p_1, \dots, p_k)$.

[Encryption Algorithm \mathcal{E}]

1. Encode the message $m \in \{0, 1\}^\nu$ ($\nu = \lfloor \log_2 (\binom{k}{\ell}) \rfloor$) into a k -bit string (s_1, \dots, s_k) of the Hamming weight ℓ as follows:
 - (a) Initialize the variable j to ℓ .
 - (b) Repeat the following from $i = 1$ to $i = k$. For convenience, we let $\begin{pmatrix} a \\ 0 \end{pmatrix} = \begin{pmatrix} 0 \\ q \end{pmatrix} = 1$ for $a \geq 1$.
 - If $m \geq \binom{k-i}{j}$ then set $s_i \leftarrow 1$ and $m \leftarrow m - \binom{k-i}{j}$ and decrease j by 1.
 - If $m < \binom{k-i}{j}$ then set $s_i = 0$.
2. Compute the ciphertext $c = \sum_{i=1}^k b_i s_i$ and return it.

[Decryption Algorithm \mathcal{D}]

1. Compute $r = c - \ell d \pmod{p-1}$.
2. Compute $u = g^r \pmod{p}$.
3. Compute (s_1, \dots, s_k) as follows:
 - If $p_i | u$ then set $s_i = 1$.
 - If $p_i \nmid u$ then set $s_i = 0$.

4. Recover the plaintext m from (s_1, \dots, s_k) as follows:
 - (a) Initialize m to 0 and the variable j to ℓ .
 - (b) Repeat the following from $i = 1$ to $i = k$.

If $s_i = 1$ then set $m \leftarrow m + \binom{k-i}{j}$ and decrease j by 1.
5. Return m .

The correctness of the decryption comes from the following fact:

$$u \equiv g^r \equiv g^{c-\ell d} \equiv g^{\sum_i s_i b_i - \ell d} \equiv g^{\sum_i s_i a_i} \equiv \prod_i (g^{a_i})^{s_i} \equiv \prod_i p_i^{s_i} \pmod{p}$$

Nguyen and Stern (2005) show that breaking the OTU00 scheme is reducible to the shortest vector problem or the closest vector problem. However, since these problems are NP-hard, the reductions do not provide an effective attack.

5.2 The KKNY05 Scheme

Kawachi, Koshiya, Nishimura and Yamakami (Kawachi et al. 2005a) proposed a semantically secure (in a weak sense) quantum public-key cryptosystem based on the worst-case hardness of the graph automorphism problem. Actually, they introduced a computational problem of distinguishing between two specific quantum states as a new cryptographic problem to design the quantum public-key cryptosystem. The computational indistinguishability between quantum states is a generalization of the classical indistinguishability between two probability distributions, which plays an important role in computational cryptography. Their problem QSCD_{ff} asks whether we can distinguish between two sequences of identical samples of $\rho_{\pi}^+(n)$ and of $\rho_{\pi}^-(n)$ for each fixed hidden permutation π for each length parameter n of a certain form. Let S_n be the *symmetric group* of degree n and let

$$\mathcal{K}_n = \{\pi \in S_n : \pi^2 = id \text{ and } \forall i \in \{1, \dots, n\} [\pi(i) \neq i]\}$$

for $n \in N$, where id stands for the identity permutation and $N = \{2(2n' + 1) : n' \in \mathbb{N}\}$. For each $\pi \in \mathcal{K}_n$, let $\rho_{\pi}^+(n)$ and $\rho_{\pi}^-(n)$ be two quantum states defined by

$$\begin{aligned} \rho_{\pi}^+(n) &= \frac{1}{2n!} \sum_{\sigma \in S_n} (|\sigma\rangle + |\sigma\pi\rangle)(\langle\sigma| + \langle\sigma\pi|) \text{ and} \\ \rho_{\pi}^-(n) &= \frac{1}{2n!} \sum_{\sigma \in S_n} (|\sigma\rangle - |\sigma\pi\rangle)(\langle\sigma| - \langle\sigma\pi|) \end{aligned}$$

The cryptographic properties of QSCD_{ff} follow mainly from the definition of the set \mathcal{K}_n of the hidden permutations. Although the definition seems somewhat artificial, the following properties of \mathcal{K}_n lead to cryptographic and complexity-theoretic properties of QSCD_{ff}:

- (i) $\pi \in \mathcal{K}_n$ is of order 2, which provides the trapdoor property of QSCD_{ff}
- (ii) For any $\pi \in \mathcal{K}_n$, the conjugacy class of π is equal to \mathcal{K}_n , which enables one to prove the equivalence between the worst-case/average-case hardness of QSCD_{ff}
- (iii) The graph automorphism problem is (polynomial-time Turing) equivalent to its subproblem with the promise that a given graph has a unique non-trivial automorphism in \mathcal{K}_n or none at all. This equivalence is exploited to give a complexity-theoretic lower bound of QSCD_{ff} that is, the worst-case hardness of the graph automorphism problem.

Their problem QSCD_{ff} is closely related to a much harder problem: the hidden subgroup problem on the *symmetric groups* (SHSP). Note that no known subexponential-time quantum

algorithm exists for SHSP. Hallgren et al. (2003) introduced a distinction problem between certain two quantum states, similar to QSCD_{ff}, to discuss the computational intractability of SHSP by a “natural” extension of Shor’s algorithm (1997) with the quantum Fourier transformation. An efficient solution to this distinction problem gives an answer to a pending question on a certain special case of SHSP. To solve this distinction problem, as they showed, the so-called *weak Fourier sampling* on a single sample should require an exponential number of samples. This result was improved by Grigni et al. (2004) and Kempe et al. (2006). On the contrary, Hallgren et al. (2006) and Hayashi et al. (2008) proved that no time-unbounded quantum algorithm solves the distinction problem even from $o(n \log n)$ samples. Kawachi et al. (2005a) showed that the above distinction problem is polynomial-time reducible to QSCD_{ff}. This immediately implies that we have no time-unbounded quantum algorithm for QSCD_{ff} from $o(n \log n)$ samples. Even with sufficiently many samples for QSCD_{ff} there is no known subexponential-time quantum algorithm for QSCD_{ff} and thus finding such an algorithm seems a daunting task.

One can move to the description of the quantum public-key cryptosystem in Kawachi et al. (2005a). Usually public-key cryptosystems consist of three algorithms for key generation, encryption, and decryption.

[Public-Key Generation Algorithm]

Input: $\pi \in \mathcal{K}_n$

Procedure:

Step 1. Choose a permutation σ from S_n uniformly at random and store it in the second register. Then, the entire system is in the state $|0\rangle|\sigma\rangle$.

Step 2. Apply the Hadamard transformation to the first register.

Step 3. Apply the Controlled- π to both registers.

Step 4. Apply the Hadamard transformation to the first register again.

Step 5. Measure the first register in the computational basis. If 0 is observed, then the quantum state in the second register is ρ_π^+ . Otherwise, the state of the second register is ρ_π^- . Now, apply the conversion algorithm to ρ_π^- .

The encryption algorithm consists of two parts: one is the conversion algorithm below and the other is so simple that we describe it in the description of the total system.

[Conversion Algorithm]

The following transformation inverts, given ρ_π^+ , its phase according to the sign of the permutation with certainty.

$$|\sigma\rangle + |\sigma\pi\rangle \mapsto (-1)^{\text{sgn}(\sigma)}|\sigma\rangle + (-1)^{\text{sgn}(\sigma\pi)}|\sigma\pi\rangle$$

Since π is odd, the above algorithm converts ρ_π^+ into ρ_π^- .

Finally, we give a description of the decryption algorithm.

[Decryption Algorithm]

Input: unknown state χ which is either ρ_π^+ or ρ_π^- .

Procedure:

Step 1. Prepare two quantum registers: The first register holds a control bit and the second one holds χ . Apply the Hadamard transformation H to the first register. The state of the system now becomes

$$H|0\rangle\langle 0|H \otimes \chi$$

Step 2. Apply the Controlled- π operator C_π to the two registers, where $C_\pi |0\rangle|\sigma\rangle = |0\rangle|\sigma\rangle$ and $C_\pi |1\rangle|\sigma\rangle = |1\rangle|\sigma\pi\rangle$ for any $\sigma \in S_n$.

Step 3. Apply the Hadamard transformation to the first register.

Step 4. Measure the first register in the computational basis. Output the observed result.

The following is the description of the total cryptosystem consisting of two phases: key transmission phase and message transmission phase.

[Key Transmission Phase]

1. Bob chooses a decryption key π uniformly at random from \mathcal{K}_n .
2. Bob generates sufficiently many copies of the encryption key ρ_π^+ by using the public-key generation algorithm.
3. Alice obtains encryption keys from Bob.

[Message Transmission Phase]

1. Alice encrypts 0 or 1 into ρ_π^+ or ρ_π^- , respectively, by using the conversion algorithm, and sends it to Bob.
2. Bob decrypts Alice's message using the decryption algorithm.

6 Quantum Digital Signature

Gottesman and Chuang (2001) proposed a quantum digital signature scheme. In the classical case, the Lamport signature (Lamport 1979) is based on one-way functions. The GC01 scheme is a quantum counterpart of the Lamport signature scheme. In the classical case, the existence of one-way functions is unproven. They allowed one-way functions to have the image of quantum states and showed the existence of (extended) one-way functions in the information-theoretic sense. Note that if the one-way function in the GC01 scheme is replaced with any one-way function in the computational sense then the security (the existential unforgeability against the chosen message attack) of the GC01 scheme holds in the computational sense. The original GC01 scheme has the non-repudiation property based on our choice of parameters. (The non-repudiation property means that once the signer creates a signed message he cannot repudiate the validity of the signed message.)

6.1 The GC01 scheme

For simplicity, we give the description of a version of the GC01 scheme without the non-repudiation property.

[Key Generation Algorithm \mathcal{G}]

1. Let f be an extended quantum one-way function.
2. Randomly choose $x_0^{(i)}$ and $x_i^{(i)}$ from $\{0, 1\}^n$ for $i = 1, \dots, s$ and return them as the secret key.
(How to determine the value of s will be mentioned later.)
3. For $i = 1, \dots, s$, make t copies of $(|\psi_0^{(i)}\rangle, |\psi_1^{(i)}\rangle) = (|f(x_0^{(i)})\rangle, |f(x_i^{(i)})\rangle)$ and distribute them to at most t verifiers.

[Signature Algorithm \mathcal{S}]

For a target bit $b \in \{0, 1\}$ to be signed, produce its signature σ as follows:

$$\sigma = (\sigma_1, \dots, \sigma_s) = (x_b^{(1)}, \dots, x_b^{(s)})$$

[Verification Algorithm \mathcal{V}]

1. Check the validity of (b, σ) by using the public key $(|\psi_0^{(i)}\rangle, |\psi_1^{(i)}\rangle)$.
2. Compute $(f(\sigma_1), \dots, f(\sigma_s))$ from the signature $(\sigma_1, \dots, \sigma_s)$.
3. Check the equivalence between $f(\sigma_i)$ and $\psi_b^{(i)}$ for $i = 1, \dots, s$ by using the swap-test (Buhrman 2001). If all the swap-tests pass, then accept (b, σ) as a valid signed message. Otherwise, reject (b, σ) .

6.2 Swap Test

As seen, the swap-test is used to check the equivalence between $|f(\sigma_i)\rangle$ and $|\psi_b^{(i)}\rangle$ in the verification algorithm \mathcal{V} . In general, the swap-test checks the equivalence between $|\phi\rangle$ and $|\psi\rangle$. Exactly speaking, the swap-test performs the following:

$$(H \otimes I)(c\text{-SWAP})(H \otimes I)|0\rangle|\phi\rangle|\psi\rangle \quad (1)$$

where c-SWAP exchanges the last two registers if the first qubit is 1. Then [Eq. 1](#) is written as

$$\frac{1}{2}|0\rangle(|\phi\rangle|\psi\rangle + |\psi\rangle|\phi\rangle) + \frac{1}{2}|1\rangle(|\phi\rangle|\psi\rangle - |\psi\rangle|\phi\rangle)$$

If $|\phi\rangle = |\psi\rangle$ then the measurements on the first register always give the value 0. Let $\delta = \langle\phi|\psi\rangle$. If $|\phi\rangle \neq |\psi\rangle$ then the probability that the measurements on the first register give the value 0 is $\frac{1}{2}(1 + \delta^2)$. Since the swap-test is a one-sided error algorithm, the error probability is at most $\frac{1}{2}(1 + \delta^2)$.

Now we assume that $|\langle f(\sigma_i)|\psi_b^{(i)}\rangle| < \delta$ for every $i = 1, \dots, s$. Then, the probability that \mathcal{V} accepts an invalid signed message is the same as the probability of all the swap-tests in the case that $\sigma_i \neq x_b^{(i)}$ for all $i = 1, \dots, s$. Since it is less than $\left(\frac{1+\delta^2}{2}\right)^s$, we have to set s so that $\left(\frac{1+\delta^2}{2}\right)^s$ becomes negligible.

7 Quantum Commitment and Oblivious Transfer

Since the BB84 protocol (Bennett and Brassard 1984) was shown to be secure unconditionally, some other cryptographic protocols such as bit commitment and oblivious transfer schemes were expected to achieve security without any computational assumption.

The security of bit commitment schemes consists of a concealing property and a binding property. A concealing property satisfies even if a cheating receiver cannot predict the committed value before the reveal phase. A binding property satisfies even if a cheating sender

cannot reveal two different values in the reveal phase. In the classical setting, either the concealing or the binding property must be computational. By introducing quantum states into the bit commitment scheme, we expected that unconditionally secure bit commitment schemes would be realized.

First, Crépeau and Kilian (1988) showed a construction from unconditionally secure quantum commitment schemes to 1-out-of 2 quantum oblivious transfer schemes. Its information-theoretic security was proved in Crépeau (1994), Mayers and Salvail (1994), and Yao (1995). (Note that such a reduction in the classical setting is unknown.) Unfortunately, it was later shown that commitment schemes with unconditional concealing and binding properties are impossible even if quantum states are applicable (Lo and Chau 1997; Mayers 1997). Thus, alternative approaches such as quantum string commitment (Kent 2003) or cheat-sensitive quantum bit commitment (Aharonov et al. 2000; Hardy and Kent 2004; Buhrman et al. 2008) have been studied. Since those approaches do not reach a satisfactory level, yet another approach will be considered. If either the concealing or the binding condition of the bit commitment scheme is allowed to be computational, interesting commitment schemes utilizing quantum information are still possible. Dumais, Mayers and Salvail (Dumais et al. 2000) proposed a perfectly concealing and computationally binding noninteractive quantum bit commitment scheme under the assumption of the existence of quantum one-way permutations. Koshiba and Odaira (2009) generalized the Dumais–Mayers–Salvail (DMS) scheme to obtain a statistically concealing and computationally binding noninteractive quantum bit commitment scheme under the assumption of the existence of a quantum one-way function of the special form. The use of quantum information enables us to transform from a computationally concealing and computationally binding bit commitment scheme to a statistically concealing and computationally binding (interactive) scheme (Crépeau et al. 2001). Since the former is constructible from any quantum one-way function, so is the latter.

Here, let us see some issues in defining quantum bit commitment. Though we can define the concealing condition of quantum bit commitments as in the classical case, some care must be taken to define the binding condition in the quantum case. In the classical case, the binding property means that the probability that the bit value committed in the commit phase can be revealed as both 0 and 1 is negligibly small. However, this definition is too strong in the quantum case. Suppose that a sender in some quantum bit commitment scheme could generate the following state:

$$\frac{1}{\sqrt{2}}|0\rangle|\phi_0\rangle + \frac{1}{\sqrt{2}}|1\rangle|\phi_1\rangle$$

where $|\phi_0\rangle$ (resp., $|\phi_1\rangle$) is a quantum state to be sent when 0 (resp., 1) is honestly committed in the commit phase. Then the sender Alice sends the quantum state only in the second register to the receiver Bob and keeps the quantum state in the first register at her side. Alice can change the committed value with probability 1/2 by measuring the quantum state left at her side just before the reveal phase. Since the above situation is essentially inevitable, the straightforward extension of the binding condition in the classical case is not satisfied in the quantum case. Thus, we have to weaken the definition of the binding condition in the quantum case. Actually, Dumais, Mayers and Salvail (Dumais et al. 2000) considered that the binding condition is satisfied if $p_0 + p_1 - 1$ is negligibly small, where p_0 (resp., p_1) is the probability that the committed value is revealed as 0 (resp., 1).

The following is the description of the quantum bit commitment scheme in Dumais et al. (2000). Let $f: \{0, 1\}^n \rightarrow \{0, 1\}^n$ be any quantum one-way permutation.

[Commit Phase]

1. Alice decides $w \in \{0, 1\}$ as her committing bit. She also chooses $x \in \{0, 1\}^n$ uniformly at random, and then computes $f(x)$.
2. Alice sends $|f(x)\rangle$ to Bob if $w = 0$ and $H^{\otimes n}|f(x)\rangle$ otherwise.

[Reveal Phase]

1. Alice announces x and w to Bob.
2. If $w = 1$, Bob applies $H^{\otimes n}$ to the state sent from Alice. Otherwise, he does nothing to the state.
3. Bob measures the resulting state in the computational basis. Let y be the outcome. He accepts if and only if $y = f(x)$.

Finally in this section, we mention a conversion from quantum bit commitment scheme with computational assumption to quantum oblivious transfer with computational assumption. In Crépeau and Kilian's conversion from quantum bit commitment to 1-out-of 2 quantum oblivious transfer, the commitment scheme must be statistically secure. Thus, since the security proof (Yao 1995) is information-theoretic, his proof is not applicable to the computational security. Crépeau et al. have shown a way to convert a statistically concealing and computationally binding string commitment scheme of some non-standard type to 1-out-of-2 quantum oblivious transfer (Crépeau et al. 2004).

8 Quantum Zero-Knowledge Proof

At any round of interaction to simulate, a simulator typically generates a pair of a question from the verifier and a response from the honest prover. If this produces a pair that is inconsistent in itself (or with the other parts of the transcript of the interaction simulated so far), the simulator “rewinds” the process to simulate this round again. We now mention why the “rewinding” technique is not generally applicable to quantum verifiers. First, quantum information cannot be copied and the fact is also known as the no-cloning theorem. Second, measurements are generally irreversible processes. This difficulty was explicitly pointed out by van de Graaf (1997).

Since then, the study of quantum zero-knowledge has developed from the computational point of view. For example, Watrous (2002) defined the quantum counterpart of honest verifier statistical zero-knowledge and studied its properties. We denote by **HVQSZK** the class of languages that have honest verifier quantum statistical zero-knowledge proof systems. In Watrous (2002), the following statements are shown:

1. There exists a complete promise problem, which is a natural generalization of a complete promise problem in statistical zero-knowledge (**SZK**) due to Sahai and Vadhan (2003).
2. **HVQSZK** is contained by **PSPACE**.
3. **HVQSZK** is closed under the complement.
4. Any **HVQSZK** protocol can be parallelized to a one-round **HVQSZK** protocol.

Kobayashi (2003) defined noninteractive quantum perfect zero-knowledge (**NIQPZK**) and noninteractive quantum statistical zero-knowledge (**NIQSZK**) and studied their properties. Specifically:

1. If the prover and the verifier do not beforehand have any shared randomness and any shared entanglement, languages that have noninteractive quantum zero-knowledge proof systems are in **BQP**.
2. Assuming that the verifier and the prover share polynomially many Einstein–Podolsky–Rosen (EPR) pairs a priori, **NIQPZK** with the one-sided error has a natural complete promise problem, which is a generalization of a complete promise problem in noninteractive statistical zero-knowledge (**NISZK**) due to Goldreich, Sahai and Vadhan (Goldreich et al. 1999).
3. The graph non-automorphism (GNA) problem has a **NIQPZK** proof system with prior EPR pairs. (Since it is unknown whether GNA is in **BQP** or not, **NIQPZK** with prior EPR pairs includes a nontrivial language.)

In order to circumvent problematic issues caused by the rewinding technique, Damgård, Fehr and Salvail (Damgård et al. 2004) showed a way to construct a computational QZK proof and perfect QZK argument against quantum adversaries in the *common reference string* model, wherein it is assumed that an honest third party samples a string from some specified distribution and provides both the prover and verifier with this string at the start of the interaction. They have also given a construction of unconditionally concealing and computationally binding string commitment protocols against quantum adversaries.

Watrous (2006) resolved in many cases the problematic issues caused by the rewinding technique in quantum zero-knowledge by introducing a success probability amplifying technique, which is successfully utilized to amplify the success probability in the Quantum Merlin–Arthur protocol without increasing witness sizes (Marriott and Watrous 2004). Specifically he showed:

1. The graph isomorphism problem is in perfect zero-knowledge (**PZK**) even against the adversarial verifier who uses quantum computation to cheat.
2. If quantum one-way permutations exist, every problem in **NP** has ZK proof systems even against the adversarial verifier who uses quantum computation to cheat.
3. **HVQSZK=QSZK**, where **QSZK** denotes the class of problems having quantum statistical zero-knowledge proof systems.

Together with his proof construction, this implies that all the properties proved for **HVQSZK** in Watrous (2002) are inherited to **QSZK** (except for those related to the round complexity).

Kobayashi (2008) proves a number of general properties on quantum zero-knowledge proofs, not restricted to the statistical zero-knowledge case. Specifically, for quantum computational zero-knowledge proofs, letting **QZK** and **HVQZK** denote the classes of problems having quantum computational zero-knowledge proofs and honest-verifier quantum computational zero-knowledge proof systems, respectively, he showed:

1. **HVQZK = QZK**.
2. Any problem in **QZK** has a public-coin quantum computational zero-knowledge proof system.
3. Any problem in **QZK** has a quantum computational zero-knowledge proof systems of perfect completeness.

Abstract

The concept of completeness is one of the most important notions in theoretical computer science. **PromiseBQP**-complete problems are those in **PromiseBQP** to which all other **PromiseBQP** problems can be reduced in classically probabilistic polynomial time. Studies of **PromiseBQP**-complete problems can deepen our understanding of both the power and limitation of efficient quantum computation. In this chapter we give a review of known **PromiseBQP**-complete problems, including various problems related to the eigenvalues of sparse Hamiltonians and problems about additive approximation of Jones polynomials and Tutte polynomials.

1 Introduction

A celebrated discovery in theoretical computer science is the existence of **NP**-complete problems. A decision problem is **NP**-complete if it is in **NP**, and all other problems in **NP** reduce to it in deterministic polynomial time. After Cook (1971) (and Levin (1973) independently) showed that the Satisfiability problem is **NP**-complete, Karp (1972) found that 21 natural combinatorial problems, mostly problems on graphs, are **NP**-complete as well. Since then, thousands of problems arising from various disciplines such as mathematics, physics, chemistry, biology, information science, etc. have been found to be **NP**-complete (Garey and Johnson 1979).

Why is the notion of **NP**-completeness so important? First, showing a problem to be **NP**-complete means that the problem is very unlikely to be solvable in polynomial time. This makes **NP**-completeness an “important intellectual export of computer science to other disciplines” (Papadimitriou 1997). Second, the number of **NP**-complete problems that arise naturally is huge; thus **NP**-complete problems give a nice classification of **NP** problems. Actually, all but a few **NP** problems are known to be either in **P** or **NP**-complete. Nowadays, whenever people find a new problem in **NP** and cannot quickly find a polynomial-time algorithm, they start to consider whether it is **NP**-complete. Third, the notion of completeness provides a useful method to study a whole class by concentrating on one specific problem. For example, if one wants to separate **NP** from **P**, it is enough to show that any **NP**-complete problem does not have a deterministic polynomial-time algorithm. Of course, if one tries to explore the possibility of **NP** = **P** by designing efficient algorithms for **NP**, it is also sufficient to find an efficient algorithm on any one of the **NP**-complete problems.

Complete problems do not only exist in **NP**, they also exist in other computational classes, although the requirement for the reduction algorithm may vary from case to case. To study a property of a class, it is enough to show the property for one complete problem in the class, as long as the reduction used in the completeness definition does not destroy the property. For example, the fact that Graph 3-Coloring has a (computational) Zero-Knowledge protocol immediately implies that all **NP** problems have a Zero-Knowledge protocol, because for an arbitrary **NP** problem, the prover and verifier can first map the input to a Graph 3-Coloring instance and then run the Zero-Knowledge protocol for the latter (Goldreich et al. 1991).

Quantum computing is a new paradigm rapidly developed since the mid-1990s. Since Shor’s fast quantum algorithm for Factoring and Discrete Log caused great excitement in both the physics and computer science communities, many efforts have been put into designing quantum algorithms with exponential speedup over their classical counterparts. However, the progress of this line of research has been disappointingly slower than what people had

expected. There are a few quantum algorithms with exponential speedup, such as Hallgren's polynomial-time quantum algorithm for solving Pell's equation (Hallgren 2007) and Kuperberg's $2^{O(\sqrt{n})}$ time quantum algorithm for solving the Hidden Subgroup Problem (Lomont 2004) for a dihedral group (Kuperberg 2005); see a recent survey (Childs and van Dam 2010) for a more comprehensive review. But all the problems are number-theoretical or algebraic. (One exception is the oracle separation for the Glued Tree problem by Childs et al. based on a continuous quantum walk (Childs et al. 2003), but the problem is somewhat artificial.) Why does it seem that fast quantum algorithms are much harder to design and what should one do next? In a survey (Shor 2004), Shor gave a couple of possible reasons, including that one does not have enough intuition and experience in dealing with quantum information, and that there may not be many natural problems in quantum computers that can have speedup. He also suggested to try to first study problems that are solvable on a classical computer, aiming at developing algorithmic designing tools with extensive usefulness. It is hoped that studies of BQP-complete problems can shed light on these questions and deepen our understanding of the power and limitation of quantum computation.

BQP is the computational class containing decision problems that are solvable probabilistically on a polynomial-time quantum computer. Since a central problem in quantum computing is the comparison between the computational power of quantum and classical computation, it is natural to see what extra power a quantum computer gives one. In this regard, let **BQP**-completeness be defined with the reduction being **BPP** algorithms, that is, those (classical) probabilistic polynomial-time algorithms. In other words, a problem is **BQP**-complete if it is in **BQP**, and all other **BQP** problems can reduce it by probabilistic polynomial-time classical algorithms. Analogous to the fact that **NP**-complete problems are the “hardest” problems in **NP** and thus capture the computational power of efficient nondeterministic computation, **BQP**-complete problems are the hardest problems in **BQP** and thus capture the computational power of efficient quantum computation.

Like many other “semantic” complexity classes, **BQP** is not known to contain complete problems. What people usually study for completeness, in such a scenario, is the class containing the *promise* problems, that is, those decision problems for which the union of Yes and No input instances is not necessarily the whole set of $\{0,1\}$ strings. In our quantum case, it is the class **PromiseBQP**, that is, the collection of promise problems solvable in polynomial time on a quantum computer. There are mainly two tracks of **PromiseBQP**-complete problems. The first track contains problems on the eigenvalues of a local or sparse Hamiltonian or unitary matrix (Wocjan and Zhang 2006; Janzing and Wocjan 2007; Janzing et al. 2008). In the first work (Wocjan and Zhang 2006) along this line, Wocjan and Zhang considered the local Hamiltonian eigenvalue sampling (LHES) and local unitary phase sampling (LUPS) problems: Given a classical string $x \in \{0, 1\}^n$ and a $2^n \times 2^n$ dimensional local Hamiltonian $H = \sum_j H_j$ or $U = \prod_j U_j$, where each H_j or U_j are operating on a constant number of qubits, one is approximately sampling the eigenvalues of H or U under the distribution $\langle x | \eta_j \rangle$, where $|\eta_j\rangle$ are the corresponding eigenvectors. These two problems have close connections to other well-known problems in quantum algorithm and complexity theory: LHES is the natural sampling variant of estimating the minimum eigenvalue of a local Hamiltonian, a **QMA**-complete problem (Kitaev et al. 2002; Kempe et al. 2006), and LUPS is the natural sampling variant of estimating the eigenvalue of a unitary on a given eigenvector, a powerful algorithmic tool called phase estimation (Kitaev 1995). Though not defined as a promise problem, it will be shown in this survey that one can easily transform them into promise problems and thus be **PromiseBQP**-complete.

Later, the work was extended in two ways. In Janzing et al. (2008), Janzing, Wocjan, and Zhang showed that even if one restricts the local Hamiltonians in LHES to translationally invariant ones operating on a one-dimensional qudit chain, the problem is still **PromiseBQP**-complete. The other extension, done by Janzing and Wocjan (2007), views the Hamiltonian as a ± 1 weighted graph and lifts the graph to power k , where k is part of the input. Then estimating a diagonal entry is **PromiseBQP**-complete.

The second line of research on **PromiseBQP**-complete problems is about approximating the Jones polynomial and Tutte polynomial (Freedman et al. 2002b, c; Aharonov and Arad 2006; Aharonov et al. 2006, 2007a; Wocjan and Yard 2006). The Jones polynomial is an important knot invariant with rich connections to topological quantum field theory, statistical physics (Wu 1992) and DNA recombination (Podtelezhnikov et al. 1999). The main result for the Jones polynomial in the studies of **PromiseBQP**-completeness is that approximating the Jones polynomial of the plat closure of the braid group at $e^{2\pi i/k}$ to within some precision is **PromiseBQP**-complete. Both the efficient quantum algorithm and the universality for constant k were implicitly given by Freedman et al. (2002b, c), but recent results by Aharonov et al. (2006) and Aharonov and Arad (2006) gave an explicit and simpler algorithm and a hardness proof, which also extend the results to any k bounded by a polynomial of the size of the input braid.

The multivariate Tutte polynomial is more general than the Jones polynomial; the Tutte polynomial has many connections to algebraic graph theory and the Potts model in statistical physics. In Aharonov et al. (2007a), Aharonov, Arad, Eban, and Landau gave an efficient algorithm for additively approximating this general polynomial and also showed that the approximation for some ranges is **PromiseBQP**-complete.

The rest of the chapter is organized as follows. ◻ [Section 2](#) gives precise definitions of **BQP** and **PromiseBQP**. In ◻ [Sects. 3](#) and ◻ [4](#), the two lines of research on **PromiseBQP**-complete problems are studied. ◻ [Section 5](#) concludes with some questions raised.

2 Preliminaries

A promise problem is a pair $(L_{\text{Yes}}, L_{\text{No}})$ of nonintersecting subsets of $\{0, 1\}^*$. A language is the set of Yes instances of a promise $(L_{\text{Yes}}, L_{\text{No}})$ satisfying $L_{\text{Yes}} \cup L_{\text{No}} = \{0, 1\}^*$. For more discussions on promise problems versus languages (and why the former is important and sometimes necessary for complexity theory), the readers are referred to Goldreich's survey (Goldreich 2005).

Definition 1 (**PromiseBQP**) **PromiseBQP** is the class of promise problems $(L_{\text{Yes}}, L_{\text{No}})$ such that there is a uniform family of quantum circuits $\{U_n\}$ operating on $p(n) = \text{poly}(n)$ qubits, with the promise that for any n , applying U_n on $|x, 0^{p(n)-n}\rangle$ and measuring the first qubit gives the outcome 1 with probability at least $2/3$ for all $x \in L_{\text{Yes}}$, and at most $1/3$ for all $x \in L_{\text{No}}$.

Definition 2 (**BQP**) **BQP** is the class of languages L_{Yes} with $(L_{\text{Yes}}, \{0, 1\}^* - L_{\text{Yes}})$ in **PromiseBQP**.

Like many other “semantic” classes, **BQP** is not known to have complete problems. However, if one extends languages to promise problems, then **PromiseBQP** has canonical complete

problems for any model, such as the quantum Turing machine (Bernstein and Vazirani 1997), quantum circuit (Yao 1993), adiabatic quantum computer (Aharonov et al. 2004), and quantum one-way computer (Browne and Briegel 2006). For the quantum circuit model, for example, the canonical complete problem is the following.

Definition 3 The *canonical complete problem* for **PromiseBQP** in the circuit model has input $(\langle U \rangle, x)$, where $\langle U \rangle$ is the description of a uniform family of quantum circuits $\{U_n\}$ working on $p(n) = \text{poly}(n)$ qubits, with the promise that applying U_n on $|x, 0^{p(n)-n}\rangle$ and measuring the first qubit gives outcome 1 with probability at least $2/3$ for all $x \in L_{\text{Yes}}$ and at most $1/3$ for all $x \in L_{\text{No}}$. The problem is to distinguish the two cases.

The fact that this is a complete problem for **PromiseBQP** is almost by definition, which also makes the problem not so interesting. We hope to have more “natural” problems that can help us understand the class **PromiseBQP**.

3 Approximate Eigenvalue Sampling

This section provides an overview of the first track of studies on **PromiseBQP**-complete problems, that is on problems about eigenvalues of the local or sparse Hamiltonians.

➊ **Section 3.1** starts with the local Hamiltonian eigenvalue sampling (LHES) problem, defined in Wocjan and Zhang (2006), and we show that it is **PromiseBQP**-complete. The problem together with the proof contains the core ideas and techniques for this line of research.

Two extensions are then shown. First, the result in Janzing et al. (2008) is mentioned: even if the Hamiltonians are restricted to be translationally invariant on a one-dimensional qudit chain (with $d = O(1)$), the problem is still **PromiseBQP**-complete. Then ➋ **Sect. 3.2** shows the result in Janzing and Wocjan (2007) that estimating an entry in a sparse real symmetric matrix to some power k , where k is part of the input, is also **PromiseBQP**-complete.

The proofs in the three sections have similar ingredients, and an attempt is made to unify the notation and give a consistent treatment.

3.1 Phase Sampling and Local Hamiltonian Eigenvalue Sampling

The problems that one is going to see in this section have close relation to two well-known ones, local Hamiltonian minimum eigenvalue and phase estimation, which will be defined below. The local Hamiltonian minimum eigenvalue (LHME) problem is usually abbreviated as the local Hamiltonian (LH) problem, but here LHME is used to distinguish it from the other related problems, which are defined later.

Definition 4 (Local Hamiltonian minimum eigenvalue (LHME)) A tuple (H, a, b) is given where

1. $H = \sum_j H_j$ is a Hamiltonian operating on n qubits, with j ranging over a set of size polynomial in n , and each H_j operating on a constant number of qubits; it is promised that either $\lambda(H) < a$ or $\lambda(H) > b$, where $\lambda(H)$ is the minimum eigenvalue of H .
2. a and b are two real numbers such that $a < b$ and the gap $b - a = \Omega(1/\text{poly}(n))$.

The task is to distinguish between the case $\lambda(H) < a$ and the case $\lambda(H) > b$.

Definition 5 (Phase estimation (PE)) A unitary matrix U is given by black-boxes of controlled- U , controlled- U^{2^2}, \dots , controlled- $U^{2^{t-1}}$ operations, and an eigenvector $|u\rangle$ of U with eigenvalue $e^{2\pi i\varphi}$ with the value of $\varphi \in [0, 1)$ unknown. The task is to output an n -bit estimation of φ .

These two problems are both well studied in quantum computing. The Local Hamiltonian problem was shown by Kitaev et al. (2002) to be **PromiseQMA**-complete when each H_j operates on five qubits; actually it remains **PromiseQMA**-complete even when each H_j operates on only two qubits (Kempe et al. 2006). Kitaev's efficient quantum algorithm for phase estimation (Kitaev 1995) was a powerful tool for quantum algorithm design, such as for factoring (Shor 1997; Nielsen and Chuang 2000) and some recent quantum-walk based algorithms such as the general quantum walk search (Magniez 2007), formula evaluation (Ambainis et al. 2007), and its extension to span-program evaluation (Reichardt and Spalek 2008).

Let us now consider the sampling variant of the above two problems.

Definition 6 A probability distribution q on \mathbb{R} is said to *approximate* another probability distribution p on a discrete set $S \subseteq \mathbb{R}$ with *error* δ and *precision* ε if

$$\Pr_{x \sim q}[s - \varepsilon \leq x \leq s + \varepsilon] \geq (1 - \delta)p(s) \quad (1)$$

for any $s \in S$.

Intuitively, to approximate the probability distribution p , one draws a sample from another distribution q , and the outcome x is ε -close to s at least $(1 - \delta)$ times the correct probability $p(s)$, for each $s \in S$. Now one can define the sampling version of the two problems.

Definition 7 (Local Hamiltonian eigenvalue sampling (LHES)) We are given $(H, \varepsilon, \delta, b)$ where

1. $H = \sum H_j$ is a Hamiltonian operating on n qubits, with j ranging over a set of size polynomial in n , and each H_j operating on a constant number of qubits.
2. $\varepsilon = \Omega(1/\text{poly}(n))$ is the required estimation precision.
3. $\delta = \Omega(1/\text{poly}(n))$ is the required sampling error probability.
4. $b \in \{0, 1\}^n$ is a classical n -bit string.

Suppose the eigenvalues and the corresponding eigenvectors of H are $\{(\lambda_k, |\eta_k\rangle) : k \in [2^n]\}$ satisfying $|\lambda_k| < \text{poly}(n)$ for each k . Define the probability distribution $D(H, b)$ over the spectrum of H by

$$D(H, b) = \{(\lambda, \Pr(\lambda)) : \Pr(\lambda) = \sum_{\lambda_k=\lambda} |\langle b|\eta_k\rangle|^2\}. \quad (2)$$

The task is to draw a sample from some probability distribution p approximating $D(H, b)$ with error δ and precision ε .

Definition 8 (Local unitary phase sampling (LUPS)) We are given $(H, \varepsilon, \delta, b)$ where

1. U is (the description of) an n -qubit quantum circuit.
2. $\varepsilon = \Omega(1/\text{poly}(n))$ is the required estimation precision.

3. $\delta = \Omega(1/\text{poly}(n))$ is the required sampling error probability.
4. $b \in \{0, 1\}^n$ is a classical n -bit string.

Suppose the eigenvalues of U are $\{\lambda_j = e^{2\pi i \varphi_j}\}_{j=1, \dots, 2^n}$ (where $\varphi_j \in [0, 1)$ for each j), with the corresponding eigenvectors $\{|\eta_j\rangle\}_{j=1, \dots, 2^n}$. The task is to estimate φ_j with error δ and precision ε .

One can immediately see that these two problems are not even promise problems, since the output is a (sampling from a) distribution rather than a Yes/No answer. Nevertheless, they capture the power of efficient quantum computers in the following sense: First, a polynomial-time uniform family of quantum circuits can achieve the sampling requirement. Second, given an oracle for either problem, any **BQP** problem can be solved by a classical polynomial-time algorithm. These facts will be proved in the following two sections. After that, a mention will be made about how to change LHES to a promise problem so that it really becomes **PromiseBQP**-complete.

3.1.1 BQP Algorithm for LHES and LUES

In this section we prove that LHES and LUES are solvable by an efficient quantum circuit. The standard algorithm for phase estimation is first reviewed, then it is observed that the same algorithm actually gives the desired LUES solution. This is then used to show an algorithm for LHES.

Phase estimation can be solved by a quantum algorithm as follows. The working space has two registers. The first register consists of $t = n + \lceil \log(2 + 1/2\delta) \rceil$ qubits and is prepared in $|0\dots0\rangle$. The second register contains the eigenvector $|u\rangle$. Measuring $\tilde{\varphi}$ in the first register after carrying out the transformations described below gives the desired n -bit estimation of φ with probability of at least $1 - \delta$.

$$|0\rangle^{\otimes t}|u\rangle \quad (3)$$

$$\rightarrow \frac{1}{\sqrt{2^t}} \sum_{j=0}^{2^t-1} |j\rangle|u\rangle \quad (\text{apply the Fourier transform}) \quad (4)$$

$$\rightarrow \frac{1}{\sqrt{2^t}} \sum_{j=0}^{2^t-1} |j\rangle U^j|u\rangle \quad (\text{apply the controlled powers of } U) \quad (5)$$

$$= \frac{1}{\sqrt{2^t}} \sum_{j=0}^{2^t-1} e^{2\pi i j \varphi} |j\rangle|u\rangle \quad (6)$$

$$\rightarrow |\tilde{\varphi}\rangle|u\rangle \quad (\text{apply the inverse Fourier transform}) \quad (7)$$

The following observation says that the same algorithm actually works for LUES.

Fact If one feeds $|0\rangle|b\rangle$ instead of $|0\rangle|u\rangle$ as input to the above algorithm for the phase estimation problem and $t = \lceil \log \frac{1}{\varepsilon} \rceil + \lceil \log(2 + \frac{1}{2\delta}) \rceil$, then the measurement of the first register gives the desired sampling output. This implies that LUES can be solved by a polynomial-size quantum circuit.

This actually holds not only for $|b\rangle$ but also for a general state $|\eta\rangle$. To see why this is true, write $|\eta\rangle$ as $\sum_{j=1}^n \alpha_j |\eta_j\rangle$, then by the linearity of the operations, the final state is $\alpha_j |\tilde{\varphi}_j\rangle |\eta_j\rangle$. For more details, the readers are referred elsewhere (Nielsen and Chuang 2000; Chap. 5). Note that to implement the controlled- U^{2^j} operations for $j = 0, \dots, 2^t - 1$ in the above algorithm, one needs to run U for 2^t times, which can be done efficiently since $t = \lceil \log \frac{1}{\varepsilon} \rceil + \lceil \log(2 + \frac{1}{2\delta}) \rceil$ and $\varepsilon = \Omega(1/\text{poly}(n))$, $\delta = \Omega(1/\text{poly}(n))$.

Now we can give the efficient algorithm for LHES.

Theorem 1 *LHES can be implemented by a uniform family of quantum circuits of polynomial size.*

Proof By a simple scaling ($H' = H/\Lambda = \sum_j H_j/\Lambda$ where $\Lambda = \max_k |\lambda_k| = \text{poly}(n)$), one can assume that all the eigenvalues λ_k of H satisfy $|\lambda_k| < 1/4$. The basic idea to design the quantum algorithm is to use LUPS on $e^{2\pi i H}$. Note that $e^{2\pi i H}$ is unitary, and if the eigenvalues and eigenvectors of H are $\{\lambda_k |\eta_k\rangle\}$, then those of $e^{2\pi i H}$ are just $\{e^{2\pi i \lambda_k} |\eta_k\rangle\}$. Therefore, it seems that it is enough to run the LUES algorithm on $(e^{2\pi i H}, \varepsilon, \delta, b)$, and if one gets some $\lambda > 1/2$, then output $\lambda - 1$. However, note that H is of exponential dimension, so $e^{2\pi i H}$ is not ready to compute in the straightforward way. Fortunately, this issue is well studied in the quantum simulation algorithms, and the standard approach is the following asymptotic approximation using the Trotter formula (Trotter 1959; Chernoff 1968; Nielsen and Chuang 2000) or its variants. Here using the simulation technique, one obtains

$$\left(e^{2\pi i \sum_j H_j/m}\right)^m = \left(\prod_j e^{2\pi i H_j/m}\right)^m + O(1/m) \quad (8)$$

Now one runs LUES on $(b, \varepsilon, \delta/2, e^{2\pi i H})$. Whenever one needs to call $e^{2\pi i H}$, one uses $\prod_j e^{2\pi i H_j/m}$ for m times instead. Note that such substitution yields $O(1/m)$ deviation, so $t = \log \frac{2}{\varepsilon\delta} + O(1)$ calls yield $O\left(\frac{1}{\varepsilon\delta m}\right) \leq \frac{c}{m\varepsilon\delta}$ deviation for some constant c . Let $m = \frac{2c}{\varepsilon\delta^2}$, thus the final error probability is less than $\frac{\delta}{2} + \frac{c}{m\varepsilon\delta} = \delta$, achieving the desired estimation and sampling precisions.

From the proof one can see that as long as $e^{2\pi i H}$ can be simulated efficiently from the description of H , one can sample the eigenvalues of H as desired. Since sparse Hamiltonians, which contain local Hamiltonians as special cases, can be simulated efficiently (Aharonov and Ta-Shma 2003; Berry et al. 2007), we know that if we modify the definition of LHES by allowing H to be sparse then it is also BQP-complete.

3.1.2 BQP Hardness of LHES

Theorem 2 $\text{PromiseBQP} \subseteq \mathbf{P}^{\text{LHES}}$

Proof For any $L \in \text{PromiseBQP}$, there is a uniform family of polynomial size quantum circuits with ε -bounded error (for a small constant ε) that decides if $x \in L$ or $x \notin L$. Denote by

U the corresponding quantum circuit (of size n) and suppose the size of U is M , which is bounded by a polynomial in n . Further suppose that the computation is described by $U|x, \mathbf{0}\rangle = \alpha_{x,0}|0\rangle|\psi_{x,0}\rangle + \alpha_{x,1}|1\rangle|\psi_{x,1}\rangle$, where $\mathbf{0}$ is the initial state of the ancillary qubits, and $|\psi_{x,0}\rangle$ and $|\psi_{x,1}\rangle$ are pure states. After the U transform, the first qubit is measured and the algorithm outputs the result based on the outcome of the measurement. The correctness of the algorithm requires that $|\alpha_{x,0}|^2 < \varepsilon$ if $x \in L$, and $|\alpha_{x,1}|^2 < \varepsilon$ if $x \notin L$.

Now, a local Hamiltonian H is constructed encoding the circuit U and a binary string b encoding the inputs x , such that eigenvalue sampling applied to H and b yields significantly different probability distributions for the two cases of $x \in L$ and $x \notin L$.

To this end, the circuit V is constructed as follows: one first applies the original circuit U , then flips the sign for the component with the first qubit being 1, and finally reverses the computation of U . See  Fig. 1.

Suppose the original circuit U is decomposed as the product of elementary gates, that is, $U = U_{m-1} \dots U_0$, where each U_j is an elementary gate. Let V_j be the j -th gate in V , where $j = 0, 1, \dots, 2m$. Let $M = 2m + 1$, the number of gates in V . Attach a clock register to the system and define the operator

$$F = \sum_{j=0}^{M-1} V_j \otimes |j+1\rangle\langle j| \quad (9)$$

where the summation in the index is module M . Note that F is an $O(\log N)$ -local operator; we will remark how to slightly modify it to be a 4-local operator at the end of the proof. Define

$$|\varphi_{x,j}\rangle = F^j(|x, \mathbf{0}\rangle|0\rangle) \quad (10)$$

for $j \geq 0$, where F^j means that F is applied j times. It is easy to see that $|\varphi_{x,j}\rangle = |\varphi_{x, j \bmod 2M}\rangle$ for $j \geq 2M$.

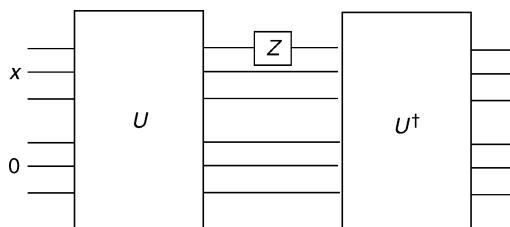

Note that due to the clock register for different j and j' in $\{0, \dots, 2M-1\}$, $|\varphi_{x,j}\rangle$ and $|\varphi_{x,j'}\rangle$ are orthogonal if $|j-j'| \neq M$. Also note that $U_{m-1} \dots U_0|x, \mathbf{0}\rangle = U|x, \mathbf{0}\rangle = \alpha_{x,0}|0\rangle|\psi_{x,0}\rangle + \alpha_{x,1}|1\rangle|\psi_{x,1}\rangle$ by definition. Therefore, we have

$$\langle \varphi_{x,j} | \varphi_{x,M+j} \rangle = \langle x, \mathbf{0} | U_0^\dagger \dots U_{m-1}^\dagger (P_0 - P_1) U_{m-1} \dots U_0 | x, \mathbf{0} \rangle = |\alpha_{x,0}|^2 - |\alpha_{x,1}|^2 \quad (11)$$

for $j = 0, \dots, M-1$, where P_0 and P_1 are the projections onto the subspaces corresponding to the first qubit being 0 and 1, respectively. To summarize, we have

$$\langle \varphi_{x,j} | \varphi_{x,j'} \rangle = \begin{cases} 0 & |j-j'| \neq M \\ |\alpha_{x,0}|^2 - |\alpha_{x,1}|^2 & |j-j'| = M \end{cases} \quad (12)$$

 Fig. 1
Circuit V .

Define the subspace $S_x = \text{span}\{|\varphi_{x,j}\rangle : j = 0, \dots, 2M - 1\}$. The key property here is that though F has an exponentially large dimension, $F|_{S_x}$ is of only polynomial dimension. Depending on the probability, we consider three cases.

Case $|\alpha_{x,0}| = 1$: The dimension of S_x is M , and $F|_{S_x}$ is a shift operator on the basis $\{|\varphi_{x,j}\rangle\}_{j=0, \dots, M-1}$, that is $F|\varphi_{x,j}\rangle = |\varphi_{x,j+1 \bmod M}\rangle$. It is not hard to see that this operator has eigenvalues and the corresponding eigenvectors

$$\lambda_k = \omega_M^k, \quad |\xi_k\rangle = \frac{1}{\sqrt{M}} \sum_{j=0}^{M-1} \omega_M^{-kj} |\varphi_{x,j}\rangle, \quad k = 0, 1, \dots, M-1 \quad (13)$$

where $\omega_M = e^{2\pi i/M}$.

Case $\alpha_{x,0} = 0$: The dimension of S_x is M , and $F|_{S_x}$ is almost a shift operator on the basis $\{|\varphi_{x,j}\rangle\}_{j=0, \dots, M-1}$: $F|\varphi_{x,j}\rangle = |\varphi_{x,j+1}\rangle$ for all $j = 0, \dots, M-2$, and $F|\varphi_{x,M-1}\rangle = -|\varphi_{x,0}\rangle$. It is not hard to see that this operator has eigenvalues and the corresponding eigenvectors

$$\mu_k = \omega_M^{k+1/2}, \quad |\eta_k\rangle = \frac{1}{\sqrt{M}} \sum_{j=0}^{M-1} \omega_M^{-(k+1/2)j} |\varphi_{x,j}\rangle, \quad k = 0, 1, \dots, M-1. \quad (14)$$

Case $0 < |\alpha_{x,0}| < 1$: In this general case, S_x has dimension $2M$. To find the eigenvalues and eigenvectors of $F|_{S_x}$, define

$$|\phi_{x,j}\rangle = \frac{|\varphi_{x,j}\rangle + |\varphi_{x,M+j}\rangle}{\||\varphi_{x,j}\rangle + |\varphi_{x,M+j}\rangle\|}, \quad |\gamma_{x,j}\rangle = \frac{|\varphi_{x,j}\rangle - |\varphi_{x,M+j}\rangle}{\||\varphi_{x,j}\rangle - |\varphi_{x,M+j}\rangle\|} \quad (15)$$

for $j = 0, \dots, M-1$. Then first, because $\langle \varphi_{x,j} | \varphi_{x,N+j} \rangle = |\alpha_{x,0}|^2 - |\alpha_{x,1}|^2$ is a real number, we have $\langle \phi_{x,j} | \gamma_{x,j} \rangle = 0$. Together with [Eq. 12](#), we know that

$$\{|\phi_{x,0}\rangle, \dots, |\phi_{x,M-1}\rangle, |\gamma_{x,0}\rangle, \dots, |\gamma_{x,M-1}\rangle\} \quad (16)$$

forms an orthonormal basis of S_x . One can further observe that $F|_{S_x} = F_0 \oplus F_1$, where F_0 and F_1 act on $S_{x,+} = \text{span}\{|\phi_{x,0}\rangle, \dots, |\phi_{x,M-1}\rangle\}$ and $S_{x,-} = \text{span}\{|\gamma_{x,0}\rangle, \dots, |\gamma_{x,M-1}\rangle\}$, respectively, with the matrix representations (in the basis $\{|\phi_{x,j}\rangle\}$ and $\{|\gamma_{x,j}\rangle\}$, respectively) as follows:

$$F_0 = \begin{pmatrix} 0 & 1 & 0 & \dots & 0 & 0 \\ 0 & 0 & 1 & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & & \vdots & \vdots \\ 0 & 0 & 0 & \dots & 0 & 1 \\ 1 & 0 & 0 & \dots & 0 & 0 \end{pmatrix}, \quad F_1 = \begin{pmatrix} 0 & 1 & 0 & \dots & 0 & 0 \\ 0 & 0 & 1 & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & & \vdots & \vdots \\ 0 & 0 & 0 & \dots & 0 & 1 \\ -1 & 0 & 0 & \dots & 0 & 0 \end{pmatrix} \quad (17)$$

So F_0 and F_1 have the same matrix representations as the two operators in the previous two cases, thus having the same eigenvalues and eigenvectors (with respect to different basis vectors though). Precisely, F_0 has eigenvalues λ_k with eigenvectors $|\xi_k\rangle = \frac{1}{\sqrt{M}} \sum_{j=0}^{M-1} \omega_M^{-kj} |\phi_{x,j}\rangle$; F_1 has eigenvalues μ_k with eigenvectors $|\eta_k\rangle = \frac{1}{\sqrt{M}} \sum_{j=0}^{M-1} \omega_M^{-(k+1/2)j} |\gamma_{x,j}\rangle$. (Here one uses the same notation $|\xi_k\rangle$ and $|\eta_k\rangle$ because they are consistent with the previous cases when $|\alpha_{x,0}|^2 = 0$ or 1 respectively.)

By this, it is not hard to find the eigenvalue sampling probabilities:

$$|\langle \varphi_{x,0} | \xi_k \rangle|^2 = |\langle \varphi_{x,0} | \frac{1}{M} \sum_j w_M^{-kj} \phi_{x,j} \rangle|^2 \quad (18)$$

$$= \frac{1}{M} |\langle \varphi_{x,0} | \phi_{x,0} \rangle|^2 \quad (\text{by Eq. 12}) \quad (19)$$

$$= \frac{1}{M} \left| \left\langle \varphi_{x,0} \left| \frac{\varphi_{x,0} + \varphi_{x,M}}{\|\varphi_{x,0}\rangle + |\varphi_{x,M}\rangle\|} \right. \right\rangle \right|^2 \quad (\text{by def of } |\phi_{x,0}\rangle) \quad (20)$$

$$= \frac{|\alpha_{x,0}|^2}{M} \quad (\text{by Eq. 12}) \quad (21)$$

and similarly we have

$$|\langle \varphi_{x,0} | \eta_k \rangle|^2 = \frac{|\alpha_{x,1}|^2}{M} \quad (22)$$

Now the local Hamiltonian is constructed as

$$H = (F + F^\dagger)/2. \quad (23)$$

It is easy to verify that H is a local Hamiltonian. And further, suppose the eigenvalues of F are $\{\kappa_j\}$ with the eigenvectors $\{|\psi_j\rangle\}$, then the eigenvalues of H are just $\{(\kappa_j + \kappa_j^*)/2\}$ with the same corresponding eigenvectors. Thus H has eigenvalues $\cos(2k\pi/M)$ and $\cos((2k+1)\pi/M)$ for $k=0, 1, \dots, (M-1)/2$, and the distribution $D(H, |\varphi_{x,0}\rangle)$ is $\{\cos(2k\pi/M)\}$ with probability $|\alpha_{x,0}|^2/M$, and $\cos((2k+1)\pi/M)$ with probability $|\alpha_{x,1}|^2/M$.

Now if $x \in L_{\text{Yes}}$, then $|\alpha_{x,0}|^2$ is very small, thus with high probability the sample gives a random value uniformly chosen from $\{\cos(2k\pi/M): k = 0, \dots, (M-1)/2\}$. If $x \in L_{\text{No}}$, then $|\alpha_{x,1}|^2$ is very small, thus with high probability the sample gives a random value uniformly chosen from $\{\cos((2k+1)\pi/M): k = 0, \dots, (M-1)/2\}$. Since any two values chosen from these two sets are at least $\Omega(M^{-2})$ away from each other, an approximator with precision $O(M^{-2})$ suffices to distinguish between these two cases.

Finally, to obtain a 4-local LHES, $|i\rangle$ is replaced by $|e_i\rangle = |0\dots010\dots0\rangle$ for $i = 0, \dots, N-1$, where the only 1 appears at coordinate i . Modify the operator F to be

$$F = \sum_{j=0}^{M-1} V_j \otimes |e_{j+1}\rangle\langle e_j| \quad (24)$$

Note that $|e_j\rangle\langle e_{j-1}|$ and $|e_0\rangle\langle e_{N-1}|$ are 2-local. The remaining proof passes through. This completes the proof for $\textcircled{2}$ [Theorem 2](#).

Changing It to a Promise Problem

Now that we have completed both the algorithm and the completeness, it is not hard to see that the sampling problem can be modified to a promise problem as follows. We can derive its **PromiseBQP**-completeness from the above proofs. Since this was not mentioned in the previous work (Wocjan and Zhang 2006), a bit more detail is given below. Let

$$p_0(M) = \text{uniform distribution over } \{\cos(2k\pi/M): k = 0, 1, \dots, (M-1)/2\};$$

$$p_1(M) = \text{uniform distribution over } \{\cos((2k+1)\pi/M): k = 0, 1, \dots, (M-1)/2\}.$$

Definition 9 (Local Hamiltonian eigenvalue distribution (LHED)). We are given $(H, \varepsilon, \delta, b, M)$ where

1. $H = \sum H_j$ is a Hamiltonian operating on n qubits, with j ranging over a set of size polynomial in n , and each H_j operating on a constant number of qubits.
2. $\varepsilon = \Omega(1/\text{poly}(n))$, $\delta = o(M^{-2})$ is the required estimation precision.

3. $\delta = \Omega(1/\text{poly}(n))$, $\delta < 1/10$ is the required sampling error probability.
4. $b \in \{0, 1\}^n$ is a classical n -bit string.
5. $M = \text{poly}(n)$.

Suppose the eigenvalues and the corresponding eigenvectors of H are $\{(\lambda_k | \eta_k)\}$: $k \in [2^n]$ satisfying $|\lambda_k| \leq \text{poly}(n)$ for each k . The input has the promise that the probability distribution $D(H, b)$, given by [Eq. 2](#), approximates exactly one of $p_0(M)$ and $p_1(M)$ with error δ and precision ε . The task is to determine which one, $p_0(M)$ or $p_1(M)$, $D(H, b)$ approximates.

Restricted to One-Dimension Chain

It turns out that even if one restricts the LHER problem to the Hamiltonian on a one-dimensional qudit chain for $d = O(1)$, the problem is still **PromiseBQP**-complete (Janzing et al. 2003). The Hamiltonian is constructed along the same lines as above, with some additional treatment, following the ideas of (Aharonov et al. 2007b), to make it translationally invariant on a one-dimensional qudit chain.

3.2 Lifting the Matrix to a Power

One may find the sampling nature of the previous problems not natural, and would like to consider the average eigenvalue of a local Hamiltonian. (The authors of Wocjan and Zhang (2006) gave the credit for the question about the average eigenvalue to Yaoyun Shi.) If the distribution is, as before, induced by a vector $|b\rangle$, such that the average is $\sum_k |\langle b | \xi_k \rangle|^2 \lambda_k$, then it is not an interesting problem to study for **PromiseBQP**: Note that the value is equal to $\langle b | H | b \rangle$, and further

$$\langle b | H | b \rangle = \langle b | \sum_j H_j | b \rangle = \sum_j \langle b | H_j | b \rangle \quad (25)$$

Since each $\langle b | H_j | b \rangle$ can be easily computed even deterministically, one can obtain the exact average eigenvalue of a local Hamiltonian deterministically in polynomial time.

However, if one raises the matrix to some power, then the problem becomes **PromiseBQP**-complete again. This is the subject of this section, based on the result in Janzing and Wocjan (2007).

Definition 10 The sparse matrix powered entry (SMPE) problem is defined as follows. The input is a tuple $(A, b, m, j, \varepsilon, g)$ where

1. $A \in \mathbb{R}^{N \times N}$ is a symmetric matrix with the operator norm $\|A\| \leq b$, A has no more than $s = \text{polylog}(N)$ nonzero entries in each row, and there is an efficiently computable function f specifying for each given row the nonzero entries and their positions.
2. $m = \text{polylog}(N)$ is a positive integer, $j \in [N]$, $\varepsilon = 1/\text{polylog}(N)$ and $g \in [-b^m, b^m]$.

The input has the promise that either $(A^m)_{jj} \geq g + \varepsilon b^m$ or $(A^m)_{jj} \leq g - \varepsilon b^m$. The task is to distinguish between these two cases.

The main theorem is now given.

Theorem 3 *The problem SMPE is **PromiseBQP**-complete.*

The algorithm is very similar to the one in the last section, except that now the efficient quantum algorithm is used to simulate the process e^{-iAt} for general sparse Hamiltonians A (Berry et al. 2007). Next, an account of the proof of the **PromiseBQP**-hardness is given.

From the definition of H in [Eq. 23](#), one can see that

$$H^t = \sum_k \cos^t(2k\pi/M) |\xi_k\rangle\langle\xi_k| + \sum_k \cos^t((2k+1)\pi/M) |\eta_k\rangle\langle\eta_k| \quad (26)$$

Thus the distribution $D(H^t|\varphi_{x,0})$ is $\{\cos^t(2k\pi/M)\}$ with probability $|\alpha_{x,0}|^2/M$, and $\cos^t((2k+1)\pi/M)$ with probability $|\alpha_{x,1}|^2/M\}$, whose average is

$$\begin{aligned} \langle \varphi_{x,0} | H^t | \varphi_{x,0} \rangle &= \frac{1}{M} |\alpha_{x,0}|^2 \left(1 + \sum_{k=1}^{(M-1)/2} \cos^t(2k\pi/M) \right) \\ &\quad + \frac{1}{M} |\alpha_{x,1}|^2 \left(-1 + \sum_{k=0}^{(M-3)/2} \cos^t((2k+1)\pi/M) \right) \end{aligned} \quad (27)$$

When t is large enough, say $t = M^3$, all the cosine terms combined become negligible compared to the 1 or -1 in the summation. Thus, depending on whether $|\alpha_{x,1}|^2$ is close to 1 or 0, the average eigenvalue $\langle \varphi_{x,0} | H^t | \varphi_{x,0} \rangle$ will be close to either $-1/M$ or $1/M$, respectively. Therefore, estimating the average eigenvalue can determine whether $|\alpha_{x,1}|^2$ is close to 1 or 0, solving the starting **PromiseBQP** problem.

4 Additive Approximation of the Jones Polynomials and Tutte Polynomials

A completely different vein of research on **PromiseBQP**-completeness is the study of approximation of Jones polynomials and Tutte polynomials (Freedman 2002b, c; Aharonov et al. 2006, 2007a; Aharonov and Arad 2006; Wocjan and Yard 2008). There are at least two interesting aspects of this line compared to the problems discussed in the previous section. First, the problems look less quantum, at least by the definition. Second, the algorithms do not use quantum Fourier transform as many other quantum algorithms with exponential speedup over their classical counterparts do. What the algorithms use is the homomorphism property of a representation.

Next, this line of research is introduced in [Sect. 4.1](#) to give some background about the Jones polynomial and Tutte polynomial, mainly about their connections to physics and combinatorics. [Section 4.2](#) presents the efficient quantum algorithms for approximating Jones polynomials of trace closure of the braid group at some roots of unity. Finally a brief account is given of two subsequent (unpublished) results: the **PromiseBQP**-hardness of approximating Jones polynomials (Aharonov and Arad 2006) in [Sect. 4.3](#) and the algorithms and complexity of approximating the Tutte polynomials (Aharonov et al. 2007a) in [Sect. 4.4](#).

4.1 About Jones Polynomials and Tutte Polynomials

A short discussion about the connections of the Jones polynomial and the Tutte polynomial to other fields is given. The definitions are a bit involved and thus deferred to later sections.

In knot theory, the Jones polynomial is a knot invariant discovered by Jones (1985). Specifically, it is, for each oriented knot or link, a Laurent polynomial in the variable \sqrt{t} with integer coefficients. The Jones polynomial is an important knot invariant in low dimensional topology; it is also related to statistical physics (Wu 1992) and DNA recombination (Podtelezhnikov et al. 1999).

The connection between the Jones polynomial and quantum computing is already known. Freedman et al. (2002b, c) showed that a model of quantum computing based on topological quantum field theory and Chern–Simons theory (Freedman 1998; Freedman et al. 2002a) is equivalent to the standard quantum computation model up to a polynomial relation. Note that these results actually already imply an efficient quantum algorithm for approximating the Jones polynomial at $e^{2\pi i/5}$, though the algorithm was not explicitly given. In Aharonov et al. (2006b), Aharonov, Jones and Landau gave a simple and explicit quantum algorithm to approximate the Jones polynomial at all points of the form $e^{2\pi i/k}$, even if k grows polynomially with n . At the universality side, the result in Freedman et al. (2002) implies that approximating the Jones polynomial of the plat closure of a braid at $e^{2\pi i/k}$ is **PromiseBQP**-hard for any constant k . In Aharonov and Arad (2006), Aharonov and Arad generalized this by showing that the problem is **PromiseBQP**-hard also for asymptotically growing k , bounded by a polynomial of size of the braid. These together give a new class of **PromiseBQP**-complete problems.

The usual Tutte polynomial is a two-variable polynomial defined for graphs (or more generally for matroids). It is, essentially, the ordinary generating function for the number of edge sets of a given size and connected components. Containing information about how the graph is connected, it plays an important role in algebraic graph theory. It contains as special cases several other famous polynomials, such as the chromatic polynomial, the flow polynomial and the reliability polynomial, and it is equivalent to Whitney’s rank polynomial, Tutte’s own dichromatic polynomial, and the Fortuin–Kasteleyn’s random-cluster model under simple transformations. It is the most general graph invariant defined by a deletion–contraction recurrence. See textbooks (Bollobás 1998; Biggs 1993; Godsil and Royle 2001) for more detailed treatment.

The result in Aharonov et al. (2007a) focuses on the multivariate Tutte polynomial, which generalizes the two-variable case by assigning to each edge a different variable; see survey (Sokal 2005). This generalized version has rich connections to the Potts model in statistical physics (Wu 1982).

On the complexity side, the exact evaluation of the two-variable Tutte polynomial for planar graphs is **#P**-hard. Both positive and negative results are known for the multiplicative approximation FPRAS (fully polynomial randomized approximation scheme); see Aharonov et al. (2007a) for more details.

4.2 Additive Approximation of the Jones Polynomials

4.2.1 Definitions and the Main Theorems

This section presents an efficient quantum algorithm to additively approximate the Jones polynomial of trace and plat closures of braids at roots of unity. We begin by defining the Jones polynomial. A set of circles embedded in \mathbb{R}^3 is called a *link* L . If each circle has a direction, then we say that the link is oriented. A link invariant is a function on links that is

invariant under isotopy of links. That is, the function remains unchanged when the links are distorted (without being broken). An important link invariant is the Jones polynomial $V_L(t)$, which is a Laurent polynomial in \sqrt{t} over \mathbb{Z} .

Definition 11 (Writhe) The *writhe* $w(L)$ of an oriented link L is the number of positive crossings (I_+ in Fig. 2) minus the number of negative crossings (I_- in Fig. 2) of L .

Definition 12 (Bracket Kauffman polynomial) The *bracket Kauffman polynomial* $\langle L \rangle$ of an oriented link L is

$$\langle L \rangle = \sum_{\sigma} \sigma(L) \quad (28)$$

where the summation is over all the crossing-breaking states. A crossing-breaking state σ is an n -bit string indicating how to break all crossings by changing each crossing in one of the two ways as shown in Fig. 3. Define $\sigma(L) = A^{\sigma_+ - \sigma_-} d^{|\sigma|-1}$, where σ_+ and σ_- are the numbers of choices of the first and the second case respectively, when breaking all crossings in L , $|\sigma|$ is the number of closed loops in the resulting link, and $d = -A^2 - A^{-2}$.

Definition 13 (Jones polynomial) The *Jones polynomial* of an oriented link L is

$$V_L(t) = V_L(A^{-4}) = (-A)^{3w(L)} \langle L \rangle \quad (29)$$

where $w(L)$ is the writhe of L , and $\langle L \rangle$ is the bracket Kauffman polynomial of L .

There are different ways of forming links. In particular, one can obtain a link from a *braid*. First, an intuitive geometrical definition of a braid is given here. Consider two horizontal bars each with n pegs, one on top of the other; see Fig. 4. The pegs on the upper bar are called the *upper pegs*, and we index them from left to right using $i = 1, \dots, n$; similarly for the *lower pegs*. Each strand goes from an upper peg, always downwards, to a lower peg, so that finally each peg has exactly one strand attached to it. The n -strand braid group B_n is the set of n -strand braids

Fig. 2

Positive and negative crossings.

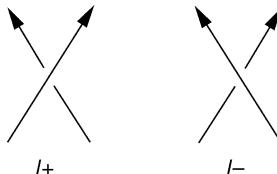

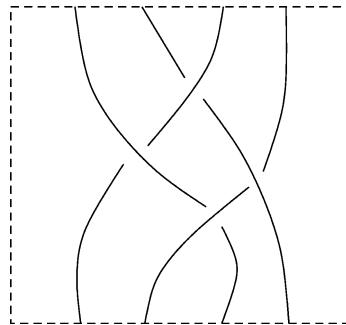

Fig. 3

Two ways to break a crossing.

Fig. 4

A braid with 4 strands.

with the multiplication defined by putting the first braid on top of the second. To be more precise, for braids b_1 and b_2 , the new braid $b_1 \cdot b_2$ is obtained by putting b_1 on top of b_2 , and removing the pegs of the lower bar of b_1 and the upper bar of b_2 with strands on the same peg connected.

The braid group B_n has an algebraic presentation by generators and relations.

Definition 14 Let B_n be the group with generators $\{1, \sigma_1, \dots, \sigma_{n-1}\}$ with relations

1. $\sigma_i \sigma_j = \sigma_j \sigma_i$ for all $|i - j| \geq 2$
2. $\sigma_i \sigma_{i+1} \sigma_i = \sigma_{i+1} \sigma_i \sigma_{i+1}$

The correspondence between the geometrical pictures and the algebraic presentation is as follows: 1 corresponds to the braid where all strands j go from upper peg j to lower peg j without crossing any other strand; σ_i corresponds to the same braid except that strand i and $i + 1$ have one crossing, with strand i in front. The above two relations are easily verified by this correspondence.

Braids are not links since the strands are not closed circles, but there are different ways of forming links from braids. Two simple ones are the *trace closure* and the *plat closure*. The trace closure B^{tr} of a braid B connects upper peg i and lower peg i without crossing any strand in B . The plat closure B^{pl} of a $2n$ -strand braid B connects its upper peg $2i - 1$ and upper peg $2i$ for all $i \in [n]$; similarly for the lower pegs. See [Fig. 5](#).

The main theorem of this section says that there are quantum algorithms additively approximating the Jones polynomials of B^{tr} and B^{pl} at $A^{-4} = e^{2\pi i/k}$ within some precision.

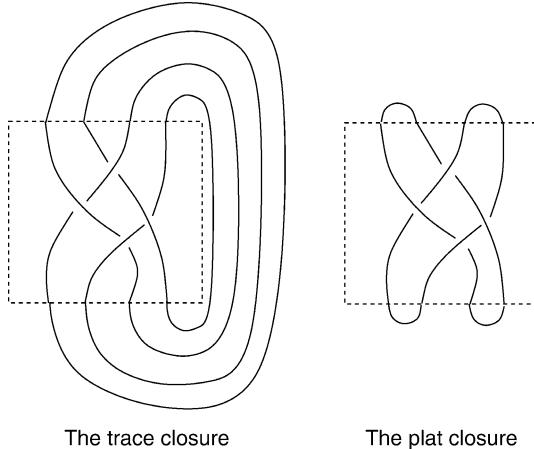

Theorem 4 There is a quantum algorithm, which on input n -strand m -crossing braid B outputs a complex number c satisfying $|c - V_{B^{\text{tr}}}(e^{2\pi i/k})| < \varepsilon(-A^2 - A^{-2})^{n-1}$ with probability $1 - 1/\exp(n, m, k)$ for some $\varepsilon = 1/\text{poly}(n, m, k)$.

Theorem 5 There is a quantum algorithm, which on input n -strand m -crossing braid B outputs a complex number c satisfying $|c - V_{B^{\text{pl}}}(e^{2\pi i/k})| < \varepsilon(-A^2 - A^{-2})^{3n/2}/N$ with probability $1 - 1/\exp(n, m, k)$ for some $\varepsilon = 1/\text{poly}(n, m, k)$. Here

$$N = \sum_{l=1}^{k-1} \sin(\pi l/k) |P_{n,k,l}| \quad (30)$$

Fig. 5

The trace and plat closures of a 4-braid.

where

$$P_{n,k,l} = \left\{ x \in \{0,1\}^n : 1 \leq 2 \sum_{i=1}^j x_i - j \leq k-1, \forall j \in [n]; 2 \sum_{i=1}^n x_i - n = l \right\} \quad (31)$$

4.2.2 The Approximation Algorithms

Main Idea and Overview

The main idea of designing the efficient quantum is to design a representation of the braid group and use the homomorphism property of the representation to decompose the computation into ones for each crossing in the braid, which can be done efficiently. This idea was also used to design classical algorithms. Let us recall an example to illustrate the idea. Consider the word problem of the free group generated by $\{a, b\}$. That is, given a sequence of elements from $\{a, b\}$, decide whether the multiplication (in that order) is the identity element of the group. There is a simple linear time algorithm using the stack (or pushdown machine, in other words), but the algorithm also uses linear space. Interestingly, Lipton and Zalcstein showed in 1977 that it can be solved in log space in a very cute manner. Basically, they used the following theorem proved by Ivan Sanov in 1947.

Theorem 6 *There are two integer matrices A, B so that the mapping $a \rightarrow A$ and $b \rightarrow B$ is a faithful representation of the free group on $\{a, b\}$.*

That means that we can replace the word problem by this question: Does a sequence of matrices over $\{A, B, A^{-1}, B^{-1}\}$ equal the identity matrix I ? Since multiplication of 2×2 matrices does not need the stack anymore, this basically gives a log space algorithm. (There is actually one more difficulty: during the computation there may be entries that are too large and cannot be stored in log-space. The solution is to do the multiplication mod p for all

p using $O(\log(n))$ bits. Then the correctness is guaranteed by the Chinese Remainder Theorem and the following well-known fact: $\prod_{p \leq t} p \geq c^t$, where the product is over primes and $c > 1$.)

The quantum algorithm to approximate the Jones polynomial also uses representation of the braid group. A high level picture is:

$$B_n \xrightarrow{\rho_A} \text{TL}_n(d) \xrightarrow{\Phi} \mathbb{C}^{r \times r} \quad (32)$$

Here, $\text{TL}_n(d)$ is the *Temperley–Lieb algebra*, which will be defined later. The mapping ρ_A is a homomorphism from B_n to $\text{TL}_n(d)$. The mapping Φ is the representation of $\text{TL}_n(d)$ by $r \times r$ unitary matrices for some r .

The analysis can be divided into three steps:

1. For the link B^{tr} , the Jones polynomial is

$$V_{B^{\text{tr}}}(A^{-4}) = (-A)^{3w(B^{\text{tr}})} d^{n-1} \text{tr}(\rho_A(B)) \quad (33)$$

The function $\text{tr}(\cdot)$ is some mapping from $\text{TL}_n(d)$ to \mathbb{C} to be defined later. By this equality, it is enough to approximate $\text{tr}(\rho_A(B))$.

2. One can calculate $\text{tr}(\rho_A(B))$ by

$$\text{tr}(\rho_A(B)) = \text{Tr}_n(\Phi \circ \rho_A(B)) \quad (34)$$

where \circ is the standard function composition, and Tr_n is defined as follows. For a matrix $W \in \mathbb{C}^{r \times r}$,

$$\text{Tr}_n(\Phi \circ \rho_A(B)) = \frac{1}{N} \sum_{l=1}^{k-1} \sin(\pi l/k) \text{Tr}(\Phi \circ \rho_A(B)|_l) \quad (35)$$

where Tr is the standard matrix trace, N is as defined in [Theorem 5](#), $W|_l$ is W restricted on some subspace. If an orthonormal basis of $\Phi \circ \rho_A(B)|_l$ is $\{|p\rangle\}$, then one can further the calculation by

$$\text{Tr}(\Phi \circ \rho_A(B)|_l) = \sum_p \langle p | \Phi \circ \rho_A(B) | p \rangle \quad (36)$$

It turns out that for each l , one can efficiently sample p almost uniformly at random (even on a classical computer). One also needs the following well-known fact in quantum computing.

Fact Given a quantum state $|\psi\rangle$ and a quantum circuit Q , one can generate a random variable $b \in \mathbb{C}$ with $|b| \leq 1$ and $E[b] = \langle \psi | Q | \psi \rangle$.

By the above analysis, one can achieve the approximation as long as one can implement $\Phi \circ \rho_A(B)$ efficiently on a quantum computer.

3. This is where the homomorphism comes into the picture. Each braid B can be decomposed into the product of a sequence of basic braids σ_i . The A and Φ are carefully designed such that $\Phi \circ \rho_A$ is a unitary representation. Thus $\Phi \circ \rho_A(B) = \Phi \circ \rho_A(\prod_i \sigma_i) = \prod_i \Phi \circ \rho_A(\sigma_i)$. Therefore, it is enough to implement $\Phi \circ \rho_A(\sigma_i)$ for each basis σ_i , and it turns out that this is not hard to do. This finishes the overview of the whole idea of designing the quantum algorithm.

More Details

Next, more details to carry out the above strategy are given. To start with, the Temperley–Lieb algebra is defined.

Definition 15 (Temperley–Lieb algebra) The *Temperley–Lieb algebra* $\text{TL}_n(d)$ is the algebra generated by $\{1, E_1, \dots, E_{n-1}\}$ with relations

1. $E_i E_j = E_j E_i$ $|i - j| \geq 2$
2. $E_i E_{i+1} E_i = E_i E_{i-1} E_i = E_i$
3. $E_i^2 = d E_i$

As the braid group B_n , the Temperley–Lieb algebra also has a nice pictorial description called Kauffman diagrams. A Kauffman n -diagram has an upper bar with n top pegs and a lower bar with n lower pegs as in a braid, but it does not have crossings or loops. A typical Kauffman 4-diagram is as shown in [Fig. 6](#).

The multiplication of two Kauffman n -diagrams $K_1 \cdot K_2$ is obtained similarly for braids: that is, putting K_1 on top of K_2 . Note that $K_1 \cdot K_2$ now may contain loops. If there are m loops, then the loops are removed and we add a factor of d^m in the resulting diagram. See [Fig. 7](#). The Kauffman diagrams over \mathbb{C} form an algebra. The correspondence between the pictures and the original definition of Temperley–Lieb algebra is shown in [Fig. 8](#).

The first mapping ρ_A is now defined in [Eq. 32](#).

Fig. 6

A typical Kauffman 4-diagram.

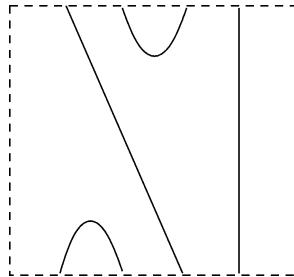

Fig. 7

Product of two Kauffman 4-diagrams.

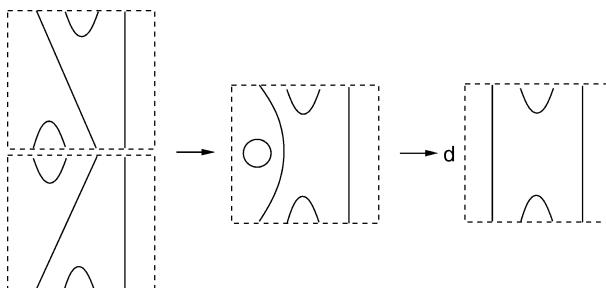

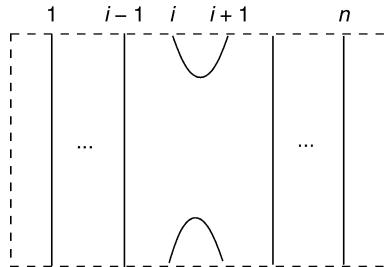

Fig. 8

Correspondence between the pictures and the Temperley–Lieb algebra.

**Fig. 9**

The graph L_{k-1} .

Definition 16 $\rho_A: B_n \mapsto \text{TL}_n(d)$ is defined by $\rho_A(\sigma_i) = AE_i + A^{-1}1$.

The following facts are easily verified.

Fact 1 The mapping ρ_A respects the two relations in the definition of the braid group.

Fact 2 If $|A|=1$ and $\Phi(E_i)$ is Hermitian for each i , then the map $\Phi \circ \rho_A$ is a unitary representation of B_n .

Now the trace function in Step 1 and 2 is defined. It is easier to define the Kauffman diagrams.

Definition 17 The *Markov trace* $tr: \text{TL}_n(d) \rightarrow \mathbb{C}$ on a Kauffman n -diagram K connects the upper n pegs to the lower n pegs of K with nonintersecting curves, as in the trace closure case. Then $tr(K) = d^{a-n}$, where a is the number of loops of the resulting diagram. Extend tr to all of $\text{TL}_n(d)$ by linearity.

For this definition, it is not hard to check that the equality in Step 1 holds.

Lemma 1 For any braid B , one has

$$V_{B^n}(A^{-4}) = (-A)^{3w(B^{\text{tr}})} d^{n-1} tr(\rho_A(B)) \quad (37)$$

Now the second mapping Φ is defined, for which the path model representation of $\text{TL}_n(d)$ will be needed. Consider a graph L_{k-1} of a line with $k-1$ points (connected by $k-2$ edges); see **Fig. 9**. Let $Q_{n,k}$ be the set of all paths of length n on L_{k-1} . That is, $Q_{n,k}$ can be identified with $\{q \in [k-1]^{n+1}: |q_i - q_{i+1}| = 1, \forall i \in [n-1]\}$. Let $r = |Q_{n,k}|$. That is, the size of $Q_{n,k}$ is the dimension of matrix $\Phi(K)$; thus one can index the row/column of the matrix by a path in $Q_{n,k}$.

To specify Φ easily, let one use the bit string representation of a path. Each path is specified by a string $p \in \{0, 1\}^n$ such that $p_i = 1$ if the i -th step goes right and $p_i = 0$ if the i -th step goes left. To guarantee that the path is always within the graph, one requires $1 \leq z_j \leq k - 1$ for any $j \in [n]$, where $z_j = 2 \sum_{i=1}^j p_i - j$ is the location of the path after first j steps. Let $H_{n,k}$ be the span of all these paths, each treated as a basis state. Denote $p_{<i} = p_1 \dots p_{i-1}$ and $p_{\geq i} = p_i \dots p_n$.

To define Φ , it is enough to define its action on each E_i , done as follows, where $\lambda_j = \sin(j\pi/k)$.

$$\Phi(E_i)|p_{<i}00p_{\geq i+2}\rangle = 0 \quad (38)$$

$$\Phi(E_i)|p_{<i}01p_{\geq i+2}\rangle = \frac{\lambda_{z_i-1}}{\lambda_{z_i}}|p_{<i}01p_{\geq i+2}\rangle + \frac{\sqrt{\lambda_{z_i+1}\lambda_{z_i-1}}}{\lambda_{z_i}}|p_{<i}10p_{\geq i+2}\rangle \quad (39)$$

$$\Phi(E_i)|p_{<i}10p_{\geq i+2}\rangle = \frac{\lambda_{z_i+1}}{\lambda_{z_i}}|p_{<i}10p_{\geq i+2}\rangle + \frac{\sqrt{\lambda_{z_i+1}\lambda_{z_i-1}}}{\lambda_{z_i}}|p_{<i}01p_{\geq i+2}\rangle \quad (40)$$

$$\Phi(E_i)|p_{<i}11p_{\geq i+2}\rangle = 0 \quad (41)$$

Theorem 7 If $d = 2 \cos(\pi/k)$, then $\Phi \circ \rho_A$ is a unitary representation of B_n in r -dimensional vector space.

Now define the subspace $H_{n,k,l}$ of $H_{n,k}$ by $H_{n,k,l} = \text{span}\{|p\rangle : z_n(p) = l\}$. Define Tr_n as in [Eq. 35](#). We are ready to show the algorithm after some final comments: The Fact in Step 2 is covered by the standard Hadamard Test on both the real and the imaginary parts; see Aharonov et al. (2006b) for details. For each basis σ_i , it is not hard to check that $\Phi \circ \rho_A(\sigma_i)$ can be implemented in polynomial time on a quantum computer. The algorithm for approximating the Jones polynomial on B^{tr} is as follows. The averaging over polynomial number of samples at the last step can be shown to give enough approximation by the standard Chernoff bound.

Algorithm 1 Approximate Jones trace closure

1. Repeat for $j = 1$ to $t = \text{poly}(n, m, k)$:
 - a. Classically, pick a random path $p \in P_{n,k}$ with probability $\Pr(p) \propto \sin(\pi l/k)$, where l is the index of the site at which p ends.
 - b. Use Hadamard Test to output a random variable x_j with $E[x_j] = \text{Re}\langle p | Q(B) | p \rangle$.
2. Use Hadamard Test to output a random variable y_j with $E[y_j] = \text{Im}\langle p | Q(B) | p \rangle$.
3. Let $r = \frac{1}{t} \sum_j (x_j + iy_j)$. Output $(-A)^{3w(\delta^{\text{tr}})} d^{n-1} r$.

The case of plat closure can be reduced to the trace closure case by the following observation. The plat closure of a braid B is isotopic to the trace closure of C , obtained by putting B on top of $n/2$ capcups, where a capcup is a cup on top of a cap. The algorithm is largely the same as the one for trace closure, except that one needs an observation that the state $|\alpha\rangle = |1, 0, 1, 0, \dots, 1, 0\rangle$ can be used to connect the Jones polynomial of the plat closure and the trace function. To be more precise, one has

$$\text{Fact 3 } \langle \alpha | \Phi \circ \rho_A | \alpha \rangle = \frac{N}{\sin(\pi/k)d^{n/2}} Tr_n(\Phi \circ \rho_A(C)).$$

By this, it is enough to estimate $\langle \alpha | \Phi \circ \rho_A | \alpha \rangle$, which can be done by Hadamard test again like in the trace closure case. The algorithm is as follows.

Algorithm 2 Approximate Jones plat closure

1. Repeat for $j = 1$ to $t = \text{poly}(n, m, k)$:
 - a. Generate the state $|\alpha\rangle = |1, 0, 1, 0, \dots, 1, 0\rangle$.
 - b. Use Hadamard Test to output a random variable x_j with $E[x_j] = \text{Re}(\langle \alpha | Q(B) | \alpha \rangle)$.
2. Use Hadamard Test to output a random variable y_j with $E[y_j] = \text{Im}(\langle \alpha | Q(B) | \alpha \rangle)$.
3. Let $r = \frac{1}{t} \sum_j (x_j + iy_j)$. Output $(-A)^{3w(B^t)} d^{3n/2-1} r \sin(\pi/k)/N$.

4.3 The PromiseBQP-Hardness of Approximating Jones Polynomials

A brief discussion of the idea in Aharonov and Arad (2006) of simulating a quantum circuit by an oracle U approximating the Jones polynomials will be presented here. First, based on a simple procedure similar to the one in [Sect. 3.1.2](#), it is enough to approximate $\langle 0 | U | 0 \rangle$ for any polynomial size quantum circuit U . So we want to efficiently construct a braid B such that B has polynomially many crossings and $\langle \alpha | \Phi \circ \rho_A(B) | \alpha \rangle \approx \langle 0 | U | 0 \rangle$. (Here the \approx sign means approximation to any desired accuracy.)

Note that in this approach, the working space has to be encoded by paths on graph L_{k-1} . Thus we need to encode the space for the original circuit U by the path space. A simple encoding uses the following four-step paths:

$$|0\rangle \rightarrow |1010\rangle, \quad |1\rangle \rightarrow |1100\rangle \tag{42}$$

Suppose U is decomposed as $U = U_m \dots U_1$, where each U_i is an elementary gate acting on at most two qubits. It can be assumed without loss of generality, that each U_i operates on adjacent qubits. Using the path encoding, U_i operates on eight qubits. Note that the path is not arbitrary in $Q_{4n, k}$ since it always returns to the original point every four steps. Denote by S the subspace spanned by all these paths; then it is sufficient if one can efficiently find $B_i \in B_{4n}$ such that $\Phi \circ \rho_A(B_i) \approx U_i$ on the subspace S to the polynomially small accuracy. It turns out that it is doable, as the following density theorem shows for B_8 .

Theorem 8 Suppose \tilde{U} is an encoded two-qubit quantum gate, then for any $\delta > 0$ and $k \geq 11$, one can find a braid $B \in B_8$ with $\text{poly}(k, 1/\delta)$ generators of B_8 such that $\|(\Phi \circ \rho_A(B))|p\rangle - (\tilde{U})|p\rangle\| \leq \delta$ for all $|p\rangle \in H_{n,k,1}$.

The proof of this theorem is the core technical part needed to show the hardness, but it is a bit far away from the **PromiseBQP**-completeness notion that is being discussed. The readers are referred to Aharonov and Arad (2006) for the details.

4.4 Additive Approximation of the Tutte Polynomials

The results for the Jones polynomials in Aharonov et al. (2006b) and Aharonov and Arad (2006) are generalized to the Tutte polynomials in Aharonov et al. (2007a). The multivariate Tutte polynomial is defined as follows.

Definition 18 (Tutte polynomial) Given an undirected graph $G = (V, E)$ with a weight function on edges $\mathbf{v} = \{\nu_e : e \in E\}$, the Tutte polynomial is

$$Z_G(q, \mathbf{v}) = \sum_{A \subseteq E} q^{k(A)} \prod_{e \in A} \nu_e \quad (43)$$

where $k(A)$ is the number of connected components in the subgraph (V, A) .

When all ν_e 's are equal to the same v , then the polynomial becomes

$$Z_G(q, v) = \sum_{A \subseteq E} q^{k(A)} v^{|A|},$$

which is essentially the same as the standard Tutte polynomial

$$T_G(x, y) = \sum_{A \subseteq E} (x - 1)^{k(A) - k(E)} (y - 1)^{|A| + k(A) - |V|} \quad (44)$$

under the change of variables

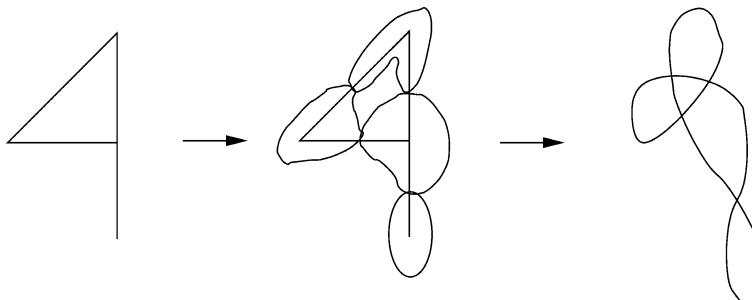

$$x = 1 + q/v, \quad y = 1 + v \quad (45)$$

$$q = (x - 1)(y - 1), \quad v = y - 1 \quad (46)$$

The main results in Aharonov et al. (2007a) are as follows. First, there is an efficient algorithm to additively approximate the multivariate Tutte polynomial of a given weighted planar graph. Second, there exists a range of complex weights and complex values of q such that the additive approximation of the multivariate Tutte polynomial at those points to within some scale is **PromiseBQP**-hard. The approximation windows in the above two results do not match that nicely in the non-unitary case, in which they modified the definition to get the **PromiseBQP**-complete problems.

The rest of this section will mainly illustrate some ideas of the algorithm. The algorithm actually takes an approach similar to that the Jones polynomial, with generalizations of various objects. First, we start at a planar graph rather than a braid. Like using closures of braids, we also change the planar graph to a knot-like object. Here the *medial graph* is used. For a planar graph G , the medial graph L_G is obtained in the following way. First encircle the facets of G with lines, and then cross the lines that surround each edge by putting a vertex in the middle of the edge. See  Fig. 10 for an illustration. Note that the resulting graph L_G is 4-regular.

 **Fig. 10**
Medial graph of a planar graph.

The regions of the medial graph can be {black,white}-colored so that no two adjacent regions have the same color. This coloring is unique up to an overall flip; let the outer region be fixed to be white.

For each crossing, there are two ways to break it, depending on whether one connects the two black or the two white regions. Let σ be an m -bit string indicating the crossing-breaking choices, where $m = |E| = |\sigma|$ is the number of the crossings. Denote by $\text{Black}(\sigma)$ the set of edges, the crossings corresponding to which are broken by σ with two black regions connected. The Kauffman bracket of the medial graph L_G can now be defined by

$$\langle L_G \rangle = \sum_{\sigma} d^{|\sigma|} \prod_{e \in \text{Black}(\sigma)} u_e \quad (47)$$

where the new variables u_e and the old ones v_e are related by $v_e = dv_e$. The following fact connects the Kauffman bracket of L_G and the Tutte polynomial of G .

Fact 4 $\langle L_G \rangle(d, \mathbf{u}) = d^{-n} Z_G(d^2, d\mathbf{u})$.

Thus it is enough to calculate the Kauffman bracket of the medial graph. To this end, one needs a generalized Temperley–Lieb algebra $\text{GTL}(d)$, where one allows an arbitrary number of strands and allows cases with different numbers of upper and lower pegs in one diagram. A diagram does not “change” by adding some trivial strands; that is, those going from an upper peg directly to a lower peg without crossing any other strand. With these relaxations, the product can be defined similarly to the Jones polynomial case (by putting one on top of the other) in a consistent manner.

Using this bridge, generalized versions of the mapping Φ and the path model representation of $\text{GTL}(d)$ can be defined. But now the representative does not need to be unitary. Again the homomorphism property of representation reduces the task to approximating each basic tangle diagram.

There is one catch, however: The final scale of the approximation window depends on the decomposition of L_G into some simple structures called *basis tangles*. The optimal decomposition is not known to be easy to obtain. This is also a drawback of the algorithm: the approximation window contains a quantity which is complicated and not directly about the graph itself (but about the layout of it on the two-dimensional plane).

5 Concluding Remarks

5.1 Some Other PromiseBQP-Completeness Related Problems

In Wocjan and Zhang (2006), it is shown that the problem of local unitary phase sampling is also **PromiseBQP**-complete, as is a problem called local unitary average eigenvalue. Even earlier, Knill and Laflamme found that the quadratically signed weight enumerators problem is also **PromiseBQP**-complete (Knill and Laflamme 2001).

In the track of the Jones polynomial and Tutte polynomial, Wocjan and Yard gave new quantum algorithms for approximating HOMFLYPT two-variable polynomials of trace closures of braids (Wocjan and Yard 2008). They also gave algorithms for approximating the Jones polynomial of a general class of closures of braids.

There are some equivalent models of efficient quantum computation, such as adiabatic quantum computation (Aharonov et al. 2004) and one-way quantum computation (Browne and Briegel 2006). One can also view the canonical problems in those models as complete problems for the standard quantum Turing machine or quantum circuit model.

One can interpret the problem of SMPE in Sect. 3.2 as approximating the total weight of cycles of length t passing a vertex j on a weighted graph. The work (Janzing and Wocjan 2007) can actually show the **PromiseBQP**-completeness even for Hamiltonians with $\{1, -1, 0\}$ entries. However, allowing the weight to be -1 makes weights on cycles cancel, giving the problem a quantum flavor. Childs recently studied the problem with the weight to be chosen only from $\{0, 1\}$ (Childs 2009).

5.2 Future Directions

There are two issues in the state of the art of **PromiseBQP**-completeness. One is that all the known **PromiseBQP**-complete problems are not “natural” enough. In some sense, they are all describing the same class using different languages, though the difficulty of translation may be at different levels. One can say that all completeness results have this feature, but the key reason why **NP**-completeness is so important is that there are so many natural and seemingly unrelated combinatorial problems in theoretical computer science, discrete mathematics, and various other branches of mathematics and science. But not many natural **PromiseBQP**-complete problems are known so far.

Another direction is to try to use the **PromiseBQP**-complete problem to study the classes **PromiseBQP** and **BQP**. For example, one of the main open questions in quantum complexity theory is whether **BQP** is in **PH**, the polynomial hierarchy. The current best known upper bound of **BQP** is **AWPP**, a not-so-natural subclass of **PP**. (See the textbooks (Arora and Barak 2009; Goldreich 2008; and Papadimitriou 1994) and the “complexity zoo” (currently at http://qwiki.stanford.edu/wiki/Complexity_Zoo) for definitions of these complexity classes.) Could the known **PromiseBQP**-complete problems shed any light on the open problem?

Abstract

The field of artificial immune systems (AIS) comprises two threads of research: the employment of mathematical and computational techniques in the modeling of immunology, and the incorporation of immune system metaphors in the development of engineering solutions. The former permits the integration of immunological data and sub-models into a coherent whole, which can be of value to immunologists in the facilitation of immunological understanding, hypothesis testing, and the direction of future research. The latter attempts to harness the perceived properties of the immune system in the solving of engineering problems. This chapter concentrates on the latter: the development and application of immune inspiration to engineering solutions.

1 Introduction

Artificial Immune Systems (AIS) is a branch of biologically inspired computation focusing on many aspects of immune systems. AIS development can be seen as having two target domains: the provision of solutions to engineering problems through the adoption of immune system inspired concepts; and the provision of models and simulations with which to study immune system theories.

The motivation for building immune-inspired solutions to engineering problems arises from the identification of properties within the immune system that are attractive from an engineering perspective. These include (de Castro and Timmis 2002a): the self-organization of huge numbers of immune cells; the distributed operation of the immune system throughout the body; pattern recognition and anomaly detection to enable the immune system to recognize pathogens; and optimization and memory to improve and remember immune responses. AIS take inspiration from these properties and associated immune processes, and have been defined as:

- ▶ “adaptive systems, inspired by theoretical immunology and observed immune function, principles and models, which are applied to problem solving.” (de Castro and Timmis 2002a)

The field of AIS also encompasses modeling and simulation techniques to understand the immune system in general (see Timmis et al. (2008a) for a review), however, this chapter focuses on immune-inspired systems for engineering problems.

This chapter is not intended as an extensive review chapter, but its purpose is to present a general introduction to the area and provide discussion on the major research issues relating to the field of AIS. Therefore, in this chapter we briefly explore the underlying immunology that has served as an inspiration for the development of immune-inspired algorithms. We have chosen not to focus on the modeling aspect of AIS, but rather on the main algorithms that have been developed over recent years. This is undertaken in [Sect. 3](#) where we discuss four main immune-inspired algorithms that dominate the literature, namely, clonal selection, immune networks, negative selection, and dendritic cell algorithms, and highlight their usage in terms of applications. [Section 4](#) follows with a discussion on AIS and how researchers have begun to evaluate current AIS and describes new frameworks and methodologies that aim to help develop AIS in a more principled manner. We also briefly discuss the application of AIS to a variety of different domains and the types of applications that AIS might be better suited to, and finally we provide a very brief outline of the modeling

approaches that can be found in the literature that are employed to help further our understanding of immunology.  [Section 5](#) provides a chapter summary.

2 The Immune System

Immunology concerns the study of the immune system and the effects of its operation on the body. The immune system is normally defined in relation to its perceived function: a defense system that has evolved to protect its host from pathogens (harmful microorganisms such as bacteria, viruses, and parasites) (Goldsby et al. 2003). It comprises a variety of specialized cells that circulate and monitor the body, various extracellular molecules, and immune organs that provide an environment within which immune cells interact, mature, and respond. The collective action of immune cells and molecules forms a complex network leading to the detection and recognition of pathogens within the body. This is followed by a specific effector response aimed at eliminating the pathogen. This recognition and response process is very complicated with many details not yet properly understood.

In mammals, the immune system can be classified into two components based on functionality: a less specific component termed *innate* immunity and a more specific component termed *adaptive* (or acquired) immunity. The mechanisms of innate immunity are generic defense mechanisms that are nonspecific to particular examples of pathogen, but act against general classes of pathogen. They are encoded within the genes of the species, and do not adapt during the lifetime of the individual. Examples include the inflammatory response, phagocytic immune cells (those that can ingest and kill pathogens), anatomic barriers such as skin, and physiologic barriers such as temperature.

By contrast, the mechanisms of adaptive immunity enable the immune system to adapt to previously unseen pathogens based upon exposure to them (Goldsby et al. 2003). This is achieved through a learning mechanism that operates during the lifetime of the individual. Additionally, once exposed to a pathogen, memory mechanisms exist to allow the immune system to remember the *shape* of the pathogen. This enables a faster and more effective secondary response that can be elicited against the pathogen if it is encountered again. The adaptive and innate arms of the immune system interact to provide the body with a comprehensive defense mechanism against pathogens.

All immune cells, and the majority of other cells of the body, possess protein molecules on their surface that act as receptors to other extracellular molecules. When a sufficiently strong chemical bond occurs between a receptor and another molecule (a ligand), a cascade of intracellular signals is initiated, the outcome of which depends on the initiating receptors. This process provides the immune system with a mechanism for recognition at the molecular level. Two types of immune cell receptors exist: innate receptors that have evolved to recognize specific molecules; and the unique receptors of lymphocytes that are generated during the life time of the individual to recognize previously unseen molecules. The latter of these molecules are generically known as *antigens*, a term given to any molecular structure that can chemically bind to the unique receptors of adaptive immune cells, known as T and B-cells. The antigen receptors of the B-cell are called *antibodies*, and those of the T-cell are called T cell receptors (TCR). They are both generated via a stochastic process, and are vital to the body's adaptive immune response. Communication between immune cells involves a number of immune molecules. They include cytokines, immune cell receptors, antibodies, enzymes, plasma proteins, and adhesion molecules. The cytokines, for example, are signaling molecules

secreted by both immune and other bodily cells, which are then detected via specific cellular receptors. Many different types of cytokine exist and their effects include the activation, differentiation, growth, movement, and death of many types of cells (Cohen 2000).

2.1 Motivation for Immune Inspired Engineering Solutions

Why is it that engineers are attracted to the immune system for inspiration? The immune system exhibits several properties that engineers recognize as being desirable in their systems. Timmis and Andrews (2007), Timmis et al. (2008a), de Castro and Timmis (2002a) have identified these as the following.

Distribution and self-organization. The behavior of the immune system is deployed through the actions of billions of agents (cells and molecules) distributed throughout the body. Their collective effects can be highly complex with no central controller. An organized response emerges as a system-wide property derived from the low-level agent behaviors. These immune agents act concurrently making immune processes naturally parallelized.

Learning, adaption, and memory. The immune system is capable of recognizing previously unseen pathogens, thus exhibiting the ability to learn. Learning implies the presence of memory, and the immune system is able to “remember” previously encountered pathogens, as demonstrated by the phenomenon of primary and secondary immune responses. The first time a pathogen is encountered, an immune response (the primary response) is elicited; the next time that pathogen is encountered, a faster and often more aggressive response is mounted (the secondary response).

Pattern recognition. Through its various receptors and molecules, the immune system is capable of recognizing a diverse range of patterns. This is accomplished through receptors that perceive antigenic materials in differing contexts (processed molecules, whole molecules, additional signals, etc.). Receptors of the innate immune system vary little, whilst receptors of the adaptive immune system, such as antibodies and T-cell receptors, are subject to huge diversity.

Classification. The immune system is very effective at distinguishing harmful substances (typically viewed as *nonself*) from the body’s own tissues (typically viewed as *self*), and directing its actions accordingly. From a computational perspective, it does this with access to only a single class of data, self-molecules (Stibor et al. 2005). The creation of a system that effectively classifies data into two classes, having been trained on examples from only one, is a challenging task.

3 Engineering Artificial Immune Systems

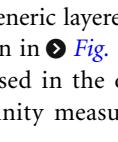

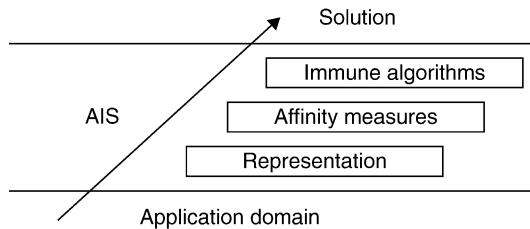

de Castro and Timmis (2002a) have proposed a flexible and generic layered approach to the development of immune-inspired engineering solutions, shown in  Fig. 1. This framework identifies the main design decisions that need to be addressed in the deployment of an immune-inspired engineering solution: representations, affinity measures, and immune algorithms.

Fig. 1

The layered framework approach to constructing AIS solutions. (Taken from de Castro and Timmis (2002a).)

Given a particular application domain, an appropriate representation of the data must be chosen. In AIS, this typically follows the notion of *shape-space* (Perelson and Oster 1979). Here, molecules m (such as receptors and antigen) exist as points in a shape space S , and can be represented as a string of attributes $m = \langle m_1, m_2, \dots, m_L \rangle$ in an L dimensional space, $m \in S^L$. The attributes m_i will represent aspects of a problem domain: patterns to be recognized, functional values to be optimized, combinations of input and proposed actions, etc. de Castro and Timmis (2002a) suggest four data types of which these attributes may belong: real valued; integer valued; hamming valued, finite length strings composed of digits with a finite alphabet; and categorically valued, where values include items such as “name,” or “color.” The affinity measures are functions or criteria through which interactions of the AIS elements are quantified. They are highly dependent on the representation chosen, for example, continuous variables typically employ the Euclidean distance measure, whereas bit string representations may use the hamming distance. Work in McEwan et al. (2008) provides a convincing critique of the shape-space paradigm and discusses the limitations of such an approach. Their paper is discussed in more detail in **Sect. 4.1**.

The highest layer of the framework details the selection of an immune-inspired algorithm to operate over the immune elements of the system. Various types of immune-inspired algorithms exist, which can operate independently of the choice of representation and affinity measure, adding dynamics to the algorithm populations based on measurements that the affinity functions provide. Despite this, immune algorithms should be chosen with care based on the problem’s data (Freitas and Timmis 2007).

In what is considered to be one of the first papers in AIS, Farmer et al. (1986) examined the immune system in the context of classifier systems, essentially highlighting the parallels of the immune network theory (Jerne 1974) and artificial intelligence. AIS has since been applied to a large range of domains that can broadly be classified as learning, anomaly detection, and optimization problems (Hart and Timmis 2008). Four main classes of AIS algorithm have been applied to these problems and each is outlined below.

3.1 Clonal Selection Theory-Inspired AIS

Clonal selection-based algorithms attempt to capture mechanisms of the antigen-driven proliferation of B-cells that results in their improved binding abilities. Using a process known as affinity maturation, the receptors of B-cell are mutated and subsequent B-cell selection results in a population of B-cells with better overall affinity for the antigen.

Clonal selection algorithms capture the properties of learning, memory, adaption, and pattern recognition (Timmis et al. 2008a).

A generic clonal selection inspired algorithm, based on CLONALG (de Castro and Von Zuben 2002, 2000), is presented in **Algorithm 1**. A set of patterns (antigens) is input to the algorithm, and output is a set of memory B-cells capable of recognizing unseen patterns. A randomly initialized set of B-cells are preferentially selected based on their affinity for the antigen. The higher affinity cells are cloned proportionally to their affinity, and mutated at a rate inversely proportional to affinity. The higher affinity clones will replace the lower affinity cells of the previous generation. Very high affinity clones compete for a place in the set of memory cells. This algorithm can be tailored toward optimization problems by removing the antigen set S , and directly representing the function or domain to be optimized as the affinity function. As clonal selection algorithms employ mutation and selection of a population of candidate solutions, they tend to be similar to other evolutionary algorithms (Newborough and Stepney 2005).

In **Algorithm 1**, a generic clonal selection algorithm is outlined, however, there are many variants in the literature that have been augmented and altered to fit specific application areas. For example, work in Watkins et al. (2004) developed a reinforcement learning approach known as AIRS (artificial immune recognition system), based on the ideas of clonal selection for the classification of unseen data items. In effect AIRS is an instance creation algorithm which acts as a preprocessor to the k -nearest neighbor approach that has been found to perform well on certain types of classification problems (Secker and Freitas 2007). In the context of dynamic learning, work by Kim and Bentley (2002a, b, c) developed a network intrusion detection system based on a dynamic variant of the clonal selection paradigm that was capable of identifying potential attacks to computer networks in an online manner and then be able to, in a limited manner, adapt to new types of attacks. As a final example, work by Kelsey and Timmis (2003), and Cutello et al. (2004a, b, 2005) have developed particularly effective optimization algorithms based on variants of clonal selection

Algorithm 1 A generic clonal selection algorithm, based on CLONALG (de Castro and Von Zuben 2000, 2002)

```

input:  $S$  = a set of antigens, representing data elements to be recognized.
output:  $M$  = set of memory B-cells capable of classifying unseen data elements.
begin
    Generate set of random specificity B-cells  $B$ .
    for all antigens  $ag \in S$  do
        Calculate affinity of all B-cells  $b \in B$  with  $ag$ .
        Select highest affinity B-cells, perform affinity proportional cloning, place clones in  $C$ .
        for all B-cell clones  $c \in C$  do
            Mutate  $c$  at rate inversely proportional to affinity.
            Determine affinity of  $c$  with  $ag$ .
        end for
        Copy all  $c \in C$  into  $B$ .
        Copy the highest affinity clones  $c \in C$  into memory set  $M$ .
        Replace lowest affinity B-cells  $b \in B$  with randomly generated alternatives.
    end for
```

by making use of novel selection and mutation mechanisms tailored specifically for certain types of optimization problems.

3.2 Immune Network Theory AIS

The immune network theory as proposed by Jerne (1974) views the immune system as a regulated network of molecules and cells that recognize each other which acts in a self-organizing manner to produce memory, even in the absence of antigen. B-cells interact via receptors to stimulate and suppress each other. This forms a regulatory network that represents an *internal image* of the antigenic patterns that the immune system observes (Farmer et al. 1986).

As with clonal selection, the immune network theory has provided inspiration for many algorithms ranging from optimization to machine learning (de Castro and Timmis 2002b; Honorio et al. 2007; Timmis and Neal 2000; de Castro and Von Zuben 2001; Bezerra et al. 2004). From a machine learning perspective, many of the systems are unsupervised and produce an instant reduction of the data space. They present clusters of this reduced data as networks of connected B-cells, where a B-cell may be considered a point m in the shape space S^L discussed above. The motivation for such algorithms is that the resulting networks highlight structures inherent in the data set and reduce the dimensionality and complexity of the data (Neal 2003). A generic immune network algorithm, based on aiNet (de Castro and Von Zuben 2001), is presented in [Algorithm 2](#). It is a modified version of CLONALG that incorporates a mechanism of suppression amongst B-cells.

In aiNet, data items are represented as antigen which B-cells (detectors) recognize. Like clonal selection algorithms ([Algorithm 1](#)), affinity maturation produces B-cells with differing specificities, and competition removes the worst of these cells from the population. A suppressive mechanism then prunes cells of similar specificities from the population. The resulting network of B-cells is then representative of clusters within the data.

Despite possessing suppressive mechanisms, early immune network algorithms suffered from an excess of B-cells, which hindered run time efficiency and rendered the resulting networks overly complex (Timmis and Neal 2000). To address this, work by Timmis and Neal (2000) incorporated the notion of an artificial recognition ball (ARB), a bounded area surrounding a point in antigenic space. All B-cells exhibiting specificities within an ARB's area are represented by that ARB, thus removing the requirement to explicitly represent each of them. To further regulate the network's population size, ARBs lie in competition with one another for a share of finite system-wide resource; ARBs that are unable to claim sufficient resource are removed from the network. Resource is allocated on the basis of ARB stimulation, derived from antigen affinity, and from low affinity to the other ARBs with which they are linked. Hence, the pressures of the algorithm are to derive clusters of linked but well spread out ARBs that represent structure in the data.

A similar, but modified, immune network algorithm was published by Neal (2003). Both cloning and hypermutation are absent in this algorithm; new ARBs are created from antigen that fall outside the range of existing ARBs in the network. The algorithm does not incorporate any stopping criteria, and can be used to create cluster-based representations of dynamically changing data. This algorithm removed the requirement for central control over the allocation of resources; ARBs are responsible for determining their own stimulation and acting accordingly. The nature of the stimulation calculation prevents ARB population explosion and

Algorithm 2 A generic immune network algorithm, based on aiNet (de Castro and Von Zuben 2001) (Taken from Timmis et al. (2008a).)

input: S = a set of antigens, representing data elements to be clustered, nt network affinity threshold, ct clonal pool threshold, h number of highest affinity clones, a number of new antibodies to introduce.

output: N = set of memory detectors capable of classifying unseen patterns.

begin

 Generate set of random specificity B-cells N .

repeat

for all antigens $ag \in S$ **do**

 Calculate affinity of all B-cells $b \in N$ with ag .

 Select highest affinity B-cells, perform affinity proportional cloning, place clones in C .

for all B-cell clones $c \in C$ **do**

 Mutate c at rate inversely proportional to affinity.

 Determine affinity of c with ag .

end for

 Select h highest affinity clones $c \in C$ and place in D .

 Remove all elements of D whose affinity with ag is less than ct .

 Remove elements of D whose affinity with other elements in D is less than ct .

 Insert remaining elements of D into N .

end for

 Determine affinity between each pair of B-cells in N .

 Systemically remove all B cells whose affinity to another B cell is less than nt .

 Introduce a new, randomly generated, B-cells into N .

until a stopping condition has been satisfied

renders the algorithm robust regarding exact parameter values. The algorithm captures well the properties of self-organization and population regulation as exhibited by the immune system. Galeano et al. (2005) provides a good review of many other immune networks that appear in the literature.

3.3 Negative Selection AIS

Inspired by the observation that the immune system protects the host body from invading pathogens, early AIS mapped these qualities to the invasion of computers and computer networks by viruses, worms, and intruders. The concept of self–nonself discrimination provided the basis for the development of various security-based AIS algorithms. Specifically, a process called negative selection was used, as inspiration, to derive a set of detectors capable of recognizing only nonself. An example of an algorithm based on Forrest et al. (1994) is shown in  *Algorithm 3*.

This algorithm was applied to protecting a computer from unauthorized changes, such as infection with a virus. There are two main stages to the algorithm: the generation of detectors; and the online monitoring of data and programs for changes. In the detector-generation stage, the collection of self strings S represents data and programs stored on the computer. The randomly generated detectors D are matched against elements in S , and those $d \in D$ that match (based on an affinity function) are removed. In Forrest et al. (1994) (this work was the

Algorithm 3 Generic negative selection algorithm (Based on Forrest et al. (1994).)

```
input:  $S$  = set of self strings characterizing benign, normal data.  
output:  $A$  = Stream of nonself strings detected.  
begin  
    Create empty set of detector strings  $D$                                 ▷ Generation of detector strings  
    Generate random strings  $C$ .  
    for all random strings  $c \in C$  do  
        for all self strings  $s \in S$  do  
            if  $c$  matches  $s$  then  
                Discard  $c$   
            else  
                Place  $c$  in  $D$   
            end if  
        end for  
    end for  
    while There exist protected strings  $p$  to check do                                ▷ Detection stage  
        Retrieve protected string  $p$   
        for all detector strings  $d \in D$  do  
            if  $p$  matches  $d$  then  
                Place  $p$  in  $A$  and output.                                         ▷ Nonself string detected  
            end if  
        end for  
    end while
```

first instance of negative selection being employed in the context of computer security) an affinity function that checked for the similarity of r consecutive characters at any point in the detector and self strings, called the r -contiguous matching rule, was used. The randomly generated detectors that are not removed from the detector collection are used to check for alterations to the system.

Negative selection algorithms have not been constrained to detection of viruses; they have also found application as intrusion detection systems. In this context the self strings S could be a concatenation of source IP, destination IP, and port addresses (Forrest and Beauchemin 2007). The detector-generation stage would be executed during a time when the network was known to be secure. Consequently, a match during the monitoring phase could indicate an anomalous connection, an intrusion. A large amount of work has been dedicated to the development of negative selection algorithms in a variety of application areas and from a theoretical perspective (Balthrop et al. 2002; Gonzalez and Dasgupta 2003; Esponda et al. 2004).

Despite a considerable amount of examples in the literature, it has been argued that negative selection suffers several drawbacks. Defining self can prove problematic; in the case of a network the total variety of safe packets can be enormous, the logistics of capturing this self set can prove difficult. In deriving the set D a huge quantity of randomly generated detectors that match self will have been deleted, thus it can become very inefficient (Freitas and Timmis 2007). Furthermore, algorithms of this variety have been seen to suffer certain scaling problems: as the universe in which self and nonself elements are defined grows (reflecting the complexity of the detection problem), the number of detectors required to effectively cover the nonself space becomes difficult to generate (Stibor et al. 2005; Timmis et al. 2008b).

3.4 Danger Theory AIS

It has been suggested that the integration of mechanisms derived from *danger theory* (Matzinger 1994) could provide for more effective intrusion detection algorithms than traditional negative selection approaches (Aickelin and Cayzer 2002). Rather than monitor for the explicit presence of the intruder, danger-theory-inspired systems could be alerted by the anomalous intruder behavior. The shift in emphasis is subtle, but significant. Such an intrusion detection system would monitor for signs of “danger,” such as abnormalities in memory usage or disk activity, unexpected or unwarranted frequencies of file changes (Aickelin and Cayzer 2002; Aickelin et al. 2003).

An interesting consequence of danger-inspired AIS lies in the interpretation of the *danger zone*. *In vivo*, this is the spatial neighborhood from where the danger signals originate. In the artificial domain, this concept need not be spatial, Secker et al. (2003) place the danger zone in the temporal domain. The concept of danger signals provides danger-theory-inspired engineering solutions with several advantages over self- and nonself-inspired approaches. Danger signals restrict the domain of nonself to a manageable size, remove the requirement to observe all self, and instill adaptability regarding scenarios where self and nonself boundaries are dynamic (Aickelin and Cayzer 2002).

The main danger-theory-inspired algorithm that has been developed is the dendritic cell algorithm (DCA) (Greensmith et al. 2005, 2006a). The DCA is a signal-processing algorithm, inspired by the behavior of dendritic cells. These reside in the body tissues and collect antigen and other (danger) signals that provide a picture of the current state of the tissues. This picture determines whether the antigen has been collected in a safe or dangerous context, and causes dendritic cells to change into a *semi-mature* or *mature* state. The task of the DCA is to classify data items (antigens) as being either benign or malignant in nature. Antigen are associated with concentrations of pathogen associated molecular pattern (PAMP) signal, danger signal, safe signal, and pro-inflammatory signals. These signals are derived from real biological signals and are mapped onto attributes associated with the data items as follows (Greensmith et al. 2006a):

- *PAMP*. A known signature of abnormal behavior. This attribute of the data item is highly indicative of an anomaly.
- *Danger signal*. A moderate degree of confidence that this attribute of the data item is associated with abnormal behavior.
- *Safe signal*. Indicative of normal system operation.
- *Pro-inflammatory signal*. A general sign of system distress.

The main challenge in implementing the DCA is defining how these signals map onto the data items derived from the problem domain (Greensmith et al. 2006a).

The DCA, shown in  [Algorithm 4](#), operates by maintaining a pool of dendritic cells (DCs). From this pool, dendritic cells are randomly selected to sample data items (and related signals) that are presented to the algorithm in a sequential manner. Based on the signals received, dendritic cells produce *semi-mature* and *mature* cytokines (immune signaling molecules). At the end of antigen processing, DCs are assigned semi-mature or mature status according to the levels of the cytokines produced. Every data item is then classified as being benign or malignant on the basis of a majority vote amongst the DCs that sampled it, each voting in accordance to its level of maturity.

Through its focus on behavioral consequences (derived from the signals described above) as opposed to physical presence (in the case of negative selection algorithms), the

Algorithm 4 The Dendritic Cell Algorithm (DCA) (Greensmith et al. 2005)

```

input:  $S$  = a set of antigens, representing data elements classified as safe or dangerous.
output:  $K$  = set of antigens classified as safe.
           $L$  = set of antigens classified as dangerous.

begin
  Create DC pool of 100 dendritic cells.
  for all antigen  $ag \in S$  do                                ▷ Perform signal processing on  $ag$ 
    for 10 randomly selected dendritic cells  $dc \in DC$  do
      Sample  $ag$ .
      Update  $dc.danger$ ,  $dc.PAMP$ , and  $dc.safe$  signals based on  $ag$ .
      Calculate and update concentration of  $dc.semimatureCytokine$  output cytokine.
      Calculate and update concentration of  $dc.matureCytokine$  output cytokine.
      Calculate and update concentration of  $dc.coStimulatory$  output molecules.
      if concentration of  $dc.coStimulatory$  > threshold then
        Remove  $dc$  from  $DC$  and place in  $M$ .
        Insert new  $dc$  into  $DC$ .
      end if
    end for
  end for

  for all dendritic cells  $dc \in M$  do                      ▷ Differentiation of dendritic cells.
    if concentration of  $dc.semimatureCytokine$  >  $dc.matureCytokine$  then
       $dc.class$  = semi/mature.
    else
       $dc.class$  = mature.
    end if
  end for

  for all antigen  $ag \in S$  do                                ▷ Classification of antigens
    for all dendritic cells  $dc \in M$  that sampled  $ag$  do
      Calculate if  $ag$  presented in mature or semimature context by  $dc$ .
    end for
    if  $ag$  presented as semimature majority of time then
      Place  $ag$  in  $K$ .                                         ▷  $ag$  is benign
    else
      Place  $ag$  in  $L$ .                                         ▷  $ag$  is malignant
    end if
  end for

```

DCA is able to operate in the presence of dynamically changing environments. However, in its current state (Greensmith et al. 2005, 2006a, b), the DCA is not able to operate in a true online fashion; data must be collected *a priori* and classification is performed as a final batch operation. Hence, anomalies cannot be detected as they occur. A second potential problem for the DCA is that misclassification can occur around the boundaries where data items switch between *safe* and *dangerous* contexts. This is due to multiple sampling of antigen by each DC. The consequence is that the DCA will exhibit significant misclassification when applied to problems where context switches in the data items are frequent (Greensmith et al. 2005). In order to overcome the limitation of operating in an off-line manner, Lay and Bate (2007) have

developed a real-time, online DCA that is capable of altering schedule overruns in real-time operating systems. The DCA has also been used for behavior classification on a robotics platform (de Castro et al. 2007a).

4 Reflections and Projections

Artificial immune systems has matured into a well recognized field that tackles a broad range of problem domains. This is best illustrated from the proceedings of the International Conference of Artificial Immune Systems ICARIS (Timmis et al. 2003; Nicosia et al. 2004; Jacob et al. 2005; Bersini and Carneiro 2006; de Castro et al. 2007b; Bentley et al. 2008). The field is now at a stage where a number of researchers are reflecting upon its contributions to the wider academic and engineering communities. A number of these reflections and proposed future directions for AIS are assessed here.

4.1 Evaluation of Current AIS

Hart and Timmis (2008) analyze a large collection of AIS engineering applications and categorize these into three classes of problem: anomaly detection, optimization, and clustering and classification. Considering key works from each class in turn, they attempt to assess and evaluate whether the application of AIS brings any benefits that could not be derived from applying alternative, existing techniques to the problem. Their criteria asserts that it is not sufficient to simply outperform other algorithms on benchmark tests; to be truly successful, the AIS must contain features that are not present in alternative paradigms.

Anomaly detection AIS are assessed by Hart and Timmis (2008) as having had limited success, but the authors make note of recent advances that danger-theory-inspired algorithms have provided, and state that significant breakthroughs are still possible. For optimization problems, it is concluded that although optimization-based AIS can and will provide comparable performance to existing methods, they will not offer any distinguishing features that cannot be found elsewhere. For classification and clustering applications, the authors conclude that the naturally distributed nature of some AIS algorithms allows for natural parallelization and distribution across several processors, offering something potentially distinctive. Regarding operation over dynamic data sets, the authors state that by definition, AIS algorithms incorporate some notion of memory, and could therefore outperform alternative learning systems which are purely reactive in nature.

Though their assessment of AIS accomplishments concludes that many are not truly successful, the authors note that this is partly due to several shortcomings that have characterized AIS design and application to date (Hart and Timmis 2008). These include: the methodology through which AIS algorithms capture their inspiring immunology; the attention paid to the effects that certain design decisions impose when engineering AIS systems; the theoretical understanding of AIS algorithms; and the nature of the problems to which AIS have been applied.

In a similar vein to Hart and Timmis (2008), Garrett (2005) studies various AIS to attempt to answer the question of whether AIS research has delivered anything *useful* to date. A useful algorithm in this context is defined by being *distinct* and *effective*. An algorithm's distinctiveness is assessed through criteria covering the algorithm's internal

representation of the problem and potential solutions, and its computational components. Effectiveness is assessed on the algorithm's performance, including the path through which solutions are obtained, the quality of results obtained through its application to benchmark problems, and the speed at which results can be obtained. In combining the two sets of criteria, an algorithm is said to be useful if it is both effective and distinctive.

The fact that work reflecting on the state of AIS is being conducted is encouraging, and is healthy for the discipline. However, it should be noted that the method and criteria employed by Garrett (2005) in arriving at its conclusions has been criticized for being more of an exercise in classification than in detailed evaluation, and for being highly subjective in nature (Timmis et al. 2008a). Additionally, the criteria focuses on performance in relation to benchmark problems. It has been suggested that a downfall of AIS research to date has been its repeated application to benchmark problems, and to areas for which many quality solutions already exist (Hart and Timmis 2008; Timmis et al. 2008a). The effectiveness criteria do not reflect the need for AIS to carve its own niche (Hart and Timmis 2008; Timmis et al. 2008a), and provide quality solutions in a problem domain that no other technique can match.

McEwan et al. (2008) question the appropriateness of the shape space representation for AIS with respect to machine-learning problems. Typical machine-learning problems entail data sets of very high dimensionality. In such a scenario, the adoption of the shape space representation can lead to the “curse of dimensionality”: as the dimension of the space increases linearly, its volume increases exponentially, and the quality of locality that affinity measures attempt to discern becomes meaningless as all points approach in equidistance to one another. It has been noted by Stibor et al. (2005) that the task of generating, maintaining, and exploiting an effective set of detectors within such a high-dimensional space is computationally intractable.

As an alternative, McEwan et al. (2008) propose marrying the machine-learning technique of *boosting* with immune inspiration. Boosting proposes a strong learning strategy that is derived as a compound decision between multiple (slightly better than random) weak learners. The authors draw analogy to the cooperative nature in which many varieties of immune cells with differing specificities and recognition targets are able to cooperatively mount an effective immune response that hones on a specific target (Cohen's *correspondence* (Cohen 2000)).

4.2 Inspiration, Frameworks, and Methodologies

In recent years, there has been a gradual shift in some AIS toward paying more attention to the underlying biological system that serves as inspiration. For example, the development of the DCA (see  Sect. 3.4) involved the input from real biological experimentation as inspiration. However, there was no reported sophisticated biological modeling to understand the underlying biology as is suggested by Stepney et al. (2005) and Timmis et al. (2006). Other examples of this shift back to the underlying biology include Wilson and Garrett (2004) and Jacob et al. (2004), who have used modeling techniques to build AIS in order to understand underlying immune properties.

The majority of AIS such as those detailed in  Sects. 3.1–3.3 have taken their inspiration from well-established immunological perspectives. In contrast, Andrews and Timmis (2005, 2007) advocate exploiting conflicting immune theories as a rich source of potential ideas for the engineer. This is an approach that has been successfully carried out by Aickelin and

Cayzer (2002), Secker et al. (2003), and Greensmith et al. (2005) in exploiting danger theory and the development of the DCA. AIS can draw significantly more inspiration from the immune system, and the immunological debate surrounding its higher functions, than the relatively simplistic subset of concepts that have served thus far.

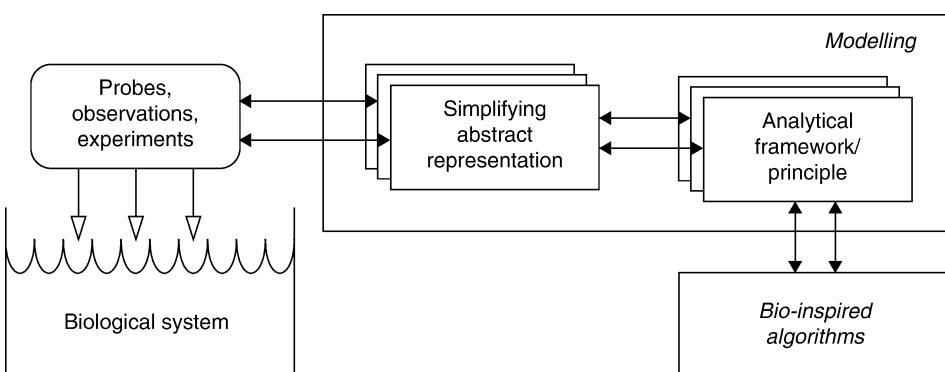

Taking this approach, the AIS engineer enjoys the freedom of adopting various immunological models and concepts that best suit the application domain. It is, however, essential to ensure that the concepts employed are correctly abstracted and reasoned about to accurately capture the emergent phenomena from which they are inspired. It has been argued that various immune-inspired algorithms have been hampered with a lack of biological accuracy (Timmis 2007). Typically, immune-inspired algorithms have fallen prey to “reasoning by metaphor,” wherein their operation and structures bear only a weak resemblance to the biological phenomenon that inspired them (Stepney et al. 2005), and, thus, consequentially fail to unlock their full potential (Hart and Timmis 2008).

To combat the problems associated with this apparent weakness in biological metaphors, a conceptual framework approach to the development of bio-inspired algorithms has been proposed (Stepney et al. 2005), shown in Fig. 2. This provides a structure and methodology for biological investigation, abstraction, modeling, and ultimately the construction of algorithms. The process should be interdisciplinary, involving at the very least biologists, mathematicians, and computer scientists. The framework aims to facilitate a better understanding of the targeted underlying biological concepts and to ultimately build more powerful bio-inspired algorithms whilst simultaneously gaining a better understanding of which application domains these algorithms are best suited to.

The first step in the conceptual framework approach is to probe the biological system through observation and experimentation. These probes are biased toward extracting information concerning the particular biological phenomena of interest. From the information gained, careful abstraction and mathematical modeling will highlight the central processes responsible for the observed biological phenomena. Analytical computational models may be constructed, which allow for the execution and animation of any underlying model, and can

Fig. 2

The conceptual framework approach to deriving biologically inspired algorithms (Stepney et al. 2005).

provide a deeper insight into its workings. The observations and mechanisms perceived at this stage will be free from any particular application bias. Finally, these insights can serve as design principles for bio-inspired algorithms, which may be applied to non-biological problems (Stepney et al. 2005; Hart and Timmis 2008).

A number of AIS works have been inspired by the conceptual framework principles. These include: a computational model of degenerate T-cell receptors (Andrews and Timmis 2006) and adaptable degenerate immune cell receptors (Andrews and Timmis 2008); and an instantiation of an artificial cytokine network (Hone and van den Berg 2007), which examined the behavior of the network to elicit any useful properties that could be applied to solving engineering problems (Read et al. 2008). Newborough and Stepney (2005) also apply many of the conceptual framework ideas to produce a generic framework for population-based bio-inspired algorithms including genetic algorithms, negative selection, clonal selection, particle swarm optimization, and ant colony optimization.

The conceptual framework of Stepney et al. (2005) also influenced Twycross and Aickelin (2005) who present a general meta-framework for models incorporating innate immunity. A table of six general properties of the innate immune system is presented and it is claimed that AIS will need to incorporate properties such as these to realize functions of the immune system. Similarly, Guzella et al. (2007) highlight a class of T cell, T regulatory cells, as inspiration for AIS. They suggest that incorporating these cells might lead to more biologically plausible models and algorithms that achieve better results in real-life problems.

While the conceptual framework offers a structured methodology for the development of immune- (and other biologically) inspired algorithms, the deployment of these AIS in a particular engineering context also requires careful consideration. Through their examination of AIS application to classification problems Freitas and Timmis (2007) note several considerations, frequently overlooked, which can significantly affect an algorithm's suitability and performance. They state that the implementor of an AIS algorithm should note the nature of the problem's data, and chose a representation that intuitively maps the data's characteristics. Altering the data to suit a particular representation, in particular, discarding data that is of a different type (e.g., disposing of categorical data to fit a continuous valued representation), is bad practice. Rather, the immune-inspired algorithm's representation should be tailored to suit the problem's data.

Freitas and Timmis (2007) also advise careful consideration of the choice of affinity measure for the chosen representation. An affinity measure can be associated with an inductive bias: some basis through which one hypothesis will be favored over another. An inductive bias is not an undesirable trait, it forms the basis of learning. Yet, care must be taken to ensure that the inductive bias incurred is appropriate for the problem at hand. For example, certain affinity measures have a positional bias, whereby the order of data within the representation can affect the outcome of the affinity measure. If the order of the data is irrelevant to the problem being tackled, then an affinity measure yielding a positional bias might be an inappropriate choice. This work is supported by empirical investigations into the effects of different affinity measures by Hart and Ross (2004) and Hart (2005).

4.3 Application Domains

It has been suggested by Hart and Timmis (2008) that there will be little benefit from applying AIS algorithms to problems of a static nature, over existing and established paradigms. The

authors conjecture that the distinctive “killer application” niche for AIS will require algorithms to exhibit the following properties (quoted verbatim):

- They will be *embodied*.
- They will exhibit *homeostasis*.
- They will benefit from interactions between *innate* and *adaptive* immune models.
- They will consist of *multiple, heterogeneous interacting, communicating components*.
- Components can be easily and naturally *distributed*.
- They will be required to perform *life-long learning*.

Recent applications of AIS in novel problem domains have started to show indications of satisfying these properties, which are reviewed here.

A central function of the immune system is its cooperation with the endocrine and neural systems in the provision of homeostasis to the host (Hart and Timmis 2008). Homeostasis is “the tendency of a system, esp. the physiological system of higher animals, to maintain internal stability, owing to the coordinated response of its parts to any situation or stimulus tending to disturb its normal condition or function” [American Psychological Association \(APA\)](#). Hence, since the domain in which *in vivo* immune systems operate is inherently dynamic; it is not unreasonable to surmise that immune-inspired algorithms might be particularly well suited to operation in dynamic environments. The immune system’s potential as inspiration for homeostasis in robotics is investigated by Owens et al. (2007). Here, homeostasis requires: the system to perceive the environment from multiple perspectives to overcome the inherent problems of sensory malfunction; a repertoire of innate responses that can affect change in the environment or the system directly; the cognition that facilitates the selection of an appropriate effector action in response to perceived input state; and the ability to adaptively correlate sensory information and effector mechanisms, such that its actions can dynamically evolve with a changing environment. Similarly, Neal et al. (2006) outline an endocrine-immune-inspired homeostatic control system. The artificial immune system allows for low-level faults (e.g., an overheating motor) to be corrected locally (e.g., by turning on a local fan), while integration with an artificial endocrine system allows for chronic faults to propagate inflammation throughout the robot’s systems. System-wide inflammation influences the higher level function of the robot in a global attempt to rectify the fault, for example, the decision by the robot to stop moving, thus allowing the motor to cool down.

The potential for AIS application in the domain of real-time systems was demonstrated by Lay and Bate (2007), who employed the dendritic cell algorithm in the detection of process deadline over runs in an embedded system. The analysis of process executions, and the insurance that all deadlines are met is typically performed statically during the development process. By incorporating adaptive AIS techniques, it is hoped that the system is rendered robust, while simultaneously reducing development time and costs.

Embodiment in bio-inspired engineering has been investigated by Stepney (2007), who examines the intimate coupled nature of a system and its environment. This includes their perceptions and consequent reactions in perturbing one another through complex high bandwidth feedback networks. The environment is open, with a quantitatively large and rich variety of information flowing through it, while the system exhibits highly nonlinear dynamics; small input perturbations need not equate to small behavioral modifications. A consequence of embodiment is the coevolution of the environment with the system. In the context of the danger theory of the immune system (Matzinger 2002), immune cells (system) have learnt to perceive danger signals just as the body (environment) has learnt to

provide them. Pathogens experience evolutionary pressure to evade detection, thus contributing to the environment's dynamics (Stepney 2007). Thus, the two are intimately bound. This concurs with the argument for the complex systems view of immunology presented by Cohen (2000). Thus, for engineers to truly capture the complexity of the biology from which they derive their inspiration, they must embody the artificial system within its artificial environment, rather than deliberately engineer the interfaces, sensors, and actuators through which the system interacts with its environment.

Though no AIS currently satisfies the conceptual features of embodiment as outlined in Stepney (2007), Bentley et al. (2005) go some way in addressing similar issues by suggesting that a layer is missing from AIS design. They outline the concept of an artificial tissue layer acting as an interface between a problem space and an AIS. The tissue layer performs some data preprocessing before presenting it to the AIS, allowing for the incorporation of domain-specific knowledge and the integration of several data sources, and is the medium through which the AIS responds. An analogy is drawn by Bentley et al. (2005) between the artificial tissue providing an innate response and the AIS providing the adaptive response. As a preliminary investigation, two tissue algorithms are presented by Bentley et al. (2005). In a similar work, Twycross and Aickelin (2006) present a framework that facilitates the complete encapsulation of an AIS, providing: artificial anatomical compartments within which the AISs immune elements may operate; and generic receptors for other immune cells, antigens, and cytokines contained within the compartment. The framework was partially motivated through the possibility to evaluate the performance of several alternative AIS algorithms on the same problem, but the manner in which it interfaces the AIS with the environment, and performs preprocessing is interesting from the perspective of embodiment.

4.4 Modeling and Simulating the Immune System

In recent years, building models and simulations of the immune system have become an important aspect of AIS, both as stand-alone pieces of work, and as steps toward producing engineering applications using methodologies such as the conceptual framework approach of Stepney et al. (2005). Forrest and Beauchemin (2007) note that there is a vast range of modeling approaches applicable to modeling the immune system, each with their own advantages and disadvantages operating at different levels of abstraction.

An overview of many mathematical techniques used for modeling the immune system is provided by Perelson and Weisbuch (1997). A large number of these approaches involve the use of differential equations, although other techniques can be applied, such as Boolean networks (Weisbuch and Atlan 1988) and the work of Kelsey et al. (2008) which present and analyze a Markov chain model of a cytokine network. Recently, process calculi have been applied to models of the immune system such as Owens et al. (2008). Process calculi are formal languages from computer science that are used to specify concurrent systems. As biological systems are inherently concurrent, these types of languages seem well suited to biological modeling.

Forrest and Beauchemin (2007) provide a review of many of the modeling approaches in immunology, with a focus on agent based modeling (ABM). In ABM, components such as cells (and sometimes molecules) are represented individually as *agents*, rather than as homogenous populations such as in differential equation techniques. Different agent types typically represent different immune cell types. These agent types are encoded with simple

rules extracted from the real biology that govern how they behave and interact. ABM techniques typically employ an explicit notion of space, such as that used in cellular automata-like models (Kleinsteiner and Seiden 2000). The advantage of ABM is that it allows the observation of agent population dynamics as they emerge from the interactions of individual agents. An example of ABM is Beauchemin et al. (2006) who investigate the dynamics of in vitro infection with a strain of influenza. ABM has also been used to study more computational aspects of applied AIS such as a series of work by Hart and Ross (2004), Hart (2005, 2006), and Hart et al. (2006). These works use a simulation of an idiotypic network to investigate how different models of shape-space and affinity affect the dynamics of the network, such as memory capacity and the structures formed, emphasizing the need for careful choice of parameters in the engineered systems.

Diagrammatic tools have also been used to model the immune system, the most widely used being the unified modeling language (UML) (Fowler 2000), which consists of a set of 13 different types of diagram that can model different aspects of structure and behavior. The advantage of the UML is its non-domain-specific nature and subsequent ability to capture abstractions. The UML (and related diagrams such as statecharts) have started to become a powerful tool in modeling aspects of biological systems. By far the most advanced use of the UML and statecharts in immunology is that of Efroni et al. (2003), who have built a sophisticated and predictive model of T cell maturation in the thymus using a tool called reactive animation, which combines the use of statecharts and other UML diagrams. In addition to the UML, there are other techniques used in software engineering, which Bersini (2006) suggests can facilitate the development and *communication* of immune modeling. These include object-oriented technologies such as object-oriented programming and design patterns (Gamma et al. 1995). The perceived benefit is the clarification of immune objects and their relationships. To support this, Bersini (2006) provides an example of how clonal selection can be modeled with a simple state diagram.

5 Summary

This chapter is intended as an overview of the area of artificial immune systems (AIS), predominantly from an engineering solutions perspective. It is not meant to be an exhaustive bibliography, but serves to illustrate that AIS is an area of great diversity, actively reflecting upon itself, and expanding into new areas and meeting new challenges. The spectrum of AIS research ranges from the modeling of immune systems in aid of immunological study, to the development of algorithms for specific engineering applications. While the predominant focus of this chapter has been on the algorithmic aspect of AIS, the other aspects of AIS research are no less significant. The principled development of immune-inspired algorithms that capture, in a more than superficial manner, the properties and characteristics of the immune system are equally valuable to the discipline's continuing success. This is highlighted to different degrees in Stepney et al. (2005) and Timmis et al. (2006) who advocate the careful consideration of the underlying biological system, the use of modeling to help understand that system, and the principled abstraction of algorithms and general frameworks from those models.

It is worth noting that there are many different aspects of the immune system that have served as inspiration for AIS. Only the main strands have been reviewed in this chapter, namely: clonal selection, immune networks, negative selection, and danger theory. However, there remain many untapped possibilities that are worthy of consideration and study within

principled frameworks, such as the conceptual framework of Stepney et al. (2005). In addition, the area of AIS should seek out challenging application areas that exploit the immune metaphor further than it has to date.

As pointed out by Timmis et al. (2008a), a recent paper by Cohen (2007) identifies three types of AIS researcher. The first type he calls the literal school, they build artificial systems that attempt to perform analogous tasks to the actual immune system (e.g., build computer security systems that discriminate between self and nonself); the second type are those of the metaphorical school who take inspiration from the immune system and build artificial systems based on analogies (so the application may be far from analogous to what the immune system does); and a third type of researcher aims to understand immunity through the development of computational and mathematical models. This goes to illustrate the diversity of research that lies within the discipline of AIS, and renders it a promising avenue for truly interdisciplinary research.

Abstract

Increasing numbers of books, websites, and articles are devoted to the concept of “swarm intelligence.” Meanwhile, a perhaps confusing variety of computational techniques are seen to be associated with this term, such as “agents,” “emergence,” “boids,” “ant colony optimization,” and so forth. In this chapter, we attempt to clarify the concept of swarm intelligence and its associations, and to provide a perspective on its inspirations, history, and current state. We focus on the most popular and successful algorithms that are associated with swarm intelligence, namely, ant colony optimization, particle swarm optimization, and (more recently) foraging algorithms, and we cover the sources of natural inspiration with these foci in mind. We then round off the chapter with a brief review of current trends.

1 Introduction

Nature provides inspiration to computer scientists in many ways. One source of such inspiration is the way in which natural organisms behave when they are in groups. Consider a swarm of ants, a swarm of bees, a colony of bacteria, or a flock of starlings. In these cases and in many more, biologists are of the opinion (and as we have often seen for ourselves) that the group of individuals itself exhibits a behavior that the individual members do not, or cannot. In other words, if the group itself is considered as an individual – the *swarm* – in some ways, at least, it seems to be more intelligent than any of the individuals within it.

This observation is the seed for a cloud of concepts and algorithms, some of which have become associated with swarm intelligence. Indeed, it turns out that swarm intelligence is only closely associated with a small portion of this cloud. If one searches nature for scenarios in which a collection of agents exhibit behavior that the individuals do not (or cannot), it is easy to find entire and vast subareas of science, especially in the biosciences. For example, any biological organism seems to exemplify this concept, when the individual organism is considered as the “swarm” and its cellular components as the agents.

One might consider brains, and nervous systems, in general, as a supreme exemplar of this concept, when individual neurons are considered as the agents. Or one might zoom in on certain inhomogeneous sets of biomolecules as our “agents,” and herald gene transcription, say, as an example of swarm behavior. Fortunately, for the sake of this chapter’s brevity and depth, it turns out that the swarm intelligence literature has come to refer to a small and rather specific set of observations and associated algorithms. This is not to say that computer scientists are uninspired by the totality of nature’s wonders that exhibit such “more than the sum of the parts” behavior – much of this volume makes it clear that this is not so at all. However, if the focus is on the specific concept of swarm intelligence and the attempt to define it intentionally, the result might be a useful behavior that emerges from the cooperative efforts of a group of individual agents in which

1. The individual agents are largely homogeneous
2. The individual agents act asynchronously in parallel
3. There is little or no centralized control
4. Communication between agents is largely effected by some form of stigmergy
5. The “useful behavior” is relatively simple (finding a good place for food, or building a nest – not writing a symphony, or surviving for many years in a dynamic environment)

So, swarm intelligence is not about how collections of cells yield brains (which falls foul of at least items 1, 4, and 5), and it is not about how individuals form civilizations (violating mainly items 4 and 5), and it is not about such things as the life cycle of the slime mould (item 5). However, it is about individuals cooperating (knowingly or not) to achieve a definite goal, such as, ants finding the shortest path between their nest and a good source of food, or bees finding the best sources of nectar within the range of their hive. These and similar natural processes have led directly to families of algorithms that have proved to be very substantial contributions to the sciences of computational optimization and machine learning.

So, originally inspired, respectively, by certain natural behaviors of swarms of ants, and flocks of birds, the backbone of swarm intelligence research is built mainly upon two families of algorithms: ant colony optimization, and particle swarm optimization. Seminal works on ant colony optimization were by Dorigo et al. (1991) and Colorni et al. (1992a, b), and particle swarm optimization harks back to Kennedy and Eberhart (1995). More recently, alternative inspirations have led to new algorithms that are becoming accepted under the swarm intelligence umbrella; among these are search strategies inspired by bee swarm behavior, bacterial foraging, and the way in which ants manage to cluster and sort items. Notably, this latter behavior is explored algorithmically in a subfield known as swarm robotics. Meanwhile, the way in which insect colonies collectively build complex and functional constructions is a very intriguing study that continues to be carried out in the swarm intelligence arena. Finally, another field that is often considered in the swarm intelligence community is the synchronized movement of swarms, in particular, the problem of defining simple rules for individual behavior that led to realistic and natural behavior in a simulated swarm. “Reynolds’ rules” provided a general solution to this problem in 1987, and this can be considered an early triumph for swarm intelligence, which has been exploited much in the film and entertainment industries.

In the remainder of this chapter we expand on each of these matters. ➤ [Section 2](#) gives an account of the natural behaviors that have inspired the main swarm intelligence algorithms. ➤ [Section 3](#) then discusses the more prominent algorithms that have been inspired by the techniques in ➤ [Sect. 2](#), and ➤ [Sect. 4](#) notes some current trends and developments and offers some concluding remarks.

2 Inspiration from Nature

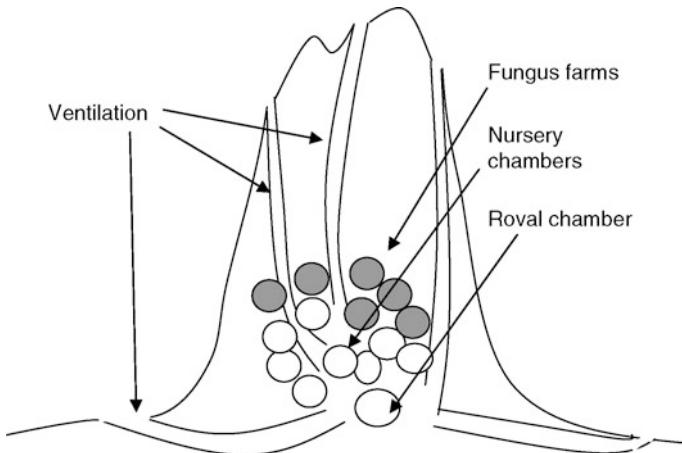

2.1 Social Insects and Stigmergy

Ants, termites, and bees, among many other insect species, are known to have a complex social structure. Swarm behavior is one of several emergent properties of colonies of such so-called *social insects*. A ubiquitous characteristic that is seen again and again in such scenarios is *stigmergy*. Stigmergy is the name for the *indirect* communication that seems to underpin cooperation among social insects (as well as between cells, or between arbitrary entities, so long as the communication is *indirect*).

The term was introduced by Pierre-Paul Grassé in the late 1950s (Grassé 1959). Quite simply, stigmergy means communication via signs or cues placed in the environment by one entity, which affect the behavior of other entities who encounter them. Stigmergy was originally defined by Grassé in his research on the construction of termite nests. ➤ [Figure 1](#) shows a simplified schematic of a termite nest. We will say more about termite nests in

Fig. 1

A highly simplified schematic of a termite nest.

➤ Sect. 2.1.3, but for now it suffices to point out that these can be huge structures, several meters high, constructed largely from mud and from the saliva of termite workers. Naturally, the complexity and functionality of the structure is quite astounding, given what we understand to be the cognitive capabilities of a single termite.

Following several field trips to Africa in the late 1930s and 1940s studying termites and their nests, among other things, Grassé showed that the regulation and the coordination of the nest-building activity did not depend on the termite workers themselves, but was instead achieved by the nest itself. That is, some kind of stimulating configuration of materials triggers a response in a termite worker, where that response transforms the configuration into another configuration that may, in turn, trigger yet another, possibly different, action performed by the same termite or by any other termite worker in the colony. This concept of stigmergy was attractive and stimulating, but at the time, and often today, it was and is often overlooked by students of social insects, because it leaves open the important operational issue of how the specific trigger-response configurations and stimuli must be organized in time and space to allow appropriate coordination. But despite the general vagueness of Grassé's formulation, stigmergy is recognized as a very profound concept, the consequences of which are still to be fully explored. Stigmergy is not only of potential importance for our understanding of the evolution and maintenance of social behavior in animals, from communally breeding species to highly social insects, but it is also turning out to be a crucial concept in other fields, such as artificial intelligence, robotics, or the social, political, and economic sciences. Meanwhile, in the arena of natural computing, stigmergy is the fundamental concept behind one of the main swarm intelligence algorithms, as well as several others.

Apart from termite nests, another exemplary case of stigmergy in nature is that of pheromone deposition. Ants deposit pheromone along their paths as they travel; an ant striking out on its own will detect pheromone trails, and prefer to follow such trails already travelled. In general, the concept of stigmergy captures underlying commonalities in (usually) insect behaviors that are underpinned by indirect communication. This covers more emergent behaviors than trail following, and (the original inspiration for the term) the construction of

structures such as termite mounds and bee hives. Stigmergy also seems key to behaviors such as brood sorting and cemetery clustering – some ant species are known to spatially cluster their young into age-groups within the nest, and they keep their nests tidy by removing dead nest mates and piling them into clusters outside.

The phenomenon of stigmergy has early evolutionary roots; it is now used to explain the morphologies of multicellular organisms, seashells, and so forth. Essentially, individual cells position themselves in a way influenced by deposits left behind by their colleagues or precursors. A useful way to think of it is that stigmergic communication involves a “stigmergy structure,” which is like a notepad, or an actual structure, built from cues left by individuals.

The structure itself may be a spatially distributed accumulation of pheromone, or a partially built hive, or a partially constructed extracellular matrix. The structure itself influences the behaviors of the individuals that “read” it, and these individuals usually also add to the structure. Army ants find their directions of travel influenced by pheromone trails, and they add to the trails themselves. Termites are triggered by particular patterns that they see locally in the partially built mound, and act in simple and specific ways, resulting in additions to the structure itself. An authoritative overview of stigmergy-associated behaviors in nature is by Bonabeau et al. (1997), while Theraulaz (1994) provides a comprehensive survey of self-organization processes in insect colonies. As hinted above, when the stigmergic processes often observed in nature are considered, the most prominent sources of inspiration from the swarm intelligence viewpoint are those of navigation to food sources, sorting/clustering, and the collective building of structures. Each of these processes are briefly considered next.

2.1.1 Natural Navigation

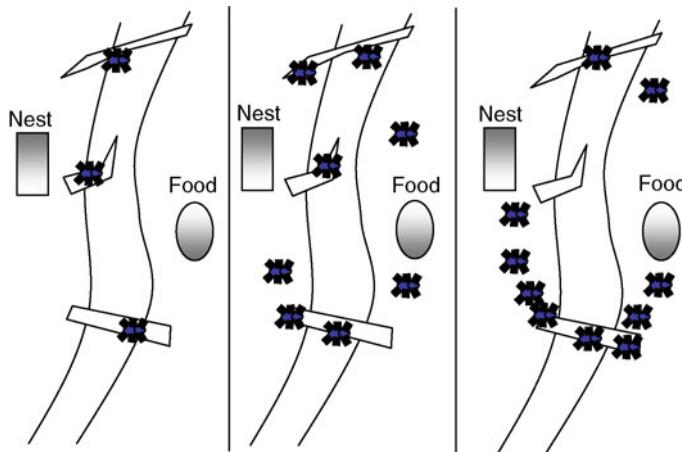

Navigation to food sources seems to depend on the deposition of pheromone by individual ants. In the natural environment, the initial behavior of a colony of ants in seeking a new food source is for individual ants to wander randomly. When an ant happens to find a suitable food source it will return to its colony; throughout, the individual ants have been laying pheromone trails. Subsequent ants setting out to seek food will sense the pheromone laid down by their precursors, and this will influence the path they take up. Over time, of course, pheromone trails evaporate. However, consider what happens in the case of a particularly close food source (or, alternatively, a faster or safer route to a food source). The first ant to find this source will return relatively quickly. Other ants that take this route will also return relatively quickly, so that the best routes will enjoy a greater frequency of pheromone laying over time, becoming strongly fancied by other ants. The overall collective behavior amounts to finding the best path to a nearby food source, and there is enough stochasticity in the process to avoid convergence to poor local optima – trail evaporation ensures that suboptimal paths discovered earlier are not converged upon too quickly, while individual ants maintain stochasticity in their choices, being influenced by but not enslaved by the strongest pheromone trail they sense.

Figure 2 shows a simple illustration, indicating how ants will converge via stigmergy toward a safer and faster way to cross a flow of water between their nest and a food source.

Figure 2 shows three contrived snapshots of a simple scenario over time. On the left, ants need to cross a narrow stream of flowing water toward a tempting food source, and three crossings – fallen twigs – present themselves. Initially, ants are equally likely to try each one. Each of these ants lays its trail of pheromone as it makes its journey toward the right. Over time, however, the path toward the middle twig becomes less laid with pheromone, simply

Fig. 2

Convergence to a safer crossing over time.

because, unlike the situation with the upper and lower twigs, there are no ants laying pheromone *on their way back* from that particular path. Eventually, on the right, we see several ants following the path defined by the lower twig, both attracted by, and further multiplying, the steady buildup of pheromone on this path, which is faster than that on the path defined by the upper twig. Although the upper twig provides a fairly short journey, it is more perilous, since it is quite narrow, and several ants fall off before being able to strengthen the path.

Actually, this is one of the simplest and most straightforward activities in social insects related to pheromones. The term “pheromone” itself was promoted for this context in 1959 (the late 1950s was clearly a fruitful period for swarm intelligence vocabulary) (Karlson and Lüscher 1959), to encompass the broad range of biologically active chemicals used by insects for varieties of communicative purposes. The context in which we describe it above is known in biology as “recruitment,” referring broadly to tasks in which individuals discover an opportunity (usually a food source) and need to recruit others to help exploit it. However, there are many other behaviors that are associated with pheromones, such as indicating alarms or warnings, interactions between queens and workers, and mating. An excellent source of further information is Vander Meer et al. (1998b), and in particular Vander Meer et al. (1998a).

2.1.2 Natural Clustering

Turning now to a different style of swarm behavior, it is well known that ant species (as well as other insect species) exhibit emergent sorting and clustering of objects. Two of the most well-known examples are the clustering of corpses of dead ants into cemeteries (achieved by the species *Lasius niger*, *Pheidole pallidula*, and *Messor sancta* (Depickere et al. 2004)), and the arrangement of larvae into similar age groups (so-called brood-sorting, achieved by *Leptothorax unifasciatus* (Franks and Sendova-Franks 1992)).

For example, in *L. unifasciatus* ant colonies, the ants' young are organized into concentric rings called annuli. Each ring comprises young of a different type. The youngest (eggs, and micro-larvae) are clustered together in the central cluster. As one moves outward from the center, progressively older groups of larvae are encountered. Also, the spaces between these rings increase as one moves outward.

In cemetery formation, certain ant species are known to cluster their dead into piles, with individual piles maintained at least a minimal distance from each other. In this way, corpses are removed from the living surroundings, and cease to be a hindrance to the colony. One aspect of this behavior in particular is that it is arguably not exemplary of swarm behavior; that is, it is perhaps not *collective* intelligence. The explanatory model that seems intuitively correct and confirmed by observation (Theraulaz et al. 2002) is one in which an individual operates according to quite simple rules while otherwise generally wandering around randomly:

1. If not carrying a corpse, and a single corpse (or quite small cluster of corpses) is encountered, pick it up.
2. If carrying a corpse and a relatively large cluster of corpses is encountered, put it down.

A single ant could achieve the clustering observed in nature that seems to operate according to these rules (Theraulaz et al. 2002). However, the emergent clusters are produced faster when a collection of ants are involved. Gaubert et al. (2007) is a useful reference for discussion of mathematical and other models of these behaviors. Meanwhile, a steady line of recent research is investigating computational clustering methods that are directly inspired by these natural phenomena (Handl and Meyer 2007). The first such inspired clustering algorithm was proposed by Lumer and Faieta (1994), closely based on the Deneubourg et al. (1991) model of the natural process. In recent work (Handl et al. 2006), an ant-based clustering method called ATTA is tested, and the case is made convincingly that ant-based clustering algorithms certainly have a niche in data mining, performing particularly well on problems where the number of clusters are not known in advance, and where the clusters themselves are highly variable in size and shape. In this article, our focus stays with optimization and we will say a little more about clustering; the reader is again referred to a review by Handl and Meyer (2007) for further study on this topic.

2.1.3 Natural Construction

We now consider the extraordinary collective behavior that leads to the construction of achievements such as wasp nests, termite mounds, and bee hives. Brood-sorting, considered above, exemplifies a simple structure that arises from collective behavior. However, the more visible and impressive structures such as termite mounds have always impressed observers, and often confounded one when one tries to imagine how such simple minds can lead to such creations. As will be clear from context, stigmergy seems to be the key to understanding these buildings; patterns inherent in partial elements of structures are thought to trigger simple rule-based behavior in the insect, which in turn changes the perceived patterns, and so on, until a complete hive or nest is built. Much computation-based study has been made of this by Bonabeau, Theraulaz, and coworkers.

In nature, the sizes of such social insect structures can reach an astounding 30 m in diameter (Grassé 1984). An impressive example of the complexity of these structures comes from the African termites *Macrotermes*, “the fungus growers.” In a mature nest of this

species, there are typically seven distinct elements of structure (this description is adapted from Bonabeau et al. 1998):

1. The protective and ribbed cone-shaped outer walls (also featuring ventilation ducts).
2. Brood chambers within the central “hive” area. They have a laminar structure and contain the nurseries where the young termites are raised.
3. The hive consists of thin horizontal lamellae supported by pillars.
4. A flat floor structure, sometimes exhibiting cooling vents in a spiral formation.
5. The royal chamber: a thick walled enclosure for the queen, with small holes in the walls to allow workers in and out. This is usually well protected underneath the hive structure, and is where the queen lays her eggs.
6. Garden areas dedicated to cultivating fungi. These are arranged around the hive, and have a comb-like structure, arranged between the central hive and the outer walls.
7. Tunnels and galleries constructed both above and below ground which provide pathways from the termite mound to the colony’s known foraging sites.

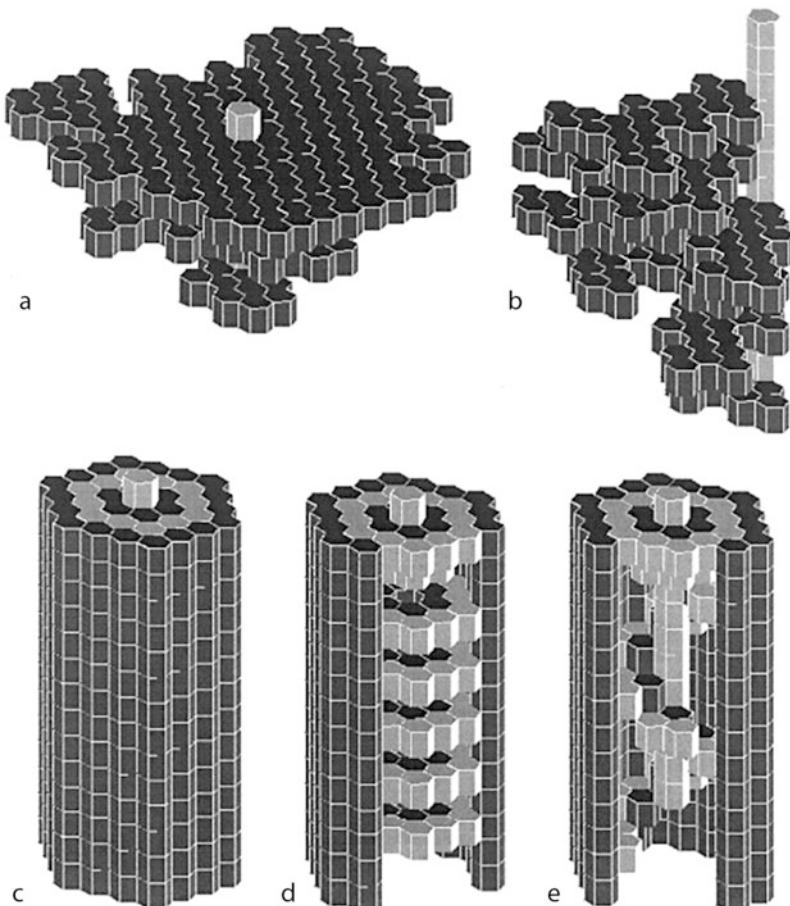

So, how does a collection of termites make such a structure? Perhaps this is the most astonishing example of natural swarm intelligence at work. The observations and descriptions of such structures from the biology literature have tended to focus on *description*, elucidating further and finer details from a variety of species, but have done little to clarify the mechanism. However, computational simulation work, such as Theraulaz and Bonabeau (1995), has indicated how such behavior can emerge from collections of “micro-rules,” where patterns of the growing structure perceived by an individual termite (or ant, wasp, etc.) act as a stigmergic trigger, perhaps in tandem with other environmental influences, leading to a specific response that adds a little new structure. Theraulaz and Bonabeau (1995) and Bonabeau et al. (2000) have shown how specific collections of such micro-rules can lead to, in simulation, a variety of emergent structures, each of which seems convincingly similar to wasp nests from specific wasp species. ↗ *Figure 3* shows examples of three artificial nests, constructed in this fashion, that closely resemble the nest structures of three specific wasp species; several more are presented in Theraulaz and Bonabeau (1995) and in Bonabeau et al. (2000).

↗ *Figure 4* shows some examples of micro-rules of the kind that can lead to the types of structures shown in ↗ *Fig. 3*. A micro-rule simply describes a three-dimensional pattern of “bricks”; in the case of the experiments that led to ↗ *Fig. 3*, a brick has a hexagonal horizontal cross section, and there are two types of bricks (it was observed that at least two different brick types seem necessary for interesting results). The three-dimensional pattern describes the immediate neighborhood of a single central brick, including the seven hexagonal cells above it (the upper patches of hexagons in ↗ *Fig. 4*), the six that surround it, and the seven below it. In the figure, a “white” hexagonal cell is empty – meaning no brick here; otherwise there are two kinds of bricks, distinguished by different shadings in the figure. A micro-rule expresses the following building instruction: “if the substructure defined by this pattern is found, with the central cell empty, then add the indicated type of brick in the central position.”

Intuition suggests how the construction by a collection of agents such as wasps of artifacts such as those in ↗ *Fig. 3*, or even more complex artifacts, may be facilitated by specific collections of micro-rules; however, that does not make it easy to design a set of micro-rules for a specific target construction. Sets of micro-rules achieving the illustrated results were obtained by using a carefully designed evolutionary algorithm. Interested readers should

Fig. 3

Figure 2 from Bonabeau et al. (2000), reproduced with permission. These show results from artificial colonies of ten wasps, operating under the influence of stimulus-response micro-rules based on patterns in a 3D hexagonal brick lattice. (a) A nest-like architecture resembling the nests of *Vespa* wasps, obtained after 20,000 building steps; (b) an architecture resembling the nests of *Parachartergus* wasps, obtained after 20,000 building steps; (c) resembling *Chatergus* nests, obtained after 100,000 building steps; (d, e) showing internal structure of (c).

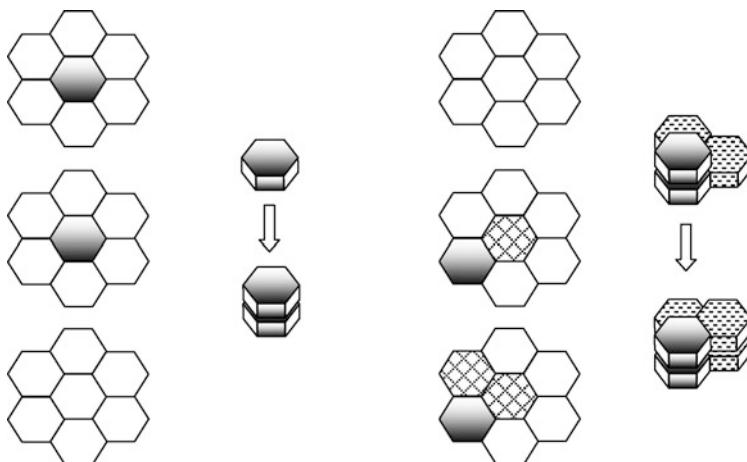

consult Bonabeau et al. (2000) for further details, including analyses of the operation of the emerging rule sets, revealing the requirement for various types of coordination implicitly built into the micro-rule collection.

Meanwhile, it is a long way from wasp nests to termite mounds, especially mounds of the complexity hinted at above. However, by considering and extending partial models for elements of termite mounds, in Bonabeau et al. (1998) some basis is provided for the suspicion that such complexity may be explained by the interaction of stimulus-response-based (“micro-rule”) processes and pheromone-based triggers that modify the stimulus-response behavior, unfolding over time as a controlled morphogenetic process.

Fig. 4

An illustration of two “micro-rules” from the space of such rules that can lead to structures such as those in Fig. 3. A single micro-rule defines a building instruction based on matching a pattern of existing bricks. A single column of three groups of seven hexagonal cells is a micro-rule, by describing a structure around the neighborhood of the central cell (which is empty in the matching pattern). The building instruction is to fill the central cell with the indicated type of “brick.” In this figure, two examples of micro-rules are shown, each further illustrated by “before” and “after” building patterns on the right.

Finally, we note that much of what was discussed in this subsection forms part of the basis for the new field of “swarm robotics.” This area of research (Sahin 2005; Mondada et al. 2005) focuses on what may be achievable by collections of small, simple robots furnished with relatively non-sophisticated ways to communicate. Chief among the motivating elements of such research are the qualities of robustness, flexibility, and scalability that swarm robots could bring to a number of tasks, ranging through agriculture, construction, exploration, and other fields. Imagine that one wishes to build a factory on Mars, for example. One might imagine this could be performed, in some possible future, by a relatively small collection of very sophisticated and intelligent robots. However, in the harsh conditions of Mars, one can expect that loss or destruction of one or more of these is quite likely. Swarms of simple robots, instead, are far more robust to loss and damage, and may present an altogether more manageable, shorter-term, and more adaptable approach than the “super-robot” style.

As yet, swarm robotics has not risen to such heights, although there is published discussion along these lines, drawing from the sources of natural inspiration already discussed (Cicirello and Smith 2001). Meanwhile, interesting and useful behaviors have been demonstrated in swarm robotics projects, after, in almost all cases, considerable work in design, engineering, and construction of the individual “bots.” Supporting these studies, a large part of swarm robotics research is into how to design the individual robots’ behaviors in such a way that the swarm (or team) achieves an overall goal or behavior. Unsurprisingly to many, it turns out that the judicious use of evolutionary computation proves effective for this difficult design problem (Waibel et al. 2009). However, hand-design or alternative principled methods for designing behaviors remains a backbone of this research, especially when the desired overall

behavior is complex, involving many tasks (e.g., Ducatelle et al. 2009), and in general there are several emerging issues in swarm robotics that have sparked active current lines of research, such as the problem of “interference” – swarm robots, whether cooperating on the same task or not, often physically interfere with each others’ operation (Pini et al. 2009) – and the problem of achieving tasks with minimal energy requirements (Roberts et al. 2008).

Relatively impressive behaviors from swarm robotics research has so far included cooperative transport of one or more objects, and cooperation toward moving up a vertical step (as large as the bots involved); readers may visit the European project “Swarmbots” and “Swarmanoids” websites for explanation and many other resources, at <http://www.swarmbots.org/>, and at <http://www.swarmanoid.org/> as well as similar resources such as <http://www.pherobot.com/>. Hardware and related technology issues remain a bottleneck that still inhibit a full exploration of social insect swarm intelligence in robotics; however, this work continues toward that end and will be observed with great interest.

2.2 Foraging

There are broadly two types of natural processes that go by the term “foraging,” and in turn provide sources of inspiration for optimization (or resource allocation) methods. In both cases, the overall emergent behavior is that the swarm finds and exploits good food sources, adaptively moves to good new sources as current ones become depleted, and does all of this with efficient expenditure of energy (as opposed to, e.g., brute force search of their environment). The means by which this behavior is achieved is rather different in these two sources of inspiration.

In one case, that of “bacterial foraging” (Passino 2002), individual bacteria are (essentially) directed toward rich areas via *chemotaxis*; that is, they exist in an environment in which their food source diffuses, so they can detect and respond to its presence. In particular, chemotaxis refers to movement along a chemical gradient. An individual *Escherichia coli* bacterium has helical appendages called *flagellae* which spin either clockwise or anticlockwise (one can think of them as analogous to propellers). When they spin in one direction, the bacterium will “tumble”; this is an operation which ends up moving the bacterium a short distance, and leaving it with an essentially random new orientation. When the flagellae spin in the other direction, the bacterium’s movement will be a “run” – this is a straight-line movement in the direction the bacterium was facing at the beginning, and continues as long as the flagellae continue to spin in the same direction.

In a nutrient-free and toxin-free environment, an individual bacterium will alternate between clockwise and anticlockwise movement of its flagellae. So, it tumbles, runs, tumbles, runs, and so forth. The effect of this behavior is a random search for nutrients. However, when the bacterium encounters an increasing nutrient gradient, that is, a higher concentration of nutrient in its direction of movement, its internal chemistry operates in a way that causes the runs to be of longer duration. It still alternates between tumbles and runs, but maintains longer run lengths so long as the gradient continues to increase. The effect of this is to explore and exploit the food source, moving upward along the nutrient gradient, while maintaining an element of stochastic exploration.

In addition, under certain conditions we know that bacteria secrete chemicals that attract each other. There is speculation that this can happen in response to nutrient-rich environments, so that additional bacteria are recruited to exploit the food source, where

the attractive secretions build further on the attraction provided by the chemical gradient. Also, there is evidence that bacteria release such an attractant under stressful conditions too, which in turn may be a protective response; as they swarm into a sizeable cluster many individuals are protected from the stressful agent. These self-attractant and chemotactic behaviors are known to lead to pattern formations under certain conditions (Budrene and Berg 1991). These and many other details have been elucidated for *E. coli* and similar bacteria via careful experimentation, for example: Berg and Brown (1972), Segall et al. (1986), and DeRosier (1998).

The other broad style of efficient collective foraging behavior is that exhibited by the honeybee (among other insects). When a bee discovers a food source some distance from the hive, it returns to the hive and *communicates the direction, distance, and quality* of the food source to other bees. The details of this communication, achieved by specialized “dances,” are quite remarkable, and have emerged from a series of ingenious experiments and observations, largely by Karl von Frisch (1967). The essential details are these: in context, the dance is performed in alignment with a particular aspect of the hive structure, which provides an absolute reference against which the bee audience can perceive specific angles. The main dance is the “waggle” dance, which consists of a straight-line movement, during which the bee waggles from side to side along the way. This straight-line movement is done upward at a particular angle from the vertical. At the end of the straight-line part, the bee loops round to the starting point and repeats the dance (actually, it alternates the direction of this loop, drawing a figure “8”). The angle of this dance from vertical indicates to the bee audience the direction they need to take with respect to the current position of the sun. Among various extraordinary aspects of this, it is known that the bee automatically corrects for movement of the sun during the day, and communicates the correct direction. Also, at times, the bee will pause its dance and allow watching bees to sample the nectar it is carrying, giving an indication of the quality of the food source.

More interesting from the algorithmic viewpoint, however, is that the abundance of the food source is communicated by the duration of the dance (essentially, the number of times the figure “8” is repeated). An individual enjoying this performance may or may not decide to follow these directions and be “recruited” to this particular source. Such an individual may also be exposed to rival performances. However, the longer the duration, the more bees will see this dance, and the more will be recruited to this dance rather than others. In this way, the bee colony sports the emergent behavior of smart resource allocation, with more bees assigned to better sources, and adaptation over time as returning bees gradually provide shorter and shorter dances as the source becomes depleted.

As we will see later, both bee and bacterial foraging have been taken as the inspiration for general optimization methods, as well as for approaches to the specific problem domain of optimal resource allocation.

2.3 Flocking

Perhaps the most visible phenomenon that brings to mind swarm intelligence is the travelling behavior of groups (flocks, swarms, herds, etc.) of individuals that all are familiar with. The mesmerizing behavior of large flocks of starlings is a common morning sight over river estuaries. Swarms of billions of monarch butterflies, herds of wildebeest, schools of tuna fish, swarms of bees, all share common emergent behaviors, chiefly being:

1. The individuals stay close to each other, but not too close, and there seem to be no collisions.
2. Swarms change direction smoothly, as if the swarm was a single organism.
3. *Unlike* a single organism, yet still smoothly and cleanly, swarms sometimes pass directly through narrow obstacles (in the way that a stream of water passes around a vertical stick placed centrally in the stream's path).

In some ways, such swarm behavior is arguably less mysterious than other emergent behaviors; it seems clear that we might be able to explain this behavior via a built-in predisposition for individuals to stay with their colleagues, and we can readily imagine how evolution will have favored such behavior: there is safety in numbers. However, the devil is in the detail, and it took seminal work by Reynolds (1987) to outline and demonstrate convincing mechanisms that can explain these behaviors. Reynolds' work was within the computer graphics community, and has had a volcanic impact there. Now known as "Reynolds' rules," the recipe that achieves realistic swarm behavior (with some, but not obtrusively much, parameter investigation needed depending on the species simulated) is this triplet of steering behaviors to be followed by each individual in a swarm:

Separation: steer to avoid coming too close to others.

Alignment: steer toward the mean heading of others.

Cohesion: steer toward the mean *position* of others.

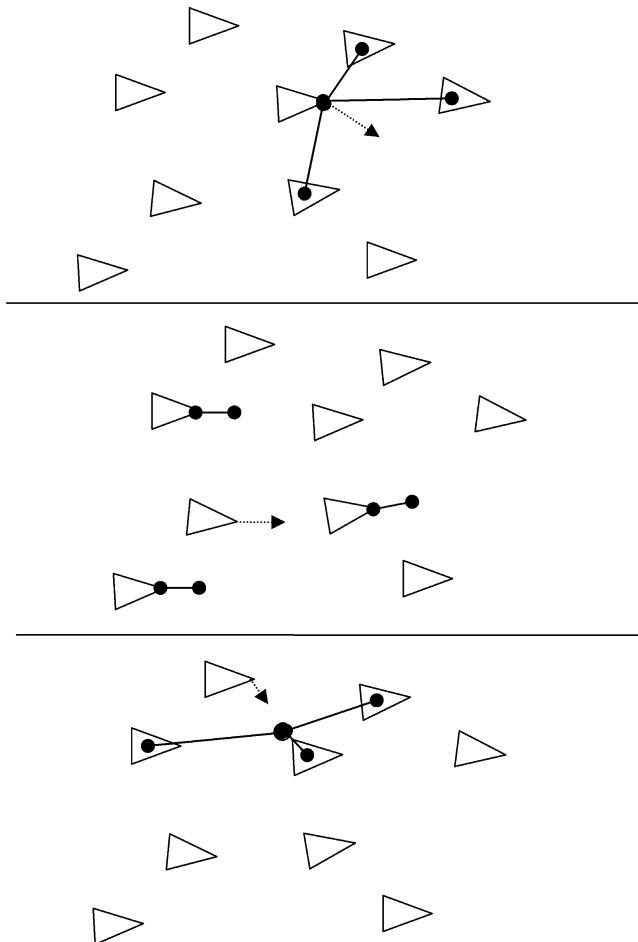

A basic illustration of each rule is given in Fig. 5. In the figure, the common terminology of "boid" is taken to refer to an individual in a flock. The figure shows examples of the adjustments that might be made under the guidance of the rules. To understand how realistic swarm simulation works, it is important to note that each boid has its own perceptual field – that is, it could only "see" a certain distance, and had a specific field of view (e.g., boids cannot see behind them). The adjustments it makes to its velocity at any time are therefore a function of the positions and velocities of the boids in its perceptual field, rather than a function of the flock as a whole.

The rules are key ingredients to a realistic appearance in simulated flocks, but there are several other details, particularly regarding obstacle avoidance and goal-seeking behavior. Interested readers may consult Reynolds (1987) and the many works that cite it. It is important to note that these rules are not strictly nature inspired, in the sense that Reynolds was not attempting to explain natural swarming behavior, he was simply attempting to emulate it. However, the resulting behavior was found to agree well with observations of natural flocking behavior (e.g., Partidge (1982) and Potts (1984)), and Reynolds (1987) reported that "many people who view these animated flocks immediately recognize them as a representation of a natural flock, and find them similarly delightful to watch." These techniques are now common in the film industry; among the earliest uses were in the film Batman Returns (1992, director Tim Burton), in which Reynolds' rules lay behind the simulated bat swarms and flocks of penguins.

Meanwhile, natural flocking behavior also turns out to be one of the sources of inspiration for the highly popular and successful particle swarm optimization algorithm, which appears in the next section as one of the prominent flagships for swarm intelligence. It is not obvious why flocking behavior might lead to an optimization algorithm; however, it soon becomes clear when the dynamics of flocking and the tendency of optimization landscapes to be locally smooth are considered. In the case of bacterial foraging, the dynamics of the natural behavior are such that individuals will tend to congregate around good areas. With the bacterial

Fig. 5

Illustrating Reynolds' rules, which lead to natural-looking behavior in simulated swarms. *Upper:* Separation: each boid makes an adjustment to velocity which prevents it from coming too close to the flockmates in its perceptual field. *Middle:* Alignment: a boid adjusts its heading toward the average of those in its perceptual field. *Lower:* a boid makes an adjustment to velocity that moves it toward the mean position of the flockmates in its perceptual field.

example, nature provides mechanisms for suggesting appropriate directions of movement, while there is a clear goal for the bacterial colony to achieve – find nutrient-rich (and toxin free) areas. For the current context in particular, the secretion of attractant chemicals is a mechanism that promotes bacteria swarming together, while an individual's position in its environment directly provides it with a level of “fitness” that it can sense in terms of nutrient concentration.

When the flocking behavior in birds is considered, however, Reynolds' work provides clues about appropriate ways to move together as a swarm, but there is no clear mirror of a “fitness” in the environment. Often, birds will migrate from A to B, knowing where they are going,

rather than seeking new environments. However, if flocks *did* have a goal to move toward “fitter” positions in the landscape they travel, then it becomes intuitively reasonable to consider the cohesive swarm behavior as a sensible way to achieve local exploration around fit areas, perhaps enabling the sensing of even fitter areas that may then sway the overall movement of the flock. In this way, flocking behavior combines with a little algorithm engineering to achieve a very successful optimization mechanism.

3 Two Main Concepts for Swarm Intelligence Algorithms

When we consider the impact of swarm intelligence so far on computer science, two families of algorithms clearly stand out in terms of the amount of work published, degree of current activity, and the overall impact on industry. One such family is inspired directly by the pheromone-trail following behavior of ant species, and this field is known as ant colony optimization (ACO). The other such family is inspired by flocking and swarming behavior, and the main exemplar algorithm family is known as particle swarm optimization (PSO). Also in this family are algorithms based on bacterial foraging, and some of the algorithms that are based on bee foraging; these share with PSO the broad way in which the natural phenomenon is mapped onto the concept of search within a landscape. In this section, these two main families will be discussed in turn.

3.1 Ant Colony Optimization

Ant colony optimization (ACO) was introduced in 1996 via an algorithm called “Ant System” (AS) (Dorigo et al. 1996). The basic approach used in AS remains highly characteristic of most ACO methods in current use, as we will describe next.

Recall that, in the natural case, an ant finds a path from its nest to a food source by following the influences of pheromone trials laid down by ants that have previously sought food (and usually returned). AS, and ACO algorithms in general, mirror aspects of this behavior quite faithfully. In short, an artificial ant builds a solution to the optimization problem at hand, and lays down simple “artificial pheromone” along the route it took toward that solution. Following artificial ants then build solutions of their own, but are influenced by the pheromone trails left behind by their precursors. This is the essential idea, and starts to indicate the mapping from the natural to the artificial case. However, there are various further issues necessary to consider making this an effective optimization algorithm. This is discussed further in the next section, with a focus on the mapping from the basic ideas of ACO to applications in optimization.

3.1.1 Applying ACO to Optimization Problems

In order to apply AS to an optimization problem, the problem needs to be represented in such a way that any candidate solution to it is a specific path along a network. This network can be conceived as having a single start node, from which (usually) every ant starts, and a single finish node, reaching which indicates that the path taken encodes a complete solution. A clear example might be the network of roads in a city, where each junction of roads is a node in the

network, and each road is an arc or edge between nodes. Consider the problem of finding the shortest path between a specific junction A and another specific junction B. In this case, A and B are clearly the start and finish nodes, and one can imagine an ACO approach which maps very closely indeed to the natural case. However, with a little thought, it is clear that each individual ant's path construction should be constrained so that it does not return to a junction it has already visited (unless this is a valid move for the problem under consideration). Also, though one might choose to simulate the preferential recruitment of new ants to shorter paths by closely following the natural case, it seems more sensible and straightforward to make the pheromone trail strength directly a function of the solution quality. That is, when an ant has completed its path, one evaluates the quality of its solution, and renders things such that better solutions lead to stronger pheromone deposits along its arcs. These pheromone deposits will decay over time; however, just as in the natural case, we can see that this will prevent premature convergence to poor solutions that happen to be popular in the early stages.

Finally, since such information is often available, and would seem useful in cases where ants have large numbers of choices, one might bias the paths available at each junction with the aid of a simple heuristic evaluation of the potential of that arc. For a shortest path problem, for example, this could be based on how much closer to B each arc would leave the ant.

With such considerations in mind, one can envisage artificial ants travelling the road network from A to B via distinct but sensible routes. At each junction, the ant senses the pheromone levels that await it at each of the arcs it can feasibly take. These levels are made from many components; arcs that are highly attractive will probably enjoy the remnants of trails from prior ants that have reported good solutions, and/or may have a good heuristic component. Arcs with low pheromone levels will probably be losers in the heuristic stakes, and have seen little activity that has led to good solutions; however, the ant may still choose such an arc, since our algorithm is stochastic.

Finally, as an individual artificial ant arrives at B, it retrospectively lays pheromone on the path it took, where the strength of that pheromone trail will reflect the quality of its solution. The next artificial ant starts from A and sees a slightly updated pheromone trail (stigmergic) pattern, and so it continues.

To apply this method to other problems, one simply needs (implicitly, at least) a network-based representation of the problem as described. If one is solving the travelling salesperson problem (TSP), for example, the network is the complete graph of the cities, each arc between cities indicates the distance or cost of that arc, and in this case an individual ant can start anywhere. As one follows an individual ant's route, one sensibly constrains its potential next-hops to avoid cycles, and along the way one may bias its choices simply by using the distance of the next arc, and it retrospectively lays pheromone once it has completed a tour of all cities. In general, an optimization problem can always be approached in this way, by suitable choices of semantics for nodes and arcs, and well-designed routines for generating and constraining an ant's available choices at each junction.

This explication can now be finished by clarifying the AS algorithm, which in fact has already been covered verbosely in the above. Once the transformation of the problem has been designed, so that an ant's path through a network provides a candidate solution, the algorithm cycles through the following two steps until a suitable termination condition is reached:

Solution Construction: A number of ants individually construct solutions based on the current pheromone trail strengths (initially, pheromone is randomly distributed). Each ant steps through the network choosing among feasible paths. At each choice point, the ant chooses among available arcs according to a function of the pheromone strength on each

arc, and of the heuristic values of each arc. In the original, and still commonly used version of this function (see Dorigo et al. (1996) and many more), the pheromone and heuristic components for each arc are exponentiated to parameters α and β respectively, allowing for tuning of the level to which the algorithm relies on exploration and heuristic support. Also, the overall attractiveness value of each arc is scaled so that the ant can treat these values as a probability distribution over its available choices.

Pheromone Update: When the ants' paths are complete, for each ant, the corresponding solution is evaluated, and pheromone is laid on each arc travelled in proportion to the overall solution quality. Also, the component of pheromone strength that arises from earlier ants is reduced. Quite simply, for any particular arc, its updated pheromone strength p_{new} is $(1 - \rho)p_{\text{old}} + \rho f$, where ρ controls the speed of pheromone decay, and f accumulates the overall quality of solutions found which involved that arc in the current iteration.

ACO has now been applied to very many problems and (clearly, or we would probably not have devoted so much time to it) has been very successful, especially when hybridized with local search or some other metaheuristic (in such hybridized algorithms, an ant will typically use the additional heuristic for a short time to find an improvement locally to its solution). Initially demonstrated for the TSP (Dorigo et al. 1996), there are an enormous number of applications of ACO now published. We mention vehicle routing (Gambardella et al. 1999), rule discovery (Parpinelli et al. 2002), and protein/ligand docking (Korb et al. 2007) just to give some initial idea of the range of applications. To discover more, recent surveys include Blum (2005a) and Gutjahr (2007), the latter concentrating on theoretical analyses. Meanwhile, Socha and Dorigo (2008) show how to apply ACO to continuous domains (essentially, ants select parameters via a probability density function, rather than a discrete distribution over a fixed set of arcs).

3.1.2 Ant-Based Routing in Telecommunications

The basic ACO idea of exploiting pheromone-trail-based recruitment is also the inspiration for a healthy subarea of research in communications networks; therein, ant-inspired algorithms are designed to assist with network routing and other network tasks, leading to systems that combine high performance with a high level of robustness, able to adapt with current network traffic and robust to network damage. Early and prominent studies in this line were by Schoonderwoerd et al. (1996, 1997), which were soon built upon by di Caro and Dorigo's AntNet (1998). To explain this application area, and the way that ACO ideas are applied therein, it will be helpful to first explore the problem and the associated solution that was studied in Schoonderwoerd et al.'s seminal work.

Schoonderwoerd et al. were concerned with load balancing in telecommunication networks. The task of a telecommunication network is to connect calls that can arise at any node, and which may need to be routed to any other node. The networks themselves, as a function of the capacities of the constituent equipment at each node, cannot guarantee successful call connections in all cases, but they aim to maintain overall acceptable performance under standard conditions. At very busy times, and/or if a particular node is overwhelmingly flooded with calls, then typically many calls will be "dropped." It is worth noting that there are problems with central control of such systems (landline telecommunication networks, mobile networks, traffic networks, and so forth). To achieve centralized control in a way that manages load-balancing or any other such target, several disadvantages are apparent. The controller

usually needs current knowledge about many aspects of the entire system, which in turn necessitates using communication links from every part of the system to the controller itself. Centrally managed control mechanisms therefore scale badly as a result of the rapidly increasing overheads of this communication, interfering with the performance of the system itself. Also, failure in the controller will often lead to complete failure of the complete system.

Schoonderwoerd et al.'s ant-inspired approach, which remains a central part of the majority of more recent ant-based approaches, was to replace the routing tables in such networks with so-called "pheromone tables." Networks of the type of interest invariably have a routing table at each node, specifying which "next-hop" neighboring node to pass an incoming call to, given the ultimate destination of that call. In Schoonderwoerd et al.'s "Ant-Based Control" (ABC) method, the routing table at a network node instead provided n probability distributions over its neighboring nodes, one for each of the n possible destinations in the network. When a routing decision is to be made, it is made stochastically according to these probabilities – that is, it is most likely that the next-hop with the highest probability will be taken, but there is a chance that the next-hop with the lowest probability will be taken instead. The entries in the pheromone table were considered analogous to pheromone trail strengths, and changed adaptively during the operation of the network. Updating of these trails in ABC is very simple – whenever a call is routed from node A to B, the entries for A in node B's routing table are all increased, with corresponding reductions to other entries. However, this simple idea has obvious intuitive benefits; first, by testing various routing decisions over time (rather than deterministic decisions), the process effectively monitors the current health of a wide variety of different routing strategies; when a link is over-used, or down, this naturally leads to diminution in its probability of use, since the associated entries in routing tables will not be updated, and hence will naturally reduce as alternatives are updated. Also, as it turns out, the pheromone levels can adapt quite quickly to changes in call patterns and loads. The ABC strategy turned out to be surprisingly effective, despite its simplicity, when Schoonderwoerd et al. compared it with a contemporary agent-based strategy developed by Appleby and Steward (1994), and found it superior over a wide range of different situations.

Research in ant-based approaches for decentralized management is increasingly very active (e.g., Hussein and Saadawi 2003; Rosati et al. 2008; Di Caro et al. 2008). The essential idea, to replace static built-in routing strategies with stochastic "pheromone tables" or similar, is applicable in almost all modern communication scenarios, ranging through ad hoc computer networks, mobile telephone networks, and various layers of the Internet. Ongoing research continues to explore alternative strategies for making the routing decisions, controlling the updates to pheromone trails, and so forth, while investigating various distinct application domains, and continuing to find competitive or better performance than alternative state-of-the-art methods used in network engineering.

3.2 Particle Swarm Optimization and Foraging

PSO was established in 1995 with Kennedy and Eberhart's paper in the international joint conference on neural networks (IJCNN) (Kennedy and Eberhart 1995). The paper described a rather simple algorithm (and time has seen no need to alter its straightforward fundamentals), citing Craig Reynolds' work as inspiration (Reynolds 1987), along with slightly later work in the modeling of bird flocks (Heppner and Grenander 1990). The basic idea is to unite the

following two notions: (a) the behavior of a flock of birds moving in 3D space toward some goal; (b) a swarm of solutions to an optimization problem, moving through the multidimensional search space toward good solutions.

Thus, a “particle” is equated with a candidate solution to an optimization problem. Such a particle has both a *position* and a *velocity*. Its position is, in fact, precisely the candidate solution it currently represents. Its velocity is a displacement vector in the search space, which (it hopes) will contribute toward a fruitful change in its position at the next iteration.

The heart of the classic PSO algorithm is in the step which calculates a new position for the particle based on three influences. The inspiration from Reynolds (1987) is clear, but the details are quite different, and, of course, exploit the fact that the particle is moving in a search space and can measure the “fitness” of any position. The influences – the components that lead to the updated position – are:

Current velocity: the particle’s current velocity (obviously).

Personal best: the particle remembers the fittest position it has yet encountered, called the personal best. A component of its updated velocity is the direction from its current position to the personal best.

Global best: every particle in the swarm is aware of the best position that any particle has yet discovered (i.e., the best of the personal bests). The final component of velocity update, shared by all particles, is a vector in the direction from its current position to this globally best-known position.

Following a random initialization of positions and velocities, the evaluation of the fitness of the particles’ current positions, and consequent initialization of the personal bests and global best, PSO proceeds in a remarkably straightforward manner. First, each particle updates its velocity by adding a vector in each of the above three component directions. To provide these vectors, in the classic algorithm, the current velocity component is left undisturbed, while the personal and global best components are each scaled by a random scalar drawn uniformly from [0,2]. The resulting vector is used to update the current velocity, and the new velocity vector is used to update the current position. The new position is evaluated, book-keeping is done to update personal and global bests, and then this is repeated.

Kennedy and Eberhart initially reported that PSO appeared to do very well over a wide range of test problems, including its use as an alternative to backpropagation for training an artificial neural network (Kennedy and Eberhart 1995). Perhaps helped by the ease of implementation of this algorithm (remarkably few lines of code are needed for the classic algorithm), an avalanche of papers began to follow, almost invariably adding to the evidence that this algorithm provides a very substantial contribution to optimization practice. Naturally, this field is now rich in variants and extensions to the original design – a number of recent surveys are available (e.g., Reyes-Sierra and Coello 2006; Yang et al. 2007) – while the published applications are as varied as one might expect from such a generally applicable algorithm.

3.2.1 Bacteria and Bees

Newer to the ranks of swarm-intelligence-based optimization, and yet to prove quite as widely successful, are techniques inspired by bacterial and bee foraging. For the most part, these algorithms follow the broad direction of PSO, in that individuals in a swarm represent solutions moving through a landscape, with the fitness of their current solution easily obtained by evaluating their position. Meanwhile, just as with PSO, an individual’s movement through

this landscape is influenced by the movements and discoveries of other individuals. The fine details of a bacterial foraging algorithm (BFA), however, are quite distinct, and in one of the more popular methods draw quite closely from what is known (and briefly touched upon above) about bacterial swarming in nature. Passino (2002) presents a fine and detailed explication of both the natural case and the BFA. It turns out that BFA-style algorithms are enjoying quite some success in recent application to a range of engineering problems (e.g., Niu et al. 2006; Tripathy and Mishra 2007; Guney and Basbug 2008).

Also inspiring, so far, a small following are algorithms that are inspired by bee foraging behavior. The authoritative sources for this are Quijano and Passino's papers, respectively, outlining the design and theory (Quijano and Passino 2007a), and application (Quijano and Passino 2007b) of a bee foraging algorithm. In Quijano and Passino (2007a) the design of a bee-foraging algorithm is presented in intimate connection with an elaboration of the mechanisms of natural bee foraging (such as briefly described earlier). The algorithm is as much a model of the natural process as it is a routine applicable to certain kinds of problem. Considering individual bees as resources, the concept here is to use bee foraging behavior as a way to ideally distribute those resources in the environment, and maintain an ideal distribution over time as it adapts to changing patterns of supply. Just as natural bees maintain an efficient distribution of individuals among the available sources of nectar, the idea is that this can be mapped to control problems which aim to maintain a distribution of resources (such as power or voltage) in such a way that some goal is maintained (such as even temperature or maximal efficiency). In Quijano and Passino (2007b), we see the algorithm tested successfully on a dynamic voltage-allocation problem, in which the task is to maintain a uniform and maximal temperature across an interconnected grid of temperature zones.

Finally, we note that bee-foraging behavior has also directly inspired techniques for internet search, again based on the notion of maintaining a maximally effective use of server resources, adapting appropriately and effectively to the relative richness of new discoveries (Walker 2000; Nakrani and Tovey 2003).

4 Current Trends and Concluding Notes

We have pointed to a number of survey papers and other works from which the reader can attain a full grasp of the current activity in swarm intelligence algorithms, but in this brief section we attempt a few notes that outline major current trends, and then we wrap up.

A notable trend in recent work on PSO, and indeed on metaheuristics in general, is toward the creation of hybrid algorithms. While themes from evolutionary computation continue to be incorporated in PSO (Shi et al. 2005), others have explored the idea of hybridization with less frequently used techniques such as scatter search and path relinking (Yin et al. 2007), immune system methods (Zhang and Wu 2008), and, indeed, ACO (Holden and Freitas 2007). Meanwhile, the range of problems to which PSO may be applied has been greatly increased with the development of multi-objective forms of PSO (Coello Coello et al. 2004).

Other work has involved the use of multiple swarms. This may allow each swarm to optimize a different section of the solution (van den Bergh and Engelbrecht 2004). Alternatively, each swarm may be configured differently to take advantage of the strengths of different PSO variants (e.g., Jordan et al. 2008), in an attempt to create a more reliable algorithm that can be applied to a wide range of problem domains.

The themes of multi-objective optimization and hybridization equally apply to recent research into ACO. While multi-objective ACO is a more mature field than multi-objective PSO (see, e.g., Mariano and Morales 1999), work continues in categorizing and comparing multi-objective approaches to ACO (e.g., García-Martínez et al. 2007), in creating generic frameworks for multi-objective ACO and in creating new multi-objective variants (e.g., Alaya 2007). Recent applications have seen single-objective ACO hybridized with genetic algorithms (Lee et al. 2008), beam search (Blum 2005b), and immune systems (Yuan et al. 2008) and multi-objective ACO used in combination with dynamic programming (Häckel et al. 2008) and integer linear programming (Doerner et al. 2006).

Other recent work has seen ACO adapted for use in continuous domains (Dreo and Siarry 2006; Socha and Dorigo 2008), while research continues into variations of ACO and new algorithm features, for example, different types of pheromone and the use of dominance rules to warn ants from searching among solutions known to be of low quality (Lin et al. 2008).

Recent work on bacterial foraging algorithms has concentrated on exploiting the effectiveness of the local search ability of the algorithm, while adapting it to improve the global search ability on high-dimensional and multimodal problems. With this aim, bacterial foraging has been hybridized with more effective global optimizers such as genetic algorithms (Chen et al. 2007; Kim et al. 2007) and PSO (Tang et al. 2007; Biswas et al. 2007).

In conclusion, we attempted to demystify the concept of swarm intelligence, and, after touring through the chief sources of natural inspiration, we distilled the essence of its impact and presence in computer science down to two major families of algorithms for optimization. No less intriguing and exciting additional topics in the swarm intelligence arena, that have also been discussed, are stigmergic construction, ant-based clustering, and swarm robotics. It is abundantly clear that the natural inspirations from swarming ants, bees, and birds (among others) have provided new ideas for optimization algorithms that have extended the state of the art in performance on many problems, sometimes with and sometimes without additional tailoring and hybridization. Ant-based clustering also seems to provide a valuable contribution, while swarm robotics, stigmergy-based construction, and a variety of other emerging subtopics have considerable promise, and will doubtless develop in directions rather difficult to foresee.

Abstract

Since its introduction as a generic heuristic for discrete optimization in 1983, simulated annealing (SA) has become a popular tool for tackling both discrete and continuous problems across a broad range of application areas. This chapter provides an overview of the technique with the emphasis being on the use of simulated annealing in the solution of practical problems. A detailed statement of the algorithm is given, together with an explanation of its inspiration from the field of statistical thermodynamics. This is followed by a brief overview of the theory with emphasis on those results that are important to the decisions that need to be made for a practical implementation. It then goes on to look at some of the ways in which the basic algorithm has been modified in order to improve its performance in the solution of a variety of problems. It also includes a brief section on application areas and concludes with general observations and pointers to other sources of information such as survey articles and websites offering downloadable simulated annealing code.

1 Introduction

Combinatorial optimization problems occur whenever there is a requirement to select the best option from a finite set of alternatives. They arise in a wide range of application areas including business, medicine, and engineering, and are renowned for being relatively simple to state but are often very difficult to solve. Until the 1980s much of the research effort into the solution of such problems concentrated on exact solution techniques, that is, techniques that are guaranteed to produce optimal solutions. Although such approaches cut down considerably on the computational requirements of complete enumeration, for many classes of problems the number of steps needed to guarantee optimality still grows exponentially with problem size – a factor that has serious repercussions for the scalability of any solution approach. By the end of the 1960s, these ideas had been formalized with the definition of an efficient algorithm as one in which the number of steps required increases polynomially with problem size (Edmonds 1965), and the conjecture that there are some problems for which no efficient solution algorithm exists. Subsequent work in theoretical computer science during the 1970s resulted in the now well-established theory of computational complexity and NP-completeness due to Cook (1971, 1972) and Karp (1972). A full treatment of these developments can be found in Garey and Johnson (1979). From a practical point-of-view, the key finding of this work is that there are many combinatorial optimization problems for which efficient algorithms that can guarantee optimality may never be found. This fact, combined with wider availability and decreasing cost of computer power during the early 1980s, lead to a change of focus from exact techniques. Instead, many researchers concentrated their efforts on the search for generic heuristic approaches that could be applied to any combinatorial optimization problem and produce high quality, if not optimal, results. Simulated annealing is one of a number of heuristics developed at this time that derive their inspiration from the natural world. In the case of simulated annealing, this inspiration comes from the behavior of fluids when they are subjected to controlled cooling such as in the production of large crystals. Since its introduction in 1983 there has been a wealth of literature on both theoretical and practical aspects. The purpose of this chapter is to provide an overview of simulated annealing, with emphasis on its use in the solution of practical problems. Nevertheless, some theoretical results are necessary in order to get the best out of a simulated annealing implementation and so these are covered

in [Sect. 4](#). More detailed treatments can be found in Aarts and Korst (1989), Aarts et al. (2005), and Salamon et al. (2002). It should also be noted that although simulated annealing was first introduced as a heuristic for combinatorial optimization, it is now also used for continuous optimization.

Simulated annealing (SA) can be regarded as an improved version of the older technique of local search. In a local search heuristic, an initial solution is gradually improved by considering small perturbations or changes; for example, changing the value of a single variable, or swapping the values of two variables. The set of solutions that can be produced in this way is known as the neighborhood of the original solution and its elements are referred to as neighbors. Starting from the initial solution, a trial solution is chosen from the set of neighbors. If this is “better” than the current solution, then it replaces it. This process continues until no improving solution exists. The replacement of the current solution by the trial solution is known as a neighborhood move. The problem with this type of approach is that the search terminates at a local, rather than global, optimum. This problem can be partially overcome by repeating the algorithm from different starting solutions, or by using more complex neighborhoods, thus widening the scope of the search. A third option used in heuristics, such as SA and tabu search (Glover 1989; Gendreau and Potvin 2005), is to allow some non-improving moves to be accepted. However, to ensure that the overall trajectory of the search is in the direction of improvement, this must be done in a controlled manner. In the case of SA, the control mechanism is inspired by the way in which thermodynamic energy is reduced when a substance is subjected to controlled cooling. These ideas are formalized in the following section.

2 Combinatorial Optimization and Local Search

A combinatorial optimization problem (S, f) consists of a finite space, S , of all possible solutions and a cost function $f : S \rightarrow \mathbb{R}$ that assigns a real cost to each $s \in S$. For a minimization problem the objective is to find s^* such that $f(s^*) \leq f(s) \forall s \in S$.

In order to apply a local search heuristic, we need to define a neighborhood structure $N(S)$ on the solution space S . For each $s \in S$, $N(s)$ defines a subset of S whose members are close to s in some way. Given the above definitions, the generic local search algorithm can be stated as follows:

Procedure local search

Begin

 Initialise (s_0)

$s_c = s_0$

 Repeat

 Select $s \in N(s_c)$

 If $f(s) < f(s_c)$ then $s_c = s$

 Until $f(s) \geq f(s_c) \forall s \in N(s_c)$

End

The above definition requires further detail concerning the selection of s . There are two common strategies; random descent and steepest descent. In random descent, the neighborhood is sampled uniformly and the first improving solution is selected, while in steepest descent, the whole neighborhood is evaluated and the lowest cost neighbor is selected.

Two examples of combinatorial optimization problems with appropriate neighborhood definitions are given below.

2.1.1 Example 1: The p-median Problem (Teitz and Bart 1968)

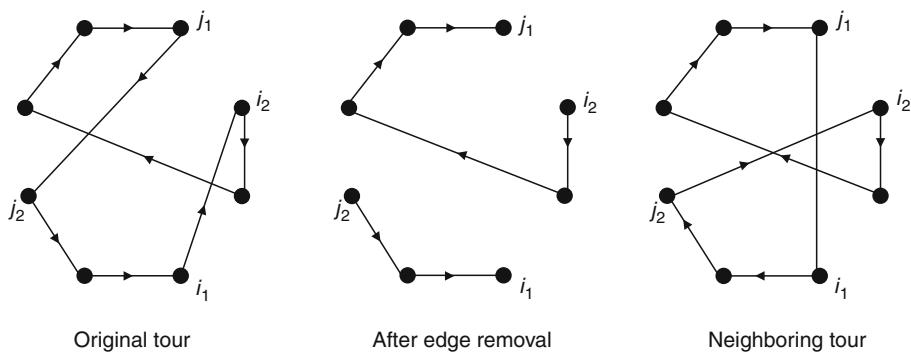

Given a set I of n supply locations, a set J of m demand locations, a cost matrix C , where c_{ij} is the cost of supplying demand location j from supply location i , and an integer constant p , find a subset of p supply locations such that the total cost of supplying J is minimized. Any feasible solution is a partition of I into a set P , containing p elements of I , and the set \bar{P} containing the remaining elements of I . The set of neighboring solutions is defined as those solutions that can be obtained by swapping an element of P for an element in \bar{P} .

2.1.2 Example 2: The Traveling Salesman Problem (TSP)

Given a set of n cities and an $n \times n$ matrix D where d_{ij} defines the distance between city i and city j , find a tour (i.e., a circular route visiting each city exactly once and then returning to the starting point) that minimizes the total distance traveled. The set of feasible solutions is the set of permutations of the cities, and any permutation can be regarded as the set of links between adjacent cities in the permutation (the n th city is regarded as being adjacent to the first city). A suitable neighborhood definition is then the set of solutions that can be obtained by removing two edges and then reconnecting the two resulting paths in such a way as to produce a feasible tour. This is illustrated in Fig. 1. Note that if the removed links are (i_1, i_2) and (j_1, j_2) the new links must be (j_1, i_1) and (j_2, i_2) if the result is to be a feasible tour. Note also that the segment between i_1 and j_2 will be reversed. Thus, if the distances are symmetric, tours in $N(s)$ will differ only by the difference in the four edges involved in the swap. However, in the case of the asymmetric problem, this may not be such a good neighborhood as the cost of the reversed segment will also have changed.

Fig. 1

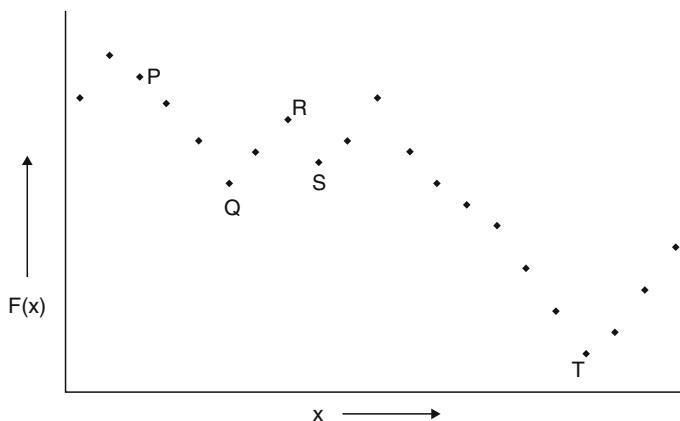

An example of a 2-opt neighborhood move for the TSP.

The advantage of local search is that it is a generic approach that simply requires the definition of a neighborhood structure on the solution space. Thus, it can be applied to almost any combinatorial optimization problem. The disadvantage is that it will converge to a local rather than a global optimum, and thus the quality of the final solution is dependent on the starting point. As a simple illustration, consider the one-dimensional function shown in Fig. 2. Let the set of neighbors of a given point, s , be the two points adjacent to s . Then, if we apply local search from solution P the result will be the local optimum at Q, whereas, if we start from R we may reach Q or S. Both solutions are clearly worse than the global optimum at T. Although this is a very simple example, the same behavior is apparent in multidimensional solution spaces associated with more complex problems.

This difficulty can be ameliorated somewhat by selecting several starting solutions. For realistically sized problems, simply selecting a set of random starting points is rarely sufficient, however, techniques such as greedy randomized adaptive search procedure (GRASP) (Feo et al. 1994) that attempt to use heuristic rules to obtain promising starting solutions and adjust these using feedback from previous iterations have had some success. An alternative approach is to define larger neighborhoods, for example, swapping k locations for the p-median problem, or k edges for the TSP. Such neighborhoods are referred to as k -opt neighborhoods. This can improve results and, in general, as k increases, the number of local optima decreases. Unfortunately, the size of such neighborhoods is exponential in k and so only small values of k are practical and solution quality remains highly dependent on the starting solution. For example, in Fig. 2 if we increase the neighborhood to those solutions within two steps of the current solution we will not be able to reach the global optimum from S, or any point to the left of S. More intelligent ways of expanding the neighborhood such as those used in variable neighborhood search or very large neighborhood search (VLNS) have been successful for some problems. The third option for dealing with local optima is to allow some uphill moves in a controlled manner. This is the method employed by simulated annealing.

An example landscape for a one-dimensional function.

3 Overview of Simulated Annealing

Simulated annealing for combinatorial optimization was introduced by Kirkpatrick et al. (1983) and independently by Černý (1985). The approach is based on an algorithm to simulate the cooling of material in a heat bath, due to Metropolis et al. (1953), a process known as annealing. When solid material is heated past its melting point and then cooled again, the structural properties of the resulting material depend on the residual energy in the material, which in turn depends on the rate of cooling. For example, large crystals represent a state of low energy and result from very slow cooling, whereas fast cooling or quenching results in crystals with high energy, resulting in imperfections. The laws of thermodynamics state that for a substance in a state of equilibrium at an ambient temperature T , the probability of an increase in energy of magnitude δE is given by

$$P(\delta E) = \exp\left(\frac{-\delta E}{kT}\right) \quad (1)$$

where k is a constant known as Boltzmann's constant. Metropolis proposed a simulation model to determine the energy of a system at its ground (or frozen) state, that is, when the temperature is reduced to its limiting value. In the simulation, the material is considered as a system of atoms. For each possible configuration of atoms, the energy of the system can be calculated. At each iteration, one atom in the current configuration is subjected to a small displacement and the increase in energy, δE , is calculated. If $\delta E \leq 0$ a new configuration is accepted automatically. Otherwise it is accepted with probability $P(\delta E)$. This is facilitated by generating a random number, r , in the interval $[0,1]$ and accepting the new configuration if $r < P(\delta E)$. The algorithm can be used to simulate the annealing process by repeatedly reducing the value of T . Once the system has reached equilibrium at the current temperature, until the system freezes at its ground state. Note that this approach can be regarded as a random descent approach in which some uphill moves are accepted according to Eq. 1. Kirkpatrick formalized these ideas by mapping the elements of the Metropolis algorithm onto the elements of a combinatorial optimization problem as given in Table 1. Note that as Boltzmann's constant is a physical constant, it is essentially suppressed and the term kT is considered as a single constant, t , which is usually referred to as the temperature.

Although this analogy is an attractive one, in order to be of use in an optimization context it must work effectively for problems where the landscape of the energy function over the states of the system displays similar features to those found in combinatorial optimization problems. This is not the case for most fluids as all the atoms are alike and are therefore

Table 1

Mapping of the Metropolis algorithm onto a combinatorial optimization problem

Thermodynamic simulation	Combinatorial optimization
System states	Feasible solutions
Energy	Cost
Change of state	Neighborhood move
Temperature	Control parameter
Frozen state	Heuristic solution

interchangeable in the solution, resulting in a single ground state. However, there are some classes of fluids that do not obey these rules. Kirkpatrick uses the example of spin-glasses. These are materials that exhibit a feature known as frustration, caused by competing sources of magnetic energy within the system. This has a similar effect on the solution landscape to the interaction between conflicting objectives and constraints in a combinatorial optimization problem and results in many different possible ground states. Thus the analogy between searching the solution space for a combinatorial optimization problem and the annealing of spin-glasses was considered worthy of further experimental investigation. Kirkpatrick's first experiments were based on a partitioning problem in computer design in which the cost function had the same form as the energy function for spin glasses. This was followed by work on problems with more general cost functions including the TSP.

The mapping in [Table 1](#) allows one to convert any local search algorithm into an annealing algorithm by accepting non-improving moves according to [Eq. 1](#). The probability of accepting such a move will be dependent on the magnitude of the increase and the temperature. Thus small increases will be accepted more often than large ones and the probability of accepting any such moves will gradually reduce to 0 as the temperature approaches 0.

A formal statement of the simulated annealing algorithm is given below.

Procedure simulated annealing

Begin

 Initialise (s_0)

$s_c = s_0$

 Repeat

 For $its = 1, nrep$ do

 Begin

 Select $s \in N(s_c)$

$\delta = f(s) - f(s_c)$

 If $\delta < 0$ then $s_c = s$

 else

$r = U[0,1]$

 if $\exp(-\delta/t) > r$ then $s_c = s$

 End

$t = \alpha(t)$

 Until stopping condition = 'true'

 End

where $U[0,1]$ is a random number in the range $[0,1]$.

In its original form, the Metropolis algorithm returns the current solution when the stopping point is reached. However, this may not be the minimum cost solution visited during the search and it is now common practice to return the best solution found rather than the final one.

The above procedure is a generic statement of the algorithm and a number of decisions must be made in order to implement it for the solution of a particular problem. These can be partitioned into two categories; those relating to the cooling process (the generic decisions) and those relating to the way in which the problem is modeled within a local search framework (the problem-specific decisions). The generic decisions include the starting temperature, the rate of cooling (governed by the function α and the parameter $nrep$) and the stopping

condition. The problem-specific decisions involve the definition of the solution space, the cost function, and the choice of neighborhood structure. These combine to define a solution landscape over which the search takes place.

Empirical research has shown that both types of decisions need to be made with care as they influence both the speed of the algorithm and the quality of the solutions obtained, while theoretical results have shown that under the right conditions asymptotic convergence to an optimal solution can be guaranteed. Unfortunately, it has also been shown that in order to guarantee a solution that is arbitrarily close to the optimum, the required number of iterations is exponential in problem size, that is, no better than an exact approach based on complete enumeration. Thus, the theory does not lead directly to a set of generic decisions. Nevertheless, it does provide some pointers as to what factors should be taken into account when making both types of decisions. We therefore review some of the results in the next section before the generic and problem-specific decisions are discussed in more detail.

4 Theory

Much of the theoretical background to simulated annealing is derived from concepts in statistical mechanics and from the theory of Markov chains. This section gives a very brief introduction to these two concepts and cites a number of sources that go into more detail.

For a constant temperature parameter, t , the behavior of simulated annealing can be modeled as a Markov chain. Thus, Markov chain theory underpins much of the theoretical work on SA. In the model, the solutions correspond to the possible states of the system and for any pair of solutions i and j the probability that the system will move from state i to state j is given by the product of the probability of generating solution j as a neighbor of i , denoted by $G_{ij}(t)$ and the probability that j will be accepted, denoted by $A_{ij}(t)$. In the basic model, it is usually assumed that each neighbor of i will be selected with equal probability and that the acceptance probability is given by \bullet Eq. 1. Thus we have

$$P_{ij}(t) = \begin{cases} G_{ij}(t)A_{ij}(t) & \text{if } i \neq j \\ 1 - \sum_{l \in S, l \neq i} G_{il}(t)A_{il}(t) & \text{if } i = j \end{cases}$$

where

$$G_{ij}(t) = \begin{cases} \frac{1}{|N(i)|} & \text{if } j \in N(i) \\ 0 & \text{otherwise} \end{cases} \quad \text{for any } t$$

and

$$A_{ij}(t) = \begin{cases} 1 & \text{if } f(j) \leq f(i) \\ \exp\left(\frac{(f(i)-f(j))}{t}\right) & \text{otherwise} \end{cases}$$

As long as the neighborhoods are strongly connected (i.e., it is possible to reach any solution from any other using a sequence of neighborhood moves) Markov chain theory states that there exists a unique stationary distribution. This distribution defines the probability of reaching solution i after an infinite number of moves at temperature t (denoted $Q_t(i)$), for each solution i . It is given by

$$Q_t(i) = \frac{\exp\left(-\frac{f(i)}{t}\right)}{\sum_{j \in S} \exp\left(-\frac{f(j)}{t}\right)}$$

Moreover, if we define the set of optimal solutions to be S^* then

$$\lim_{t \downarrow 0} Q_t(i) = \begin{cases} \frac{1}{|S^*|} & \text{if } i \in S^* \\ 0 & \text{otherwise} \end{cases}$$

This implies asymptotic convergence to an optimal solution as long as the process reaches the stationary distribution at each temperature. See Aarts and Korst (1989) for a more detailed treatment of the derivation of these results.

A corresponding result can be obtained by modeling the problem as an inhomogeneous Markov chain, in which t is reduced after each move, as long as the sequence of temperatures t_0, t_1, \dots, t_k , obey certain assumptions. In particular, Hajek (1988) showed that the rate of cooling should be related to the shape of the solution landscape and that the sequence of temperatures should satisfy $t_k \geq c/\log(2+k)$, where c is the depth of the deepest local (but not global) minimum. Although bounds on c have been derived for some combinatorial optimization problems (Kern 1986), it has also been shown that calculating c is itself an NP-hard problem. Even if c can be approximated, the number of steps required by Hajek's formula for even moderately sized problems is too large to be practically useful. Other results have suggested that the number of moves required to guarantee a stationary distribution that is arbitrarily close to the optimum will typically require a number of iterations that is exponential in problem size. For example Mitra et al. (1986) show that for the inhomogeneous case, the number of moves required is greater than the size of the solution space, while Aarts and Van Laarhoven (1985) showed that for the homogeneous model the number of steps required at each temperature would be quadratic in the size of the solution space.

The results presented above made quite stringent assumptions concerning the generation and acceptance probabilities that correspond to the basic statement of SA. However, it is possible to prove convergence under more general conditions. In particular, the generation probabilities do not need to be uniform over the neighborhood as long as they are symmetric, that is $G_{ij}(t) = G_{ji}(t)$.

In addition to results based on Markov chain theory, it has also been shown that other concepts from the field of statistical thermodynamics are relevant in the context of optimization. These include the specific heat and entropy. The specific heat of a system is defined as the rate of change in energy with respect to temperature and is given by σ_T^2/kT^2 , where σ_T^2 is the variance in energy at the current temperature T . In a physical system, a high level of specific heat indicates a fundamental change in the state of the system, and it has been suggested that the corresponding situation in an optimization context may signal the need for slow cooling. For example, in the solution of the TSP, Kirkpatrick et al. (1983) observed an increase in specific heat once the basic structure of the tour was in place. A related concept is entropy, which is a measure of the disorder of a system. The entropy at equilibrium can be defined as $S_T = -\sum_{i \in S} Q_T(i) \ln(Q_T(i))$. Fleischer and Jacobson (1999) carried out an empirical study

based on different implementations for the maximum clique problem and showed that the expected cost of the final solution was inversely related to the entropy. From an optimization viewpoint, it can be shown that as long as equilibrium is reached at each value of t , both the expected cost and entropy decrease monotonically. Furthermore, the probability of finding an

optimal solution at each temperature increases monotonically as t decreases. For a full derivation of these results, refer to Aarts and Korst (1989).

Although the above results do not provide any definitive rules for defining polynomial time cooling schedules with any performance guarantees, they still provide some guidance when making problem-specific decisions. These will be discussed in the following sections.

5 Generic Decisions

The generic decisions define the cooling schedule and comprise the starting temperature t_0 , the final temperature t_f and the temperature reduction function α . Each of these is discussed in turn.

5.1 Starting Temperature

If the final solution is to be independent of the starting point then the initial temperature must be hot enough to allow free movement through the solution space. In some cases, this can be estimated from the problem data. For example, it may be easy to calculate the mean or maximum change in cost over all uphill neighborhood moves. This can then be used to estimate the temperature at which such a move would be accepted with a reasonable probability. One commonly used formula is $t_0 = (-U)/\ln(R_{\text{acc}})$, where U is the mean increase in cost over all uphill moves and R_{acc} is the required acceptance ratio. Even if it is not possible to estimate U theoretically, it can be estimated by conducting a random walk on the solution space. However, as pointed out by Triki et al. (2005), if the landscape contains some shallow and some very deep local optima, then it may be better to base the starting temperature on an estimate of the maximum, rather than the mean. An alternative is simply to start from a low temperature and to increase it rapidly until the desired acceptance ratio is reached. At this point cooling can begin. In fact, this method is closer to the physical analogy in which a solid is heated past its melting point before being annealed slowly. This approach was taken by Kirkpatrick et al. (1983) in their experiments on a chip-placement problem arising in computer design.

5.2 Reduction Function

The success of any simulated annealing algorithm is highly sensitive to the rate at which the temperature parameter is reduced. This is governed by the function α and the number of steps at each temperature, $nrep$. It is apparent from the theory that t needs to be reduced slowly. Many different schedules have been suggested and two of the most popular are a geometric schedule based on the homogeneous model and a schedule introduced by Lundy and Mees (1986) based on the inhomogeneous model. The geometric schedule takes the form $\alpha(t) = at$, where $a < 1$. Empirical evidence from the literature supports the need for slow cooling and typical values for a are in the range 0.8 – 0.99 with a bias to higher values, that is, to slower cooling. The value of $nrep$ is often related to the size of the neighborhood, and may vary from temperature to temperature. For example, it is important to spend enough time at low temperatures to ensure that the regions around a local optimum have been fully explored.

Thus, it is common to increase $nrep$ as the temperature is reduced. $nrep$ may also be related more directly to the state of the search by using feedback from the search statistics. This results in a dynamic schedule. Simple dynamic schedules include reducing the temperature with reference to the number of moves accepted, the ratio of accepted moves to trial moves (the acceptance rate), or the ratio of accepted moves to cost increasing moves. As any of these statistics may be very small at low temperatures it is usual to impose a maximum number of moves per temperature as well. The Lundy and Mees schedule is based on the inhomogeneous model and reduces the temperature every iteration according to $\alpha(t) = t/(1+\beta t)$ where β is a suitably small value. Lundy and Mees suggest that β should be significantly smaller than $1/D$, where D is an upper bound on the maximum cost difference between any two points in the solution space. It has been shown that if the parameters for these two schedules are such that t is reduced at a similar rate over a similar range then there is little to choose between them in terms of solution speed or quality. Note that as the gradient of the Lundy and Mees schedule gets shallower as temperature decreases, an equivalent geometric schedule would involve increasing $nrep$ with every decrease in t .

In all the above schedules, the function α is constant and predetermined. Suitable parameters are often derived by trial and error and may not be robust, even for different instances of the same problem. As the theory of simulated annealing is based on the concept of equilibrium at each temperature, it has been argued that an adaptive schedule based on this idea may be a better choice. One way of achieving this is to ensure that equilibrium is reached at the initial temperature and then reduce the temperature by a sufficiently small amount so that equilibrium will be reached quickly at the new temperature. This will be true for t_0 if it is high enough to allow free movement between solutions. Thus all that is necessary is to ensure that each temperature value is sufficiently close to its predecessor. A number of reduction functions have been suggested based on estimates of the mean energy at different temperatures. An early example is the schedule of Van Laarhoven and Aarts (1987). The aim of their schedule is for the stationary distributions at consecutive temperatures to be close. This will be true if $Q_{\alpha(t)}(i) < (1+\varepsilon)Q_t(i) \forall i, t$, and for a suitably small value of ε . This leads to the derivation of the function

$$\alpha(t) = t \frac{1}{1 + \frac{\ln(1+\varepsilon)}{3\sigma_t} t}$$

where σ_t is the standard deviation of the cost at temperature t . In practice, suitably small values of ε and suitable starting and ending temperatures mean that this cooling schedule is usually too slow. One of the most popular schedules in practice is due to Huang et al. (1986). The reduction in temperature is determined by the difference in the average cost at consecutive temperatures. They use

$$\alpha(t) = t \cdot \exp(-\lambda t / \sigma_t)$$

where λ is an estimate of Δ/σ_t where Δ is the difference in the expected cost at t and $\alpha(t)$. They suggest using a value of 0.7 for λ .

Although both these schedules are designed to cope with different solution landscapes, we note that neither is parameter free. More recently, Triki et al. (2005) suggested a more general representation of this type of schedule using

$$\alpha(t) = t \cdot \left(1 - t \frac{\Delta(t)}{\sigma_t^2}\right)$$

where $\Delta(t)$ is an estimate of Δ as defined above. They point out that an appropriate choice of $\Delta(t)$ will yield both Van Laarhoven and Huang's schedules, as well as other schedules from the literature. They suggest an implementation in which the value of $\Delta(t)$ is initialized to a quantity proportional to σ (estimated from a random walk) and *nrep* is governed by a limit on the number of iterations and the number of acceptances, whichever occurs first. At this point, if the decrease in cost is sufficiently close to the target $\Delta(t)$, equilibrium is assumed and the temperature is reduced. Otherwise, another set of repetitions is carried out at this temperature. If the test for equilibrium is failed four times at the same temperature, the assumption is that the temperature was reduced too rapidly so the temperature is increased and the target function Δ is decreased.

5.3 Freezing Point

In theory, the temperature should be reduced to zero when no further uphill moves are possible and the system will terminate at a local minimum. In practice, a frozen state where no further moves are possible is often reached well before this. Lundy and Mees suggest that if the objective is to produce a solution within ε of the local optimum with probability θ then the termination point should satisfy $t_f \leq \varepsilon / \ln((|S|-1)/\theta)$. Others have suggested stopping after a predefined number of iterations without acceptance, or when the acceptance ratio falls below a certain value. Alternatively, if the average cost is measured over a small number of moves, the system may be considered frozen when the difference in consecutive calculations falls below a predefined parameter.

6 Problem-Specific Decisions

The problem-specific decisions cover the definition of the solution space, neighborhood structure, and cost function. These factors combine to define the solution landscape. Empirical results suggest that this has a significant impact on the success of a simulated annealing implementation. This coincides with the theoretical results such as Hajek's and fits well with the concept of entropy, as at the same temperature sparsely connected regions of the solution space display lower levels of entropy than denser areas, indicating that there is a smaller choice of acceptable moves. As with the generic decisions it is not possible to derive a set of definitive rules that can be applied to a given problem. Nevertheless, it is possible to outline some desirable properties. These are based on common sense, empirical investigations, and theoretical results. For many problems it may not be possible to meet all these guidelines at the same time, and some of them may even be contradictory.

The first consideration is to maintain the conditions for convergence. As outlined in the previous section, the original convergence results relied on a set of stringent conditions, but it has since been shown that it is sufficient that every solution be reachable from every other by a chain of neighborhood moves. This is usually easy to verify for well-structured problems, but may be more difficult for messy problems that occur in practice.

A second consideration stems from the requirement for slow cooling. This means that it will be necessary to execute a large number of iterations within the available computing time. Thus the calculations involved in each iteration need to be as efficient as possible. Two processes that are related to the solution landscape are required at each iteration. The first is

the generation of a randomly selected trial solution from the set of neighbors of the current solution. For many problems, a combination of the most obvious definitions of solution space and neighborhood structure results in a fast and simple neighborhood generation routine. For example, for the p-median problem all that is required is to select a member of P and a member of $I \setminus P$. This can be achieved by generating two integer random numbers within the appropriate ranges. However, this may not be the case for complex neighborhood definitions or if the solution space is highly constrained. In such cases, it may be beneficial to relax some of the constraints in the definition of the solution space and to include a penalty term in the cost function to guide the search away from infeasible solutions. This will be illustrated in the graph coloring example in the next section.

The second routine that is required at every iteration is the calculation of the difference in cost between the current solution and the trial solution. One way of doing this is to calculate the cost of the trial solution from scratch, but this is often unnecessary as it is more efficient to calculate the change in cost. For example, in the traveling salesman example, as long as the problem is symmetric, the change in cost is just the difference between the cost of the two removed edges and that of the two replacement edges. The cost calculation for the p-median problem is more complex. In an optimal solution, each demand point will be allocated to the nearest element of P . Thus changing one supply point may change the allocations of any of the demand points. Nevertheless, it is still worthwhile calculating the cost in terms of those demand points that have been reallocated rather than completely evaluating the new solution. The efficiency of such calculations can be improved by using appropriate data structures. It is worth noting that even if suitable data structures require a significant amount of updating every time a move is accepted, the number of accepted moves over a whole run is small compared to the number of trial moves evaluated. Thus their use may still save time.

In order to reach good solutions, it is desirable that the cooling schedule be as close as possible to the ideal. Hajek's result suggests that neighborhood/cost function combinations that give rise to spiky landscapes with deep troughs should be avoided. On the other hand, it is also clear that the cost function should guide the search over the landscape, rather than behave like an unbiased random walk. Thus, flat plateau-like regions resulting from groups of neighboring solutions of equal cost should also be avoided. This point will also be illustrated in the graph coloring example below. A number of theoretical and empirical results also suggest that the rate of cooling should be related to the size of the solution space and/or neighborhoods. This suggests that these should be kept as small as possible. In the case of the solution space, this observation conflicts with the idea of increasing the solution space to allow some infeasible solutions as suggested above. In some cases, it may be possible to reduce the set of solutions by applying a reduction technique to the problem beforehand. For many classical combinatorial optimization problems (e.g., set covering, maximum clique, steiner problem in graphs), such techniques have been well documented. It is however worth remembering that, by definition, these techniques remove points from the solution space and therefore care must be taken that this does not destroy the reachability property. Even if this is not the case the reduction may remove neighbors that are close in cost to the current solution, resulting in a landscape with a spiky topography and lower entropy that will be more difficult to search. In the case of the neighborhoods, it is generally agreed that neighborhoods should be small, so that neighborhood moves are truly local. Nevertheless, it is not always beneficial to use the smallest possible neighborhood as larger neighborhoods may lead to a smoother topography. Conversely, Goldstein and Waterman (1988) suggest that if the landscape is too smooth, it becomes too easy to escape from valleys and thus good optima may be missed. However, at low

temperatures, they are likely to need more iterations in order to ensure that they are sampled adequately so that the local minimum in the region is located.

The above discussion suggests that the combination of solution space, neighborhood structure, and cost function suggested for the local search solution for the TSP should also work well for simulated annealing. Neighbors are easy to generate and the change in cost is simple to calculate. The size of the solution space is $(n-1)!/2$ and the size of the neighborhood is $n(n-1)/2$. Thus the neighborhood is small compared to the size of the solution space. It is also easy to see that any solution can be reached from any other by a chain of feasible moves. In the case of the p-median problem, the local search framework is also suitable for SA, although the change in cost function cannot be calculated quite as easily as in the TSP case. The fact that more elements in the cost function are subject to change also suggests that the solution landscape may have more spikes and troughs. The next section looks at one further example – that of graph coloring, for which the problem-specific decisions present a greater challenge.

6.1 Graph Coloring

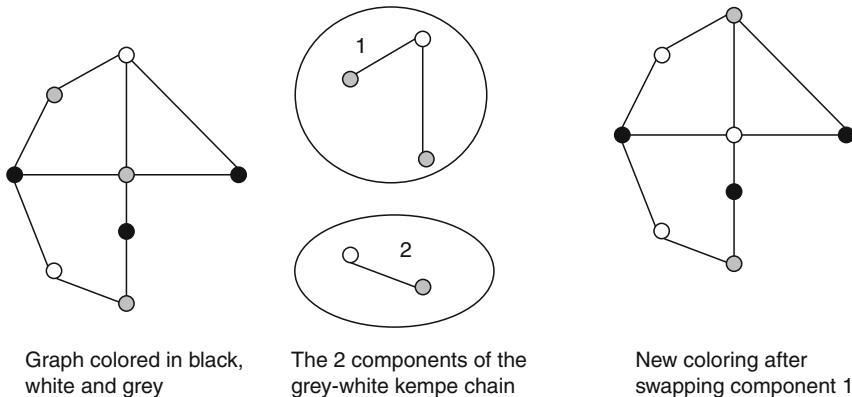

The graph coloring problem can be stated as follows. Given a graph $G(V, E)$ with vertex set V and edge set E find an allocation of colors to the vertices, such that adjacent vertices are given different colors and the number of colors used is minimized.

Unlike the traveling salesman problem, prior to the 1980s the graph coloring problem was not regarded as a natural candidate for local search. Nevertheless, there has been considerable interest in simulated annealing for graph coloring. The most obvious definition for the solution space is the set of all feasible colorings. These can be represented as partitions of the set of vertices into subsets, such that there are no edges between two vertices in the same subset. All vertices within a subset are considered to be of the same color, so the objective is to minimize the number of subsets. A natural definition for a neighborhood of a given solution is those partitions that can be obtained by moving a single vertex into a new subset. However, there is a problem with this, in that not all moves will result in a feasible solution as edges may be introduced into the subsets involved in the move. One can overcome this by limiting the moves to those subsets that are feasible. This could mean that some vertices will not have any feasible moves and also makes the generation of a neighbor more complex. A more fundamental problem is that it is easy to generate instances where the reachability condition is violated under this neighborhood. Even if the solution landscape remains connected, paths between different regions may be sparse thus making it difficult for the search to move away from the region containing the starting solution.

One way of overcoming this is to use a larger neighborhood. Morgenstern and Shapiro (1989) suggested a neighborhood based on Kempe chains. If we consider that part of the graph relating to just two colors or subsets, then it will consist of one or more components, each of which is completely disconnected from the others. Such components are known as Kempe chains. Swapping the colors (or subsets) of the vertices within one of these components will not introduce any edges between vertices in either subset, and thus the result is also a feasible coloring. This is illustrated in [Fig. 3](#). Morgenstern and Shapiro suggest defining the neighborhood as those solutions that can be reached by swapping the colors of a single Kempe chain. There is a computational overhead in generating such moves, and in calculating their effect on the cost function. Nevertheless, Kempe chain neighborhoods have been shown to outperform simple neighborhoods for some classes of graph. In addition, Thompson and

Fig. 3

Example of a Kempe chain neighborhood move for the graph coloring problem.

Dowsland (1998), Wright (1996), and Tuga et al. (2007) have all demonstrated their effectiveness in solving graph coloring-type problems arising in scheduling and timetabling.

An alternative to larger neighborhoods is to relax the definition of the solution space to include infeasible solutions and to penalize these with a suitable penalty term in the cost function. Examples of this approach will be given after a more general discussion of the cost function.

The natural definition of the cost function is the number of colors used. This is not suitable for a simulated annealing implementation as it will lead to large plateau-like areas in which the costs of neighboring solutions are identical and there is no information to guide the search toward lower cost solutions. For example, a solution in which there are k subsets each with a similar number of vertices will have the same cost as a solution with k subsets in which one subset has just one vertex. Clearly, the latter is preferable to the former as it requires just one move to reach an improved solution requiring $(k-1)$ subsets. Aarts and Korst (1989) suggest a

cost function of the form $\sum_{i=1}^q w_i(|V_i| - \lambda|E_i|)$ where V_i, E_i are the sets of vertices and edges in

the i th subset, λ is a weighting factor such that $\lambda > 1$ and q is an upper bound on the number of colors needed. w_1, \dots, w_q is a decreasing sequence of weights based on the number of vertices in subset i , and the subset index, designed to encourage lower indexed sets to be emptied in favor of those with higher indices. The optimal solution with respect to this cost function is guaranteed to be optimal in terms of the original objective, but the weights can be very large and therefore cause computational difficulties. For practical purposes, a relaxation of the condition on the weights is suggested, but this no longer guarantees that the optimal solution will correspond to an optimal coloring. Johnson et al. (1991) suggest a simpler solution based on a term to encourage large subsets and a penalty term for infeasible colorings. The form of their function is:

$$-\sum_{i=1}^q |V_i|^2 + \sum_{i=1}^q |V_i||E_i|.$$

Although optimal solutions using this function may not correspond to optimal colorings, they are guaranteed to be local optima.

An alternative way of dealing with the cost is to determine an upper bound, q , on the number of colors required, define the solution space as the set of all partitions of the vertices into q subsets, and simply minimize the sum of the $|E_i|$ values. Once this is reduced to zero, q can be reduced and the process repeated. The last value of q for which a zero-valued solution was achieved is taken as the final solution. The problem here is the requirement to find an optimal solution in a series of annealing runs. However, for practical problems, the objective is sometimes simply to find a coloring in q colors for a given q . Johnson et al. (1991) compare this approach with their penalty methods and a Kempe chain-based implementation. They conclude that for problems where the global optimum based on the penalty cost implies several more colors than the optimal coloring, the q partition method can often do better than the Kempe-chain approach. Their main conclusion is that none of the three implementations outperformed the others on all classes of graph, emphasizing the difficulty in finding the right combination of problem-specific definitions for a particular problem type.

7 Enhancements and Modifications

The previous sections have dealt with implementations of simulated annealing that adhere to the analogy with the physical cooling process. Thus the theoretical results on convergence hold for the optimization process. However, as we have seen, run times for cooling schedules that are able to give any performance guarantees tend to be too long to be of practical value. Thus, very few real implementations have the benefit of such theoretical backup. It is also the case that the theory behind many cooling schedules is based on the assumption that the returned solution is the final, and not necessarily the best solution. It is therefore arguable that there is no reason to stick rigidly to the original Metropolis simulation, and that any heuristic that searches the solution space using neighborhood moves and allows uphill moves that are controlled using a probability function based on temperature may be an equally good candidate for solving optimization problems in practice. For some generalizations the convergence proofs will still hold. Even if they do not, the heuristic may still perform well enough. This section examines a number of ways in which successful implementations have bent the rules of the classical Metropolis-based algorithm. In some cases, these modifications improve the performance of SA on problems for which it may not seem ideally suited, for example, those with spiky solution landscapes, or cost functions that are expensive to calculate. In others, they simply improve the efficiency of the search, thus allowing larger problems to be tackled.

7.1 Acceptance Probability

An obvious way of relaxing the conditions of the physical analogy is to move away from the Boltzmann distribution in determining whether or not an uphill move should be accepted. Its use in the original heuristic is entirely due to the laws of thermodynamics, which have no meaning in terms of an optimization problem. Nevertheless, it is still used by the majority of implementations. This is no doubt due to the fact that it does possess some desirable properties: solutions are accepted according to the magnitude of increase in the cost function, δ ; the probability of acceptance decreases monotonically as δ increases; and this probability tends to zero as $\delta \rightarrow \infty$. On the other hand there is some motivation for using a different distribution. Johnson et al. (1989) showed that in a straightforward implementation of annealing to a graph

partitioning problem, the calculation of $\exp(-\delta/t)$ took up approximately one-third of the execution time. They concluded that it may be beneficial to use a simpler function, thereby allowing time for additional iterations. They suggested using a linear function that approximated the exponential over an appropriate range of values but found that better results could be obtained if $\exp(-\delta/t)$ was calculated for all possible δ, t combinations beforehand and stored in a look-up table. This is obviously only possible if the number of different cost function values is reasonably small.

A very simple scheme suggested by Dueck and Sheuer (1990) and by Moscato and Fontanari (1990) is known as threshold accepting. The idea here is that t represents a threshold on the values of δ that will lead to acceptance and the probability is defined as $P(\delta) = 1$ if $\delta \leq t$, $= 0$ otherwise. Threshold accepting has proved successful for some problems and less so for others. More recently, Penna (1994) and Tsallis and Stariolo (1996) suggested a more complex acceptance probability of the form

$$P(\delta) = \begin{cases} 1 & \text{if } \delta \leq 0 \\ (1 - (1 - q)^{\frac{\delta}{t}})^{\frac{1}{1-q}} & \text{if } \delta > 0 \text{ and } (1 - q)^{\frac{\delta}{t}} \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

where q is an additional parameter such that $q \neq 1$. This allows larger jumps to be accepted occasionally depending on the value of q . If $q \rightarrow 1$ then this is equivalent to the standard Metropolis algorithm. Franz and Hoffmann (2003) have since shown that a slight modification of the Tsallis acceptance probability produced by scaling t by a factor of $(2-q)$ not only tends to the Metropolis algorithm as $q \rightarrow 1$, but also tends to threshold accepting as $q \rightarrow -\infty$. They were able to show that given an ideal cooling schedule results improve as $q \rightarrow -\infty$. Given that threshold accepting was introduced as a simplification of SA designed purely for easy implementation this is a somewhat surprising result. However, it is worth noting that performance depends on an appropriate schedule and far more is known about good schedules for the Boltzmann acceptance rules than for threshold accepting.

Many other practical implementations have been shown to benefit from changes to the acceptance rules. For example, Dowsland (1993a) found that the solution landscape for a two-dimensional rectangle packing problem contained large peaks and troughs so that moderate increases in cost were needed to escape local optima. When the temperature was high enough to accept such moves with a reasonable probability, too many small uphill moves were made. This was overcome by adding a positive constant to the change in cost. This has the effect of moving to a flatter part of the exponential curve, thus decreasing the probability of accepting small moves relative to moderate ones, while still ensuring that very large uphill moves are accepted with extremely low probability. There has also been some success with simple functions. For example, Ogbu and Smith (1990) and Vakharia and Chang (1990) use probabilities that are independent of δ on different sequencing problems, while others have used a linear function such as δ/t (Brandimarte et al. 1987).

Wright (2001) suggests an alternative rule for problems in which the objective is made up of a number of different terms, which he refers to as subcosts. This is often the case for problems with hard and soft constraints, where the objective is often to minimize a weighted linear function based on the violated soft constraints. In such cases, the conflict between the constraints may mean that it is necessary to violate several constraints in different groups in order to gain any improvement in another. Therefore, if traditional acceptance probabilities are used, the search may get trapped in regions where certain constraints are never satisfied. In order to overcome this, Wright suggests subcost-guided simulated annealing, which uses the acceptance criterion

$$P(\delta) = \exp\left(\frac{-\delta \cdot \exp(-\frac{\Theta B}{\delta})}{t}\right)$$

where B is the best improvement in any of the subcosts and Θ is a problem-specific parameter. This has the effect of improving the chances of accepting a move that results in a large improvement in one of the subcosts at the expense of several smaller increases in the others.

We have seen that it may be beneficial to include infeasible solutions in the solution space and to penalize them in the cost function. However, as pointed out by Abramson (1991), finding the right weights for such penalties can be difficult. Weights that are high enough to ensure convergence to a feasible solution tend to mean that the search becomes trapped early in a sub-region of the solution space as infeasible solutions tend never to be accepted even at moderate temperatures. Pedamallu and Ozdamar (2008) suggest a novel acceptance criterion for this situation. Instead of considering a combined cost, they monitor the sequence of feasible and infeasible solutions separately and make acceptance decisions independently within each sequence. These two ideas are incorporated into two hybrid simulated annealing methods. They also reduce the probability of accepting an uphill move by only considering acceptance if the last n trial moves were also uphill moves.

7.2 Cooling

Most simulated annealing runs that start with a high enough temperature to allow free movement and cool until the system appears to be frozen do much of their useful work in the middle part of the run. When the temperature is high the search will accept almost any solution, each one of which could have been generated as the initial solution. This part of the search can also be computationally expensive as the high acceptance rate means that there are more solution updates to be carried out. In order to overcome this, some implementations may use rapid cooling at this stage, for example, reducing temperature after just a few moves have been accepted. Others suggest starting at a lower temperature where the rate of acceptance is much lower than that suggested by the theory. Conversely, at low temperatures when few moves are accepted, SA becomes a slower version of random descent in which equal cost moves as well as improving moves are accepted. This can lead to cycling around local optima without actually making any progress. This is sometimes avoided by replacing this phase of the algorithm by a random descent phase and stopping once a local optimum has been reached (e.g., Merlot et al. (2003)).

Many practical implementations set the temperature so that just the middle phase of the cooling schedule is used. However, as long as we return the best solution found during the search, it can be argued that overall cooling may not be necessary. Boese and Kahng (1994) show that under these conditions optimal schedules may involve heating, even at the end of the search. In a practical context, Connolly (1990) suggested using a constant temperature, as long as that temperature is appropriate for the problem at hand. After experimenting with temperatures that resulted in a high measure of specific heat and finding that they did not result in high quality solutions, he suggests starting the process with a fairly quick run using the Lundy and Mees schedule over a wide temperature range, and then using most of the available time using a fixed temperature, defined as that temperature where the minimum cost solution was located. Results on the quadratic assignment problem were better than those obtained with standard cooling.

Connolly reports that a constant temperature allowed a good balance between downhill and uphill moves, thus encouraging the search to get to the bottom of local minima, but also allowing it to escape again. For spiky landscapes this may not be sufficient, and the idea of reheating as a means of escape from deep valleys has been used in a range of different ways. Glover and Greenberg (1989) point out that this is perhaps a more intuitive approach as it corresponds to making a concerted effort to move uphill once it becomes clear that further progress in the current valley is unlikely. It is worth noting that Kirkpatrick et al. did use some reheating in their initial study of the TSP, using a graphical representation of the tours to identify when the search seemed to be stuck and using manual intervention to reheat. Such manual intervention is obviously not practical for most cases and so a number of ways of automating the reheating process have been suggested. We have already mentioned Triki et al. (2005) who reheat slightly when it appears that the latest cooling step may have lowered the temperature too far. Several practical implementations reheat once a frozen state has been reached. For example, Anagnostopoulos et al. (2006) raise the temperature to twice the value where the best solution was found. This is repeated until the number of reheats without an improvement reaches a given limit. Other examples include Azizi and Zolfaghari (2004) who use the cooling function $\alpha(t) = t_0 + \lambda \ln(1+r)$ where r is a count of the number of consecutive uphill moves up to the current iteration and λ is a control parameter. The initial temperature is set to a *low* value, which is equal to the minimum value that t can take. At the start, the low temperature means that the search should move rapidly downhill. Each time an uphill move is selected, the temperature increases, thereby giving it more impetus to climb out of local minima. As soon as a downhill move is accepted, the temperature reverts to its minimum value. Dowsland (1993a) also suggests an undulating schedule. In this case, the decision as to whether to raise or lower temperature is based on whether the last move was accepted or rejected. If a move is accepted, then temperature is reduced and vice versa. Both cooling and reheating are carried out using the Lundy and Mees formula with different values of β . If $\beta_c = k\beta_h$ where β_c is used for cooling and β_h is used for heating, then the ratio of rejected to accepted moves will be approximately k . Dowsland first used this schedule with constant k for a rectangle packing problem. If k is reduced periodically, then this schedule can be used to replace standard cooling. This has been used with some success for examination scheduling (Thompson and Dowsland 1996), and as a way of ensuring that the acceptance rate drops monotonically with temperature in an implementation of SA that involves periodically selecting a new neighborhood (Dowsland et al. 2007).

7.3 Neighborhoods

In the basic algorithm, it is assumed that neighborhoods are well defined and do not change at all during the search. There are many practical examples where nonconstant definitions of the neighborhood have been shown to lead to improvements in solution time or quality. One popular ploy is to adjust the neighborhood as the temperature changes. For example, for problems such as packing or placement problems, where neighborhood moves involve moving an element over a finite distance, it is common to reduce the maximum distance allowed as the temperature reduces. Sechen et al. (1988) applied this idea to a simulated annealing approach to a VLSI design problem in which rectangular blocks are to be placed on a chip in such a way as to minimize a combination of cost factors. Valid moves are a horizontal or vertical transition of a single block. As only small transitions tend to be accepted at low temperatures,

the authors argue that time is wasted sampling and rejecting such moves, and so the maximum transition length is decreased as temperature decreases. Similar strategies have been used in SA implementations for packing problems. Such strategies are not limited to problems where moves involve physical distances and are also applied where neighborhood moves involve changing the value of a single variable where an upper limit on the magnitude of the change is reduced gradually.

A reduction in the neighborhood may also save time in situations where not all entities in the solution are contributing to cost. For example, consider a scheduling problem in which the cost function represents a series of penalties for undesirable features in the schedule and neighborhood moves involve moving a single event. Not all events will contribute to the cost and so moving such an event will not lead to an improvement. Many implementations therefore exclude these moves from the neighborhood. For example, in solving the rectangle packing problem Dowsland (1993a) found it beneficial to move only those pieces causing overlap, and in solving an examination scheduling problem. Thompson and Dowsland (1998) move only those exams causing clashes. While this strategy is a good idea for many problems, it should be used with care because it may destroy the reachability property. In view of this, Tovey (1988) suggests that the full neighborhood should be used with a given probability and the reduced neighborhood used the rest of the time.

In the context of other local search algorithms, it has been shown that using different neighborhoods, either with a fixed probability throughout the search, or at different times in the search, can be very effective (Hansen and Mladenovic 2005). Such a strategy is not straightforward in a simulated annealing context, as using different neighborhoods at different temperatures will have a significant effect on the transition probabilities, and therefore the expected cost may no longer decrease monotonically with temperature. Nevertheless, neighborhoods with significant variations have been used in some implementations. For example, Dowsland et al. (2007) use several different neighborhoods in the solution of a shipper rationalization problem and attempts to overcome this problem by using the acceptance rate to set the temperature using the undulating schedule described in the last section.

7.4 Neighborhood Sampling

In addition to the definition of the neighborhood, the transition probabilities are also affected by the probability with which each neighbor is sampled. In [Sect. 4](#), it was assumed that every neighbor was generated with an equal probability. In practice, sampling may not be uniform. In some cases, the choice of nonuniform sampling is made to simplify the neighborhood generation procedure, while in others it is an attempt to guide the search more effectively.

A simple modification that has been used in a number of implementations is the use of cyclic, as opposed to random sampling. The rationale behind this is twofold. Close to local optima, there may only be one or two moves that lead to an improvement in cost. At low temperatures it is desirable that such moves be made. However, even if the number of trials is greater than the size of the neighborhood such moves may not be sampled and eventually an uphill move may be accepted and the search may move away from the region without the local optimum having been visited. Cyclic sampling ensures that every move is considered before any is considered for a second time. Cyclic sampling also has the advantage of saving time as it does not require the generation of one or more random numbers in order to select a neighbor. Nevertheless, it is important to impose a random ordering on the cycle at the start of the run in

order to avoid introducing any form of bias. This can be illustrated by considering an approach taken by Connolly (1990) for the quadratic assignment problem in which a set of n items are to be allocated to n locations so that each location contains a single item. The natural neighborhood for this problem is to swap two items. For any solution we can therefore consider the neighborhood moves as the set of (unordered) pairs of items. If we take the natural ordering then all swaps for item 1 would be considered before those for item 2, etc. This may introduce unwanted bias and so Connolly randomizes the list and then cycles through the list in this new order. This resulted in improved performance over random sampling in terms of both time and solution quality. This example also illustrates a third potential benefit of cyclic sampling. If the list of neighborhood moves can be represented in such a way that it is valid for all solutions, as in this case, then when a move is accepted, instead of starting from the beginning of the list it makes sense to carry on from the current position. In this case, cyclic sampling will help to avoid the search cycling through a small set of solutions as it behaves like a (long) tabu list. For example, if items a and b are swapped, all other swaps will be considered before a and b can be swapped back again. Others who have used cyclic sampling to ensure the search is sufficiently diverse include Osman (1993). It should be noted, however, that other researchers have found that cyclic sampling has an adverse effect on solution quality for their particular implementations.

At low temperatures, time may be wasted in sampling many solutions (often more than once) without an acceptance. Greene and Supowit (1986) suggest the alternative of determining the probability of acceptance for each neighborhood move and then using these to weight the sampling distribution, that is, they combine the two probabilities $A_{ij}(t)$ and $G_{ij}(t)$ into a single acceptance probability. As the transition probabilities remain the same, this will not change the behavior of the algorithm. Greene and Supowit apply their method to a graph partitioning problem and show that the required probabilities are easy to maintain. For other problems this may not be the case, but this approach can be used at a local minimum at low temperatures. In this situation, it may take a long time before an uphill move is accepted. If some form of sampling without replacement is used, as each neighbor is generated, its cost can be recorded. If no move is selected before the neighborhood is exhausted, the appropriate probabilities can be calculated and a move selected according to these values.

Perhaps the most intuitive use of nonuniform sampling is to bias the selection toward low cost neighbors. For example Lin et al. (2008) consider a truck and trailer routing problem and instead of making the accept/reject decision on a single neighbor, they generate several neighbors and then use the best of these as the trial solution. Ropke and Pisinger (2006) apply a very large neighborhood search within a simulated annealing framework for a pick up and delivery problem. VLNS is a local search method that uses neighborhoods that are very large. This obviously smoothes out the solution landscape, but means that it is not practical to evaluate the whole neighborhood or even a large proportion of it. Thus VLNS is only effective when there is some form of optimization algorithm (or good fast heuristic) that can find an optimal (good) member of the neighborhood. If the neighborhood is optimized, then simulated annealing may not work well as the idea behind SA is that the pressure to move downhill should increase slowly throughout the search, and the selection of a neighbor should therefore be sufficiently random to maintain an appropriate level of flexibility. Ropke and Pisinger try to avoid this problem by introducing randomization in two ways. First, one of a number of different heuristics can be used to select the “best” element to remove/insert. This choice is random, but is biased according to previous performance. Second noise is added to the calculated cost before applying the acceptance/rejection criterion. Computational tests

show that this latter strategy gave better results than a version without noise. Anagnostopoulos et al. (2006) compare a neighborhood that includes some very large moves with one that includes only simpler moves. They conclude that the former neighborhood gives the best results. In the case of differentiable real-valued functions the concept of large neighborhoods is very attractive as local optima can be found easily using gradient methods. Wales and Scheraga (1999) coined the term “basin hopping” for a simulated annealing solution to a clustering problem, in which each trial solution was a local optimum. One problem with this approach is that the jump between starting points needs to be large enough to converge to a different basin, but close enough to maintain the spirit of a local, rather than random, search.

In the case of real-valued functions, the simplest way of generating a neighbor is to select solutions from a hyper-sphere with a given radius centered at the current solution. Alternatively, the distance is sometimes selected according to the Boltzmann distribution. This may mean that it takes a long time for the search to reach new areas of the solution space. In order to avoid this, it has been suggested that the distance moved is generated from other distributions with fatter tails, thus increasing the probability of generating larger jumps. In variable step sized simulated annealing, the distance is adjusted according to the acceptance ratio. If it is high, the search is considered to be far from the optimal and the size is increased, and vice versa (Kalivas 1992). In fast simulated annealing (Szu and Hartley 1987), the Cauchy distribution is used for this purpose.

In all the above examples, the choice of nonuniform sampling was made to improve the search. For some problems, the most straightforward way(s) of neighbor generation may not correspond to uniform sampling. For example, timetabling problems can be regarded as graph coloring problems in which the feasible solutions are the feasible colorings in q colors, and the objective is to optimize a cost function relating to the quality of the timetable. Suppose we define a neighborhood move as changing the color of a single vertex. As seen in Sect. 6, if the solution is to remain feasible, not all colors will be feasible for a given vertex. Therefore, if a neighbor is generated by selecting a vertex and then a new color for that vertex, the selection policy will tend to move vertices from “fuller” colors to “emptier” ones. An alternative with different bias might be to select two colors and then select a vertex that is free to move from the first color to the second. Such bias can affect solution results. For example, Thompson and Dowsland (1998) used this approach in the solution for an examination scheduling problem. They found that when the objective was to even out the number of students sitting exams on each day, then the first strategy performed well, but when the objective was to minimize back-to-back exams, when solutions in which alternate full and empty sessions are best, the second strategy was better. Similar results were reported using two different generators for a Kempe chain neighborhood on the same problem. Bias was also found to be a problem in Dowsland (1993b). In this case, the two natural sampling strategies introduced different biases both of which adversely affected solution quality. The final implementation used them both in alternate iterations, which removed the bias and yielded good results.

7.5 Cost Function

The standard simulated annealing algorithm does not assume any restrictions on the cost function, except that it should be well defined and constant. In practice, there are situations in which it may be necessary or advantageous to break these rules. The most obvious scenario is the case of a stochastic cost function or one that is subject to noise. There is a growing body of

literature on meta-heuristics, including simulated annealing, for such problems. Gelfand and Mitter (1989) show that if the noise in the objective function is normally distributed, then the convergence properties of SA still hold for noisy functions, while Gutjahr and Pflug (1996) generalize these results to other distributions. Others consider the situation in which the cost of a solution is estimated by sampling either from an appropriate distribution or from a simulation run. Some such as Alrefaei and Andradottir (1999) suggest storing all feasible solutions visited during the search. They then suggest that, when suitably adjusted to take account of the number of neighbors, the number of times a solution is accepted is a good measure of solution quality. Whatever measure of cost or acceptance strategy is employed, storage of all solutions is only feasible if the solution space is small.

When dealing with stochastic costs, the use of statistical tests to aid acceptance/rejection decisions is very common. These may be used simply to determine whether a move is a downhill or an uphill move. In the latter case, mean costs are then used to calculate the change in cost δ . Alternatively a t-test can be used to determine whether additional sampling is required in order to make a decision with confidence. Much of the work on stochastic cost functions is either theoretical or involves empirical analysis of small unrealistic problems and there are relatively few papers showing that these ideas work well in practice. Exceptions include Bulgak and Sanders (1988). A survey of SA for stochastic combinatorial optimization can be found in Bianchi et al. (2008).

A second reason for using an estimated cost function is that it may be computationally expensive to calculate the true cost. In  Sect. 6 we stated that if possible this situation should be avoided, but in some cases it may be worth compromising on this in order to improve other problem-specific factors. Tovey (1988) suggests that in such situations it may be possible to use a simpler approximation function. Rather than using the approximation at every iteration he suggests occasionally taking the time to calculate the true cost value. The difference between the real and estimated values at these points are then used to adjust the acceptance probabilities to compensate for the error. For example, if the true value is calculated 10% of the time and it is found that the estimated value was too high, then 90% of the time this solution will have a lower probability of acceptance. Therefore, on this occasion, the probability is increased to compensate. A drawback of this approach is that if the optimal solution is visited but its cost is overestimated it may not be returned as the best solution. An alternative approach is to use an approximation for the trial solution, but once a solution is accepted, to calculate its true value. In this way there may be some errors in the decision as to whether or not to accept a solution, but the true value of all accepted solutions will be known and the minimum of these can be retained as the final solution.

Even if the cost function is well defined and the minimum cost solutions are true global minima, it may be worthwhile considering an adjustment. This is particularly true when the cost includes one or more penalty terms relating to hard or soft constraints. Although the penalty weights may be set so that the cost is a true reflection of the relative quality of the solutions, these may not be the best weights for the annealing algorithm. For example, Wright (1991) argues that weights should reflect not only the importance of each constraint but also its difficulty. Anagnostopoulos et al. (2006) suggest that the weights need not be constant throughout the search. They adjust the weight of a penalty term up or down whenever a new best solution is accepted depending on whether the solution is infeasible or feasible. Fleischer and Jacobson's (1999) study on the relationship between entropy and the expected cost of the final solution includes experiments with a weighted penalty function for the maximum clique problem. They conclude that results can be significantly improved if the penalty function is

weighted in such a way as to smooth the solution landscape, thereby increasing the entropy of the system.

Rather than smoothing the landscape at the start, Hamacher and Wenzel (1999) adjust the landscape through changes to the cost function as the search progresses. Their approach, named stochastic tunneling (STUN), is designed not only to make it easy to descend into local optima, but also to escape from them again. They do this by adjusting the cost function so that the part of the landscape that is higher than the best solution found so far is smoothed, while the troughs in lower areas are exaggerated. This is achieved by making the transformation $f(i) \rightarrow 1 - \exp(-\lambda(f(x) - f(x_{\min})))$ where x_{\min} is the best solution to date and λ is a scaling factor. However they note that close to the global minimum this function becomes too smooth and insufficient downhill moves are made. For this reason they recommend alternating STUN with low temperature annealing. A later paper (Hamacher 2006) details further improvements.

7.6 With Other Methods

There are a large number of empirical investigations and practical case studies that show that a stand alone simulated annealing heuristic can be a very good solution approach for a wide range of problems. Nevertheless, in some cases, performance may be improved by combining it with other methods. These may be used as preprocessors to find a good starting solution or to transform the problem in some way to make it easier to solve; as post processors to make further improvements to the final solution; or as ingredients of the search process itself. The latter case may simply involve alternating a simulated annealing phase with one or more other search algorithms, or may be a true hybrid in which another method is embedded within the simulated annealing process or vice versa. The volume of papers and different possibilities for combination and hybridization are too great to provide a complete overview, so this section cites a few examples to give a flavor of this type of work.

The most common form of preprocessing is to use a heuristic to find a good starting solution instead of generating a purely random starting point. In this case, it makes sense to start with a lower temperature than normal so that all the benefits of the good solution are not destroyed. This can save time but care must be taken that this does not make the search entirely dependent on the starting solution. This not only involves ensuring that the temperature is not too low, but also that the starting solution should not be too good – for example, by using some form of randomized greedy construction rather than a totally greedy one. Bonomi and Lutton (1984) suggest an interesting way of initializing a solution for the TSP. They cluster the cities into regions and then find a good tour through the centers of the clusters. Within each cluster, the ordering is random but the clusters are ordered according to the tour. A different form of preprocessing is suggested by Chams et al. (1987). They point out that for partitioning problems such as graph coloring where the objective is to minimize the number of partitions required, a greedy algorithm that builds a solution one partition at a time is able to make good decisions early on and it is only in the later part of the construction that the myopic nature of such an approach becomes a problem. They therefore suggest building a partial solution in this way and then using SA to minimize the number of partitions required by the remaining elements. They report promising results using this approach for the graph coloring problem. More recently, Burke et al. (2008) report success with a similar approach for a stock-cutting problem. In this case, the

simulated annealing phase is also hybridized with a construction algorithm and further details are given later in this section.

Another possibility is to transform the problem, either into an easier to solve instance of the same problem, or into an equivalent problem. The possibility of reducing the size of the solution space has already been mentioned. Fleischer and Jacobson (1999) suggest that more dramatic transformations may be beneficial and illustrate their ideas by comparing the performance of SA in the solution of a maximum clique problem using a direct model and after transforming the problem into a satisfiability problem. They conclude that the level of entropy differs between the two models and that better solutions tend to result from the model with higher entropy.

The most common form of post-processing is to apply a descent phase starting from the best simulated annealing solution. This ensures that at least a local minimum has been found. In some cases, the neighborhood used for such a search may be different to that used for the annealing phase.

By far the largest body of literature covers other forms of hybridization. An approach that is becoming increasingly common for problems such as cutting and packing is to hybridize simulated annealing with a construction heuristic. The solution space is defined as a permutation of the elements of the solution, and simulated annealing explores this space. Each permutation is transformed into a solution to the original problem by applying the construction heuristic to the pieces in the order given by the permutation. Early implementations of this strategy were often abandoned as the cost function calculation proved too expensive but this is now less of a problem. For example, Burke et al. (2008) use simulated annealing to order the pieces in a two-dimensional packing problem and then pack them using a commonly used heuristic placement policy.

Search heuristics other than simulated annealing also involve acceptance/rejection decisions. There are several examples in which such decisions are made using a simulated annealing acceptance criterion. For example, in some genetic algorithm implementations, a decision as to whether or not a child is to replace its parent is required. While standard practice is to select the fittest of the two, some implementations replace the parent with the child even if the child is worse using the Boltzmann distribution. Examples of this type of approach include Pakhira (2003). Another class of algorithms that need to make acceptance/rejection decisions are hyperheuristics. A hyperheuristic is essentially a high-level heuristic that selects from a number of low-level heuristics to use at different points of the search. This choice may be made in a number of ways but is usually based on some measure of recent performance. Bai et al. (2006) compare a simulated annealing acceptance rule with other options and show that the SA rule works well.

Local search is often used as an ingredient of other search heuristics. For example, in GRASP it is an integral part, while it is now almost always used in an ant colony optimization (ACO) algorithm, and is frequently included in a genetic algorithm, when it is known as a memetic algorithm. In the simplest cases, the local search is a simple downhill search, but some implementations use simulated annealing in this role. Examples include Liu et al. (2000) in a GRASP approach to the frequency assignment problem, Chen et al. (2005) in an ACO heuristic to solve a vehicle routing problem, Guo et al. (2006) in a memetic algorithm for a knapsack problem, and Ge et al. (2007) in a particle swarm optimization algorithm to solve the job shop scheduling problem. However, unless simulated annealing is to become the primary search mechanism the time allowed must be kept relatively low. As success depends on slow cooling, the use of SA in this context has received some criticism.

The above examples involve the use of SA within another algorithm. A further class of hybrids involve the embedding of other methods within SA. Mention has already been made of VLNS and basin hopping in which optimization techniques are used to search large neighborhoods. In the case of discrete problems, examples include the use of dynamic programming, network flow models, and shortest path algorithms, while for continuous differentiable landscapes gradient methods can be applied.

In other cases, simulated annealing implementations may be enhanced by the use of ingredients from other approaches. For example, a tabu list is sometimes applied to ensure that cycling is avoided (Altiparmak and Karaoglan 2008), or a population of simulated annealing runs is used, with the worst performing members being periodically killed off and replaced by solutions found by the better runs (van Hentenryck and Vergados 2007).

Finally, there are many examples of implementations that involve several different heuristics including SA that are run independently at different points in the search.

8 Applications

As illustrated by the examples in the previous sections, simulated annealing has been used across a broad spectrum of application areas. A comprehensive survey is beyond the scope of this chapter. Instead, a few key application areas are highlighted and some examples are cited to illustrate the diversity of problems where simulated annealing has been applied successfully.

One of the earliest practical applications was in electronic engineering where it became a popular approach for placement and routing problems in VLSI design (Sechen and Sangiovanni-Vincentelli 1988; Chandy and Banerjee 1996; Wong et al. 1998). Since then it has been applied across a wide range of engineering applications. Examples include reactive power planning (Chen and Ke 2004; Jwo et al. 1995), optimizing fuel cells (Outeiro et al. 2008; Wishart et al. 2006), designing building frames (Paya et al. 2008), concrete bridge frame construction (Perea et al. 2008), and the design of steel frame structures (Degertekin 2007).

The operational research community was also quick to embrace simulated annealing and in 1990 Eglese (1990) published a paper entitled “simulated annealing: A general tool for operational research” that was recently selected by the European Association of Operational Research Societies (EURO) as one of the 30 most influential papers published in the *European Journal of Operational Research* between 1975 and 2005. Initial interest was in benchmark instances of classical problems such as the traveling salesman problem, graph coloring, etc. but this soon shifted to real-life problems in a variety of application areas. These include the fields of scheduling (Sekiner and Kurt 2007; Thompson and Dowsland 1998), routing (Tavakkoli-Moghaddam et al. 2007; Van Breedam 1995), location problems (Erdemir et al. 2008), and packing problems (Egeblad and Pisinger 2009; Gomes and Oliveira 2006).

Due to its ability to solve messy problems without any restrictions on the form of the objective function or the structure of the constraints, SA remains a popular choice of optimizer for a variety of scientific applications. A particularly vibrant area of research is in medicine, where it has been used to plan dosages in radiotherapy treatment (Jacob et al. 2008; Kubicky et al. 2008; Morton et al. 2008) and to optimize parameters in medical simulation models, for example, Marsh et al. (2007) and Choi et al. (2004). It is also widely used in the field of earth sciences and agriculture. Applications include land use allocation (Sante-Riveira et al. 2008), the study of gravity and seismic data (Yu et al. 2008), estimating sea surface

temperature (Arai and Sakakibara 2006), optimizing water distribution in irrigation canals (Monem and Namdarian 2005) and determining harvest schedules (Crowe and Nelson 2005). Examples of other fields include astronomy (Cornish and Porter 2007), genetics (Tewari et al. 2008), chemistry (De Andrade et al. 2008), and economics (Chen and Yeh 2001).

9 Conclusions

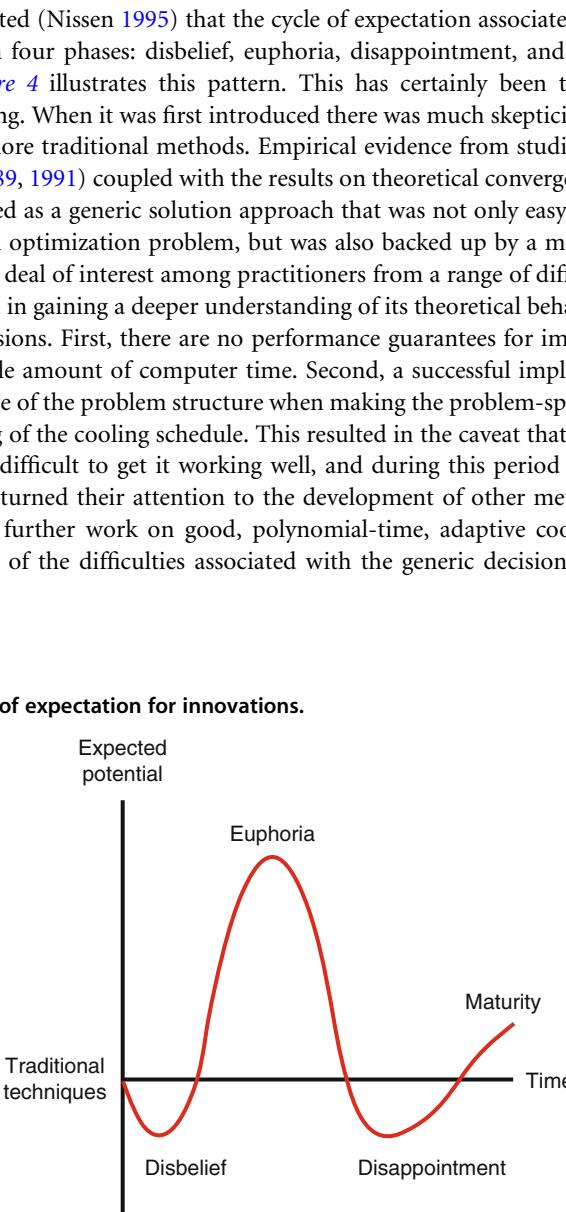

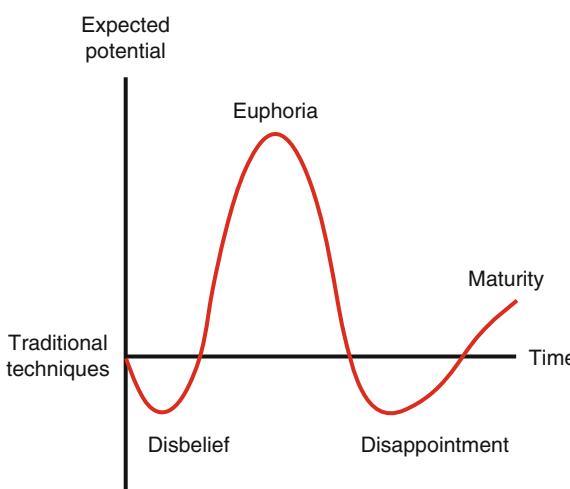

It has been suggested (Nissen 1995) that the cycle of expectation associated with any innovation goes through four phases: disbelief, euphoria, disappointment, and maturity or abandonment.  Figure 4 illustrates this pattern. This has certainly been true in the case of simulated annealing. When it was first introduced there was much skepticism about its ability to do as well as more traditional methods. Empirical evidence from studies such as those by Johnson et al. (1989, 1991) coupled with the results on theoretical convergence led to a period when SA was hailed as a generic solution approach that was not only easy to apply to almost any combinatorial optimization problem, but was also backed up by a mathematical theory. This led to a great deal of interest among practitioners from a range of different fields, as well as those interested in gaining a deeper understanding of its theoretical behavior. These studies led to two conclusions. First, there are no performance guarantees for implementations that run in a reasonable amount of computer time. Second, a successful implementation usually requires knowledge of the problem structure when making the problem-specific decisions and careful fine tuning of the cooling schedule. This resulted in the caveat that while SA is easy to get working, it is difficult to get it working well, and during this period of disillusionment, many researchers turned their attention to the development of other meta-heuristic techniques. Since then, further work on good, polynomial-time, adaptive cooling schedules has ameliorated some of the difficulties associated with the generic decisions, while a range of

 Fig. 4
The Nissen model of expectation for innovations.

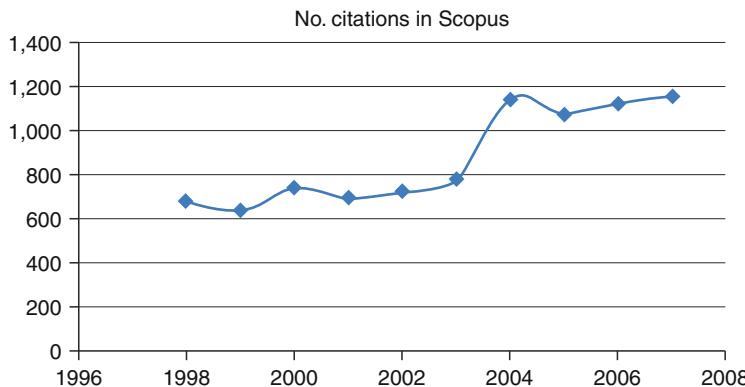

successful implementations on both real and artificial problems have been published. This has led to SA reaching maturity as a useful addition to the optimization toolkit.

As outlined in [Sect. 7](#), there has been a lot of research into ways of modifying the standard Metropolis algorithm in order to increase the range of problems that can be tackled successfully. Some of these are backed up by theory and/or are based on sound reasoning and have become common in many practical implementations. An obvious example is the use of reheating, which makes sense as the best, rather than the final, solution is returned. Others are ad hoc methods that have been shown to be successful on the problems to which they have been applied but have often not been taken up by others. Although these ideas may work for other problems, before bending the rules of SA too far, it is worth considering whether or not another heuristic, or some form of hybrid, may be more appropriate. Unfortunately there is little guidance on this. There have been a number of articles and larger projects comparing the performances of different heuristics on both benchmark and practical problems. For example, methods based on simulated annealing have performed strongly in two recent international timetabling competitions, with a simulated annealing implementation winning the 2003 competition (Kostuch [2004](#)) and a GRASP-simulated annealing hybrid coming second to a constraint-satisfaction approach in the examination scheduling track in 2008 (Gogos et al. [2008](#)). Other examples where simulated annealing has been shown to outperform other heuristics, or beat previous best-known results on benchmark problems include Egebald and Pisinger ([2009](#)), Rodriguez-Tello et al. ([2008](#)), and Zolfaghari and Liang ([2002](#)). Egebald and Pisinger consider two- and three-dimensional knapsack packing problems and produce competitive results on benchmark datasets, and Rodriguez-Tello et al. improve several best known results for benchmark problems for the minimum linear arrangement problem. Zolfaghari and Liang demonstrate that simulated annealing outperforms both genetic algorithm and tabu search methods on machine-grouping problems. However, the results from comparative studies need to be interpreted with care as the solution quality of any implementation depends as much on the skill of its designer as on the underlying heuristic. This point is clearly illustrated in Tiourine et al. ([1995](#)) in which different research groups applied one or more solution approach to the same problem with simulated annealing, tabu search, and genetic algorithms each being implemented by more than one group. The resulting implementations were then scored on a number of different factors. In all three cases, the implementations from different groups resulted in a different set of scores.

In the last 3 decades, there has been a range of competitive new heuristics, many also inspired by nature. In spite of this, an examination of the number of citations of the term “simulated annealing” in Scopus indicates that research is still prospering (see [Fig. 5](#)). The occurrence of simulated annealing-based solutions in the scientific literature increased between 2002 and 2004 and has remained steady for the last few years, suggesting that it is still regarded as a strong candidate for the solution of practical problems. In 2007, there were more than twice as many references for simulated annealing than there were for “tabu search” (including “taboo search”) or “ant colony.” Thus it remains a vibrant and exciting area of research. This is in part due to the fact that the claim of its early advocates remains true. It is very easy to get it working. For some problems a straightforward implementation using the most obvious definitions of solution space, neighborhood structure, and cost function, combined with a simple geometric or Lundy and Mees cooling schedule, may be all that is required. If this is not the case, then more sophisticated problem-specific decisions or a more complex cooling schedule can be the focus of further development. It is worth noting here that when undertaking such development, graphical information can be invaluable. If solutions are

Fig. 5

The number of citations of the term “simulated annealing” in Scopus.

easy to visualize (as with routing or packing problems) many researchers have found it worthwhile to build in routines that show how the current solution changes as the run progresses. Failing this, plots of statistics such as best cost, average cost, acceptance rate, entropy, specific heat, etc. often provide useful clues.

As shown in Fig. 5, simulated annealing continues to be of interest to researchers working in both practical and theoretical areas. This chapter has given a brief overview, with our main focus being the practical solution of combinatorial optimization problems. For a slightly different viewpoint, Aarts et al. (2005), Salamon et al. (2002), and Henderson et al. (2003) are suggested. Freely downloadable simulated annealing software is available from a variety of sources. Examples include a C language downloadable code of adaptive simulated annealing, where the algorithm parameters are automatically adjusted according to the progress of the algorithm (www.ingber.com), code for solving constrained, single-objective problems (<http://manip.crhc.uiuc.edu/CSA/>), a general purpose simulated annealing package designed for parallel machines (<http://wwwcs.uni-paderborn.de/fachbereich/AG/monien/SOFTWARE/PARSA>), and a framework for simulated annealing to be implemented within Matlab (<http://www.frostconcepts.com/software/index.html>).

Abstract

This chapter surveys the field of evolvable hardware. After a brief overview of the reconfigurable devices used in evolvable hardware, elementary principles of evolvable hardware, corresponding terminology, and open problems in the field are introduced. Then, the chapter is divided into three main parts: extrinsic evolution, intrinsic evolution, and adaptive hardware. Extrinsic evolution (i.e., evolution using simulators) covers evolutionary design of digital circuits, analog circuits, antennas, optical systems, and microelectromechanical systems (MEMS). Intrinsic evolution conducted in field programmable gate arrays (FPGAs), field programmable transistor arrays (FPTAs), field programmable analog arrays (FPAs), and some unconventional devices is discussed together with a description of the most successful applications. Examples of real-world adaptive hardware systems are also presented. Finally, an overview of major achievements and problems is given.

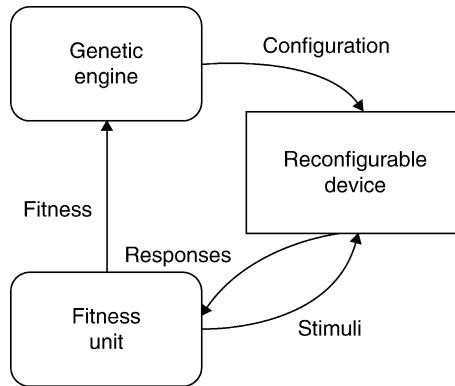

1 Introduction

At the beginning of the 1990s, researchers began using evolutionary algorithms (EAs) – population-based search algorithms (Eiben and Smith 2003) – to generate configurations for reconfigurable chips that could dynamically alter the functionality and physical connections of their circuits. This combination of EAs with reconfigurable devices spawned a new field called evolvable hardware (EHW) (Higuchi et al. 1993; de Garis 1993). Since that time, the EHW field has expanded and utilized many different combinations of EAs and biologically inspired algorithms with various reconfigurable devices including field programmable gate arrays (FPGAs), field programmable analog arrays (FPAs), reconfigurable antennas, mirrors, MEMS, and special reconfigurable materials. Research in the field of EHW can be split into the two related areas of evolutionary hardware design and adaptive hardware. While evolutionary hardware design is the use of EAs for creating innovative (and sometimes patentable) physical designs, the goal of adaptive hardware is to endow physical systems with some adaptive characteristics in order to allow them to operate successfully in a changing environment or under the presence of faults.

❶ *Figure 1* shows the basic principle of the evolvable hardware method: Electronic circuits that are encoded as bit strings (chromosomes, in the parlance of EAs) are constructed and optimized by the evolutionary algorithm in order to obtain the circuit implementation satisfying the specification given by the designer. In order to evaluate the candidate circuit, the new configuration of a reconfigurable device is created on the basis of the chromosome content. This configuration is uploaded into the reconfigurable device and evaluated for a chosen set of input stimuli. The fitness function, which reflects the problem specification, can include behavioral as well as nonbehavioral requirements. For example, the correct functionality is a typical behavioral requirement. As a nonbehavioral requirement, we can mention the requirement for minimum power consumption or minimum area occupied on the chip. Once the evaluation of the population of candidate circuits is complete, a new population can be produced. That is typically performed by applying genetic operators (such as mutation and crossover) on existing circuit configurations. High-scored candidate circuits have a higher probability that their genetic material (configuration bitstreams) will be selected for future generations. The process of evolution is terminated when a perfect solution is obtained or when a certain number of generations is evaluated.

Fig. 1

Evolvable hardware: Candidate configurations are generated by evolutionary algorithm, uploaded to a reconfigurable device and evaluated using the fitness function.

As the EA is a stochastic algorithm, the quality of resultant circuits is not guaranteed at the end of evolution. However, the method has two important advantages: (1) Artificial evolution can in principle produce intrinsic designs for electronic circuits, which lie outside the scope of circuits achievable by conventional design methods. (2) The challenge of conventional design is replaced by that of designing an evolutionary algorithm that automatically performs the design in a target place (e.g., in space). This may be harder than doing the design directly, but makes autonomy possible.

This chapter surveys the field of evolvable hardware. A more detailed explanation can be found in monographs (Zebulum et al. 2002; Thompson 1999; Greenwood and Tyrrell 2007; Higuchi et al. 2006; Sekanina 2004; Koza et al. 1999, 2003). The most important journals dealing with evolvable hardware are Genetic Programming and Evolvable Machines and IEEE Transactions on Evolutionary Computation. A lot of valuable material can be found in the conference proceedings: Evolvable Systems: From Biology to Hardware (Springer, 1996–), NASA/ESA Conference on Adaptive Hardware and Systems (IEEE, 2006–) and NASA/DoD Conference on Evolvable Hardware (IEEE, 1999–2005).

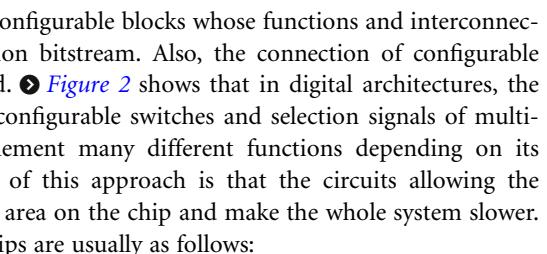

This chapter is organized as follows. [Section 2](#) presents reconfigurable devices that can be used for evolvable hardware. In [Sect. 3](#), elementary principles of evolvable hardware and corresponding terminology are introduced. [Section 4](#) surveys the area of extrinsic evolution, i.e., evolutionary hardware design using simulators. [Section 5](#) deals with the evolution conducted directly in physical hardware. Applications of evolutionary computing in the area of adaptive hardware are described in [Sect. 6](#). Some other relevant research dealing with bioinspired algorithms and hardware is discussed in [Sect. 7](#). Conclusions are given in [Sect. 8](#).

2 Reconfigurable Technology

Common electronic chips such as processors or application-specific integrated circuits have an architecture that remains fixed during the lifespan of a system. It is impossible to change the architecture at runtime when faults occur in circuit components or even when a little

modification introduced in a certain time could lead to a much better performance of the system. In recent years, we can observe a boom in the area of reconfigurable devices (Hauck and DeHon 2008). In comparison to fixed architectures, the structure and parameters of reconfigurable chips can be modified by writing configuration data to the configuration memory. While the first programmable devices (such as programmable logic arrays) used hundreds of bits to store the configuration, recent FPGAs require tens of megabytes to store their configuration data.

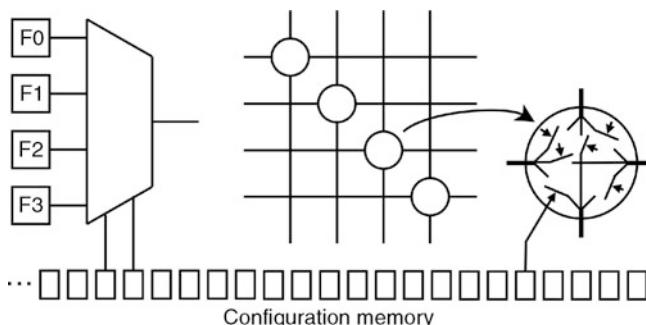

2.1 Why Reconfiguration?

Most reconfigurable devices consist of configurable blocks whose functions and interconnections are controlled by the configuration bitstream. Also, the connection of configurable blocks with I/O pins can be configured.  Figure 2 shows that in digital architectures, the configuration bits directly control the configurable switches and selection signals of multiplexers. Thus, a single chip can implement many different functions depending on its configuration. The main disadvantage of this approach is that the circuits allowing the “configurability” occupy a considerable area on the chip and make the whole system slower. The reasons for using reconfigurable chips are usually as follows:

- *Updating the firmware.* The reconfiguration extends the lifespan of a system. For example, when a new driver or peripheral device is introduced to a system, existing hardware could have a problem to communicate with it. However, if the system is implemented in a reconfigurable chip, the hardware can be updated by simply reprogramming the configuration memory. In this case, the reconfiguration is performed occasionally and only when the application is suspended.
- *Increasing the functional density.* The goal is to perform a complex task on a small chip and thus reduce the power consumption, size or weight of the application, even reduce the cost. The application has to be divided into modules whose configurations alternate on the chip. The reconfiguration is performed dynamically at runtime.
- *Increasing the reliability.* When a fault is detected and isolated, a system can be (in some cases) reconfigured to maintain its original function.

 Fig. 2

Multiplexer-based implementation of a reconfigurable functional unit (*left*) and a configurable interconnecting network implemented by configuration switches (*right*).

- *Adapting hardware.* The goal is to dynamically create electronic circuits that are optimized for a given task, time, and location of the chip.
- *Shortening the design time.* Creating a configuration for a reconfigurable device usually takes much less time than building a new application-specific chip.

The possibility of reconfiguration is typical for digital architectures. However, reconfigurable devices are now available in the areas of analog circuits, antennas, mirrors, molecular electronics, and others. Major digital and analog reconfigurable devices used in the evolvable hardware field will be briefly described.

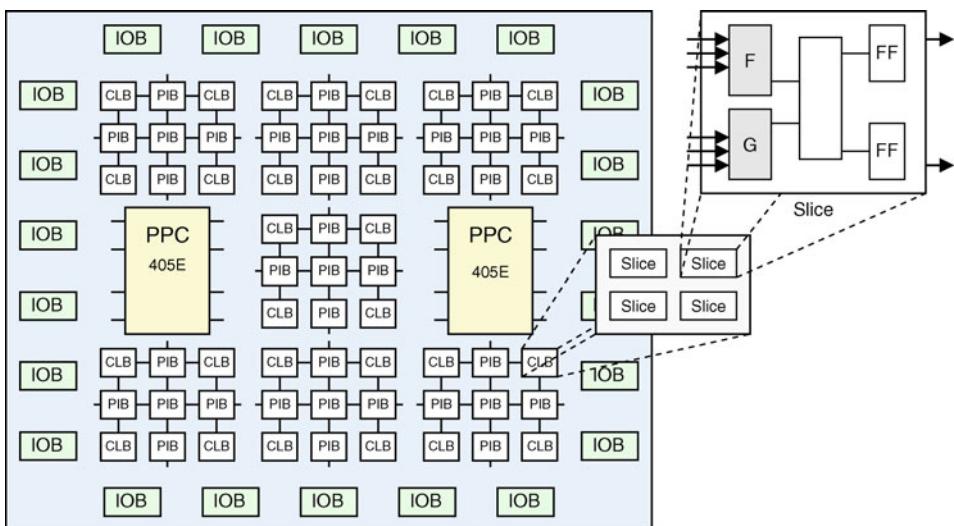

2.2 Field Programmable Gate Arrays

- ➊ *Figure 3* shows a typical architecture of a Xilinx FPGA (Xilinx Inc. 2009). It is a two-dimensional array of reconfigurable resources that include configurable logic blocks (CLB), programmable interconnect blocks (PIB), and reconfigurable I/O blocks (IOB). A CLB consists of so-called slices; each of them contains the function generators implemented using 3-, 4- or 6-input look-up tables, flip-flops, and some additional logic. The configuration bitstream is stored in the configuration SRAM memory.

The FPGA chips differ in the amount and type of resources available on the chip. The most advanced FPGAs contain more than 10 thousand CLBs and integrate, in addition to CLBs, various embedded hard cores such as SRAM memories, fast multipliers, processors, gigabit interfaces, and PCI interfaces (see PowerPC processors in ➋ *Fig. 3*). Because the existence of these cores has been identified as important to designers in the past, it is reasonable to integrate them as hard cores on the chip instead of implementing them using CLBs and other resources. Current FPGAs can compete with application-specific integrated circuits

➋ **Fig. 3**

FPGA Virtex II Pro architecture that contains two PowerPC processors.

(ASICs) in many domains, for example, in applications of advanced signal processing or embedded systems.

Some FPGAs support a dynamic partial reconfiguration, which means that some parts of the FPGA can be reconfigured while remaining parts of the FPGA perform computation. In the following sections it will be seen that the possibility of partial reconfiguration is crucial for evolvable hardware. FPGAs can be configured either externally or internally. In the case of external reconfiguration, the configuration bit stream is copied to the configuration memory from an external (flash) memory. The internal reconfiguration is available in Xilinx Virtex FPGAs via the internal access configuration port (ICAP), which allows for reading and modifying the FPGA configurations by circuits created directly in the same FPGA.

The goal of digital circuit design is to provide such an implementation of the circuit which satisfies the user specification and is available in a reasonable time. As the conventional circuit design process with FPGAs is very similar to programming, the resultant system can be obtained relatively quickly. The designer has to describe the circuit structure or behavior using a hardware description language (such as VHDL or Verilog). Then, the source code is almost automatically transformed into the configuration bit stream for a particular FPGA. The transformation, which includes the synthesis, placement and routing is performed by CAD tools. This process can be constrained using various requirements, for example, the maximum delay of the circuit can be specified. Also, it is possible to simulate intermediate results of the transformation, modify the original source code when needed, and optimize the design. In most cases, the format of the configuration bit stream is not documented for the designer (with the exception of the XC6200 family). In this way, manufacturers protect their know-how and prevent the designers from physically destroying the FPGA chip.

2.3 Field Programmable Transistor and Analog Arrays

Reconfigurable analog circuits allow, in fact, a software control of analog circuits. In comparison with FPGAs, reconfigurable analog circuits contain fewer configurable blocks and operate at lower frequencies. The reconfiguration is usually based either on configurable transistor switches, analog multiplexers, switching capacitors, or operational transconductance amplifiers (OTAs). Reconfigurable analog chips were introduced much later than FPGAs.

2.3.1 FPTA-2

The field programmable transistor array (FPTA-2) developed at NASA JPL uses transistor switches to implement the reconfiguration (Stoica et al. 2002). The FPTA-2 can implement analog, digital, and mixed signal circuits. The architecture of the FPTA consists of an 8×8 array of reconfigurable cells. Each cell has a transistor set as well as a set of programmable resources, including programmable resistors and static capacitors. The reconfigurable circuitry consists of 14 transistors connected through 44 switches in each cell. ◉ [Figure 4](#) provides a detailed view of the reconfigurable transistor array cell. A total of 5000 bits are used to program the whole chip. The pattern of interconnection between cells is similar to the one used in commercial FPGAs: each cell interconnects with its north, south, east, and west neighbors. Another FPTA was developed at the University of Heidelberg (Langeheine 2005). This chip enables developing circuits directly at the transistor level; the designer can select the transistor type (P/N), parameters (channel length and size), and interconnection.

2.3.2 Anadigm FPAA

The reconfiguration of field programmable analog arrays (FPAA) is typically based on either switched capacitors or OTAs. Switched capacitors perform the function of configurable resistors. [Figure 5](#) shows the principle: capacitor C is connected between two switches controlled by signals S_1 and S_2 . The switches are implemented using unipolar transistors and signals S_1 and S_2 are nonoverlapping clocks. The charge Q over one clock period transferred to the capacitor C is given by

$$Q = C(V_1 - V_2) \quad (1)$$

and the average current associated to this charge is

$$I_a = C(V_1 - V_2)/T \quad (2)$$

where T denotes the clock period. The value of the equivalent resistor can be calculated as

$$R = (V_1 - V_2)/I_a = T/C \quad (3)$$

Fig. 4

A single cell of the FPTA-2 chip (Stoica et al. 2002). Configuration switches are shown as circles.

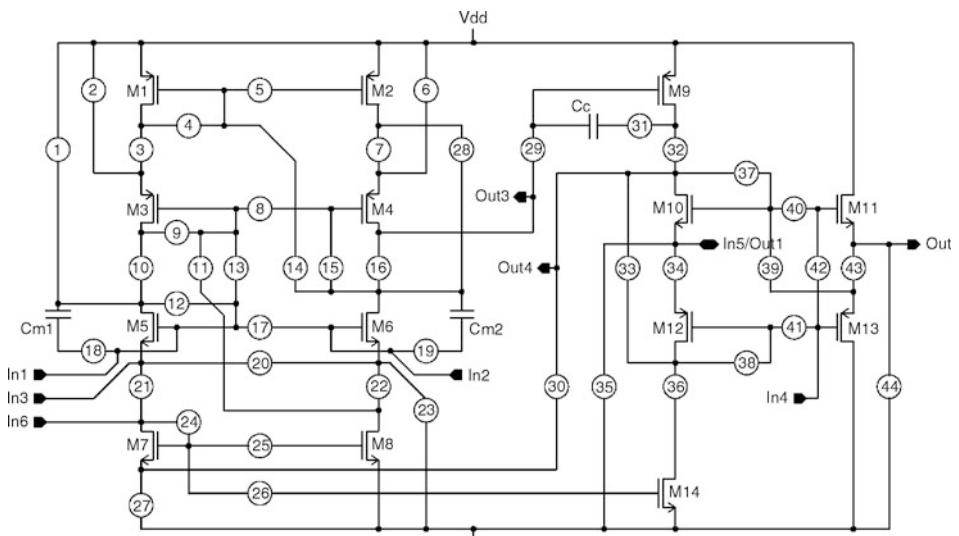

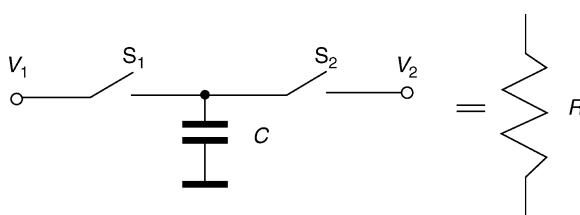

Fig. 5

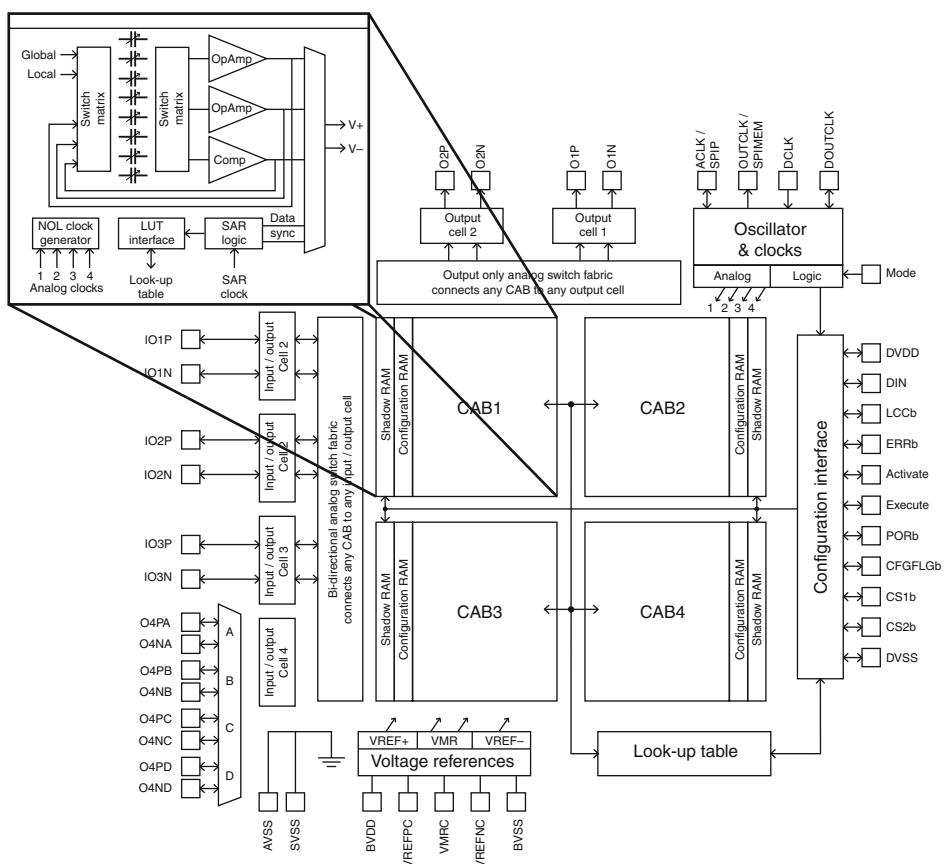

Switched capacitor and its equivalent resistor.

This resistor value can be controlled by the switching frequency $f = 1/T$. In comparison to conventional resistors, switching capacitors are advantageous in terms of linearity, dynamic range, precision, and size on the chip. As f can be controlled from software, analog circuits (such as filters and oscillators) can be easily tuned. A disadvantage might be that circuits containing switched capacitors operate in the discrete domain, that is, there is a limit on the possible operation frequency that is determined by f .

The commercially available Anadigm AN221E04 FPAA (Anadigm 2007), developed using switching capacitors, is an array of four configurable analog blocks (CAB), each of which contains two OpAmps, a comparator, and a successive approximation register (SAR) that performs 8-bit analog-to-digital conversion of signals. The device also contains one programmable look-up table that can be used to store information for the generation of arbitrary waveforms, and is shared among the CABs. The FPAA architecture is shown in Fig. 6. The configuration bit stream is stored in SRAM and the maximum switching frequency is 16 MHz.

Fig. 6
Anadigm AN221E04 FPAA (Anadigm 2007).

2.3.3 Operational Transconductance Amplifiers

Another approach to software control of analog circuits is based on operational transconductance amplifiers (OTAs). A typical OTA produces a current output I_0 that linearly depends on an input voltage present at both an inverting input (V_-) and non-inverting input (V_+):

$$I_0 = -g_m(V_+ - V_-) \quad (4)$$

where g_m is the transconductance of the circuit. The transconductance can be predefined or programmable using an external biasing current input I_{set} (see Fig. 7). Biasing currents for OTAs are generated using DACs. Ideally, the circuit has infinite values for both the input and output impedances. OTAs are the main building blocks of continuous time filters in which the transconductance (and thus the frequency characteristics) can be controlled externally. An example of an FPAA that utilizes configurable OTAs is that developed at the University of Freiburg (Henrici et al. 2007).

2.4 Other Reconfigurable Devices

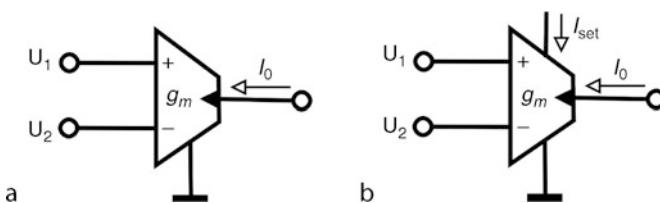

Evolutionary design has been performed for many other reconfigurable devices. Special ASICs include reconfigurable chips: POETic (Moreno et al. 2005), RISA (Greensted and Tyrrell 2007), PAMA (Zebulum et al. 2002), and REPOMO32 (Sekanina et al. 2009). Among more exotic examples, we find reconfigurable mirrors (Loktev et al. 2003), reconfigurable nanosystems (Tour 2003), reconfigurable antennas (Linden 2001) and reconfigurable liquid crystals (Harding et al. 2008). Whenever needed, detailed descriptions of these devices will be given in the sections below devoted to particular examples of evolvable systems.

3 First Approaches to Evolvable Hardware and Terminology

Practically, since the very beginning of the research in evolutionary computation, evolutionary algorithms have been applied in the area of hardware optimization. One of the earliest works was the optimization of wiring configurations for a subsystem on a ballistic missile, published in 1963 (Lohn and Hornby 2006). Various monographs (Drechsler 1998; Larsson 2005) summarize the applications from the areas of electronic circuits design, diagnostics, and testing. Later, evolutionary algorithms were applied to generate complete circuit structures, that is, not only to optimize parameters of existing circuits.

Fig. 7

Operational transconductance amplifiers with fixed transconductance (a), transconductance programmable by I_{set} (b).

3.1 Higuchi's Experiment

In their pioneering work from 1992, Higuchi et al. used a genetic algorithm to create configurations for a physical electronic chip, the GAL16Z8 – a predecessor of modern FPGAs (Higuchi et al. 1993). This chip uses a programmable AND/OR array to implement digital circuits in the form of “sum of products.” Only a part of the chip was utilized resulting in a chromosome size of 108 bits. A relatively simple combinational circuit (6-input/1-output multiplexer) was evolved only on the basis of its behavioral input/output specification. In order to obtain the fitness value, the candidate circuit response was measured for all possible input patterns (i.e., 2^6 combinations). For each correct output value, the fitness score was incremented, resulting in the maximum fitness value of 64 points. In this experiment, candidate configurations were evaluated using the GAL simulator. Only the resulting configuration was uploaded into the physical chip at the end of the evolution and tested physically. The scenario that employs a circuit simulator is known as *extrinsic evolution* (sometimes called offline evolution). This experiment is considered the birth of evolvable hardware.

3.2 Thompson's Experiment

In 1996 and the following years, Adrian Thompson performed a series of experiments, which clearly demonstrated that there can be a significant difference in the resulting behavior if candidate circuits are evaluated not in a circuit simulator but directly in a physical reconfigurable device (Thompson 1996). Thompson used an FPGA XC6216 chip to evolve a tone discriminator – a circuit discriminating between square waves of 1 and 10 kHz. With 10×10 configurable blocks of an XC6216 device, the circuit has to output 5 V for one of the frequencies and 0 V for the other. The problem is that the evolved circuit has to discriminate between input periods five orders of magnitude longer than the propagation time of each configurable block. No external components or synchronization signals were provided as is typical for conventional solutions to this problem.  [Figure 8](#) shows the experimental setup.

The goal of the evolution is to maximize the difference between the average output voltage when the 1 and 10 kHz input signals are applied:

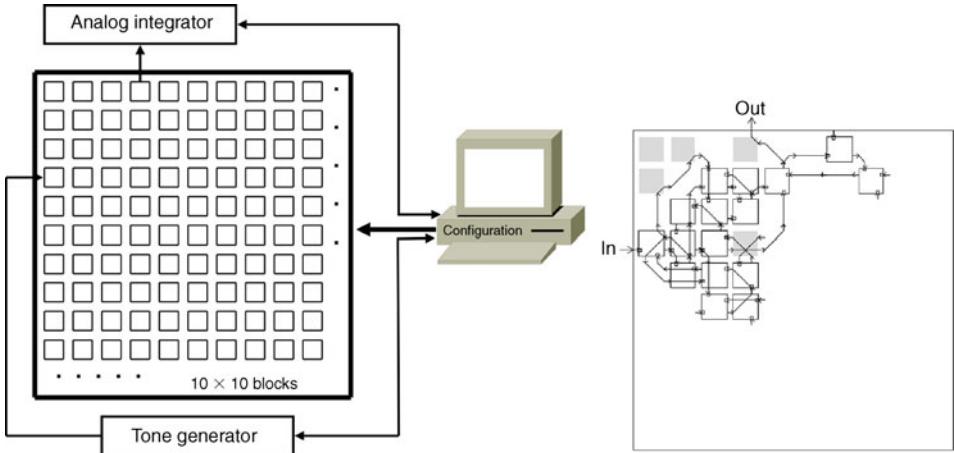

$$\text{fitness} = \frac{1}{5} |(k_1 \sum_{t \in S_1} i_t) - (k_2 \sum_{t \in S_{10}} i_t)| \quad (5)$$

where i_t represents the integrator output at the end of test tone t , S_1 is the set of 1 kHz tones, and S_{10} is the set of 10 kHz tones. k_1 and k_2 are experimentally determined constants.

Fortunately, the format of the configuration bit string of XC6216 was known to the users. Hence, Thompson could use a very efficient and fast dynamic reconfiguration to quickly generate new candidate circuits, though the experiment took 2–3 weeks because of time-consuming evaluation (around 5 s) of every individual.  [Figure 8](#) shows one of the evolved solutions. Only 21 out of 10×10 blocks contribute to the actual circuit behavior. In particular, gray-labeled blocks are very important in the solution. Although they are not connected, they also influence the circuit behavior. According to Thompson, these blocks interact with the circuit in some nonstandard ways. The evolved circuit was carefully analyzed using simulators, tested under different conditions, and on other XC6216 chips (Thompson et al. 1999). Surprisingly, Thompson was not able to create a reliable simulation model of the evolved circuit. In addition, he observed that the circuit works only in the chip used during evolution.

Fig. 8

Thompson's experiment setup (left) and utilization of logic blocks in evolved circuit (right, according to Thompson (1996)).

Although the circuit has a digital interface, its internal behavior is typical for analog circuits. It can be stated that the evolution was able to explore a full repertoire of behaviors available from the silicon resources provided to create the required behavior. This is an outstanding result, practically unreachable by means of conventional design methods. Hence, this experiment stimulated a lot of research in the evolvable hardware field.

The approach in which all candidate circuits are evaluated in a physical hardware is known as *intrinsic evolution* (sometimes called online evolution). The main advantage of the approach is that evolved circuits can be perfectly adapted to a given hardware substrate and external environment (temperature, radiation, ...) where the evolutionary design was carried out. On the other hand, intrinsically evolved solutions might not be robust and so portable to other reconfigurable devices. In order to avoid the portability problem, Stoica et al. introduced the so-called *mixtrinsic evolution*, in which some individuals are evaluated intrinsically and others extrinsically (Stoica et al. 2000).

3.3 Scalability Problems

The evolutionary circuit design is not competitive in all design problems because of the so-called *scalability problems*. From the viewpoint of the *scalability of representation*, the problem is that long chromosomes, which are usually required to represent complex solutions imply large search spaces that are typically difficult to search. In many cases, even a well-tuned parallel evolutionary algorithm running on a cluster of workstations fails to find an adequate solution in a reasonable time. In order to evolve large designs and simultaneously keep the size of the chromosome small, four main techniques have been developed:

- *Functional-level evolution* (Murakawa et al. 1996): Instead of gates and single-wire connections, the system is composed of complex application-specific functional blocks (such as adders, multipliers, and comparators) connected using multi-bit connections.

The selection of suitable functional blocks represents a domain knowledge that has to be included in the system.

- *Incremental evolution* (Torresen 1998, 2002): Target circuit is decomposed onto modules that are evolved separately. The decomposition strategy is a kind of domain knowledge that has to be supplied by the designer.
- *Development* (Kitano 1996; Koza et al. 1999): The above mentioned approaches employ a direct encoding of the target circuit (phenotype) in the chromosome (genotype). Hence, the size of the chromosome is proportional to the size of the circuit. Developmental approaches utilize indirect (generative) encodings that specify how to construct the target circuit. The phenotype is in fact constructed by a program that is encoded in the genotype. Designing these developmental encodings is not trivial and represents a domain knowledge that has to be supplied by the designer.
- *Modularization* (Walker and Miller 2008; Koza et al. 1999): Some EAs enable us to dynamically create and destroy reusable modules (subcircuits). The reuse of modules make the evolution easier even for large circuits.

Another problem is related to the fitness calculation time. In the case of the combinational circuit evolution, the evaluation time of a candidate circuit grows exponentially with the increasing number of inputs (assuming that all possible input combinations are tested in the fitness function). Hence, the evaluation time becomes the main bottleneck of the evolutionary approach when complex circuits with many inputs are evolved. This problem is known as the problem of *scalability of evaluation*. In order to reduce the time of evaluation, various techniques have been adopted:

- Only a subset of all possible input vectors is utilized. That is typical for the evolution of filters, classifiers, or robot controllers (Higuchi et al. 2006). Unfortunately, nobody can guarantee correct circuit behavior for those input combinations that were not used during evolution. Hence, evolved circuits have to be validated at the end of evolution using a test set – a representative set of input vectors that differ from the training set.
- In some cases, it is sufficient to evaluate only some structural properties (not the function) of candidate circuits that can be done with a reasonable time overhead. For example, because the testability of a candidate circuit can be calculated in a quadratic time, very large benchmark circuits (more than 1 million gates) with predefined testability properties were evolved (Pecenka et al. 2008).
- If the target system is linear, it is possible to perfectly evaluate a candidate circuit using a single input vector independently of the circuit complexity. Multiple-constant multipliers composed of adders, subtracters, and shifters were evolved for tens of outputs (Vasicek et al. 2008).

An obvious conclusion is that the perfect evaluation procedures are applicable only for small circuits or in very specific cases of large circuits. On the other hand, when more complex circuits have to be evolved, only an imperfect fitness calculation method may be employed due to time constraints.

4 Evolutionary Design Using Simulators

This section is devoted to extrinsic evolution of hardware. It covers the evolutionary design of digital circuits (at various levels), analog circuits, antennas, optical systems, and MEMS.

4.1 Gate-Level Evolution Using Cartesian Genetic Programming

Cartesian genetic programming (CGP), introduced by Miller and Thompson (2000), is a widely used method for extrinsic evolution of digital circuits and programs. CGP was originally defined for gate-level evolution; however, it can easily be extended for functional-level evolution. In its basic variant, candidate circuits are directly represented in the chromosome.

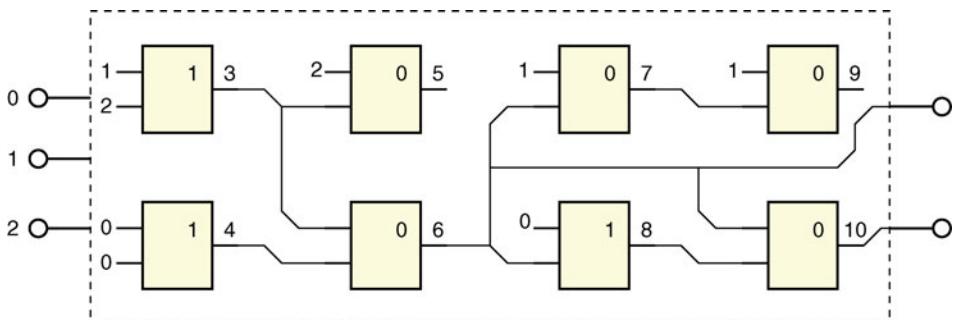

In CGP, a candidate entity (program or circuit) is modeled as an array of u (columns) \times v (rows) of programmable elements (gates). The number of inputs, n_i , and outputs, n_o , is fixed. Each node input can be connected either to the output of a node placed in the previous L columns or to some of the program inputs. The L -back parameter, in fact, defines the level of connectivity and thus reduces/extends the search space. For example, if $L = 1$ only neighboring columns may be connected; if $L = u$, full connectivity is enabled. Feedback is not allowed. Each node is programmed to perform one of n_n -input functions defined in the set Γ (n_f denotes $|\Gamma|$). As Fig. 9 shows, while the size of chromosome is fixed, the size of the phenotype is variable (i.e., some nodes are not used). Every individual is encoded using $u \times v \times (n_n + 1) + n_o$ integers. In order to make the search process easier, a common practice is to use some redundant elements in the CGP grid and a maximum value for the L -back parameter.

CGP operates with the population of $1 + \lambda$ individuals (typically, $\lambda = 5 - 20$). The initial population is randomly generated. Every new population consists of the best individual of the previous population and its λ offspring created by point mutation. If two or more individuals have received the same highest fitness score in the previous population, the individual that has not served as the parent in the previous population will be selected as the new parent. This strategy is used to ensure the diversity of population.

For the evolution of logic circuits, the fitness function is constructed in such a way that all possible input combinations are applied at the candidate circuit inputs, the outputs are collected and the goal is to minimize the difference between the obtained truth table and the required truth table. If evolution has found a solution that produces correct outputs for all possible input combinations, other parameters, such as the number of components or delay, can be optimized. The evolution is stopped when the best fitness value stagnates or the maximum number of generations is exhausted.

Fig. 9

An example of a candidate program. CGP parameters are as follows: $L = 3$, $u = 4$, $v = 2$, $\Gamma = \{\text{AND } (0), \text{OR } (1)\}$. Nodes 5 and 9 are not utilized. Chromosome: 1,2,1, 0,0,1, 2,3,0, 3,4,0, 1,6,0, 0,6,1, 1,7,0, 6,8,0, 6, 10. The last two integers indicate the outputs of the program.

The design of small multipliers is the most popular benchmark problem for gate-level evolution. Because the direct CGP approach is not scalable it works only for 4-bit multipliers and smaller multipliers.  [Table 1](#) summarizes the best-known results for various multipliers (Miller et al. 2000; Vassilev et al. 2000). For this class of circuits, CGP is able to create innovative designs, that is, circuits containing fewer gates than the best existing implementations, although only minimal domain knowledge has to be inserted into the representation.

CGP can be used to evolve compact implementations of such circuits whose efficient construction using conventional techniques is quite difficult. The construction of polymorphic circuits is a typical example (Stoica et al. 2001, 2002; Sekanina et al. 2008). Polymorphic circuits consist of conventional as well as polymorphic gates. Polymorphic gates are unconventional logic components that can switch their logic functions according to a changing environment. For example, a polymorphic gate controlled by the level of the power supply voltage exists, which operates as NAND when $V_{dd} = 3.3$ V and as NOR when $V_{dd} = 1.8$ V. Another gate operates as AND when the temperature is 27°C and as OR when the temperature is 125°C. Consider that the objective is to design a circuit that operates as a multiplier (the function will be denoted f_1) when polymorphic gates perform the NAND function and as a sorting network (the function will be denoted f_2) when polymorphic gates perform the NOR function. In order to use CGP for the design of polymorphic circuits with the minimum number of gates, the fitness function has to be modified so that a candidate circuit is evaluated in both modes. The new fitness value is defined as follows:

$$\text{fitness} = B_1 + B_2 + (u \cdot v - z) \quad (6)$$

where B_1 (resp. B_2) is the number of correct output bits for f_1 (resp. f_2) obtained as the response for all possible input combinations, z denotes the number of gates utilized in a particular candidate circuit, and $u \cdot v$ is the total number of programmable gates available. The last term is considered only if the circuit behavior is perfect in both modes; otherwise $uv - z = 0$.  [Table 2](#) summarizes the results obtained for various instances of the problem. In most cases, evolved circuits exhibit fewer gates than circuits created by multiplexing conventional implementations using polymorphic multiplexers (Sekanina et al. 2008).

4.2 Sequential Circuits

The evolution of sequential circuits is not as popular as the evolution of combinational circuits. However, evolutionary algorithms were successfully applied in the so-called state

 **Table 1**

The number of two-input gates in the best implementations of multipliers according to Miller et al. (2000) and Vassilev et al. (2000). CGP used with two-input gates AND, XOR, and AND with one input inverted, L -back is max., $\lambda = 4$

Multiplier	Best conventional	Best evolved	CGP array	Max. generations
2b × 2b	8	7	7 × 1	10k
3b × 2b	17	13	17 × 1	200k
3b × 3b	30	23	35 × 1	20M
4b × 3b	47	37	56 × 1	200M
4b × 4b	64	57	67 × 1	700M

assignment problem, the goal of which is to compute optimal binary codes for each symbolic state and construct the state transition table of a finite state machine (FSM). CGP is also used to implement combinational circuits computing the next state of the FSM. An improvement in the gate count (with respect to conventional techniques) was obtained for small circuits having up to 30 states (Nedjah and de Macedo 2005; Ali et al. 2004).

4.3 Incremental Evolution

The evolutionary design of larger gate-level circuits is usually performed using modular CGP (Walker and Miller 2008) or incremental evolution (Torresen 1998, 2002; Stomeo et al. 2006). A typical feature of circuits evolved modularly or incrementally is that they are fully functional, but no innovation is usually visible in their implementation. [Figure 10](#) shows basic approaches to the incremental evolution. The n -input/ m -output circuit can be

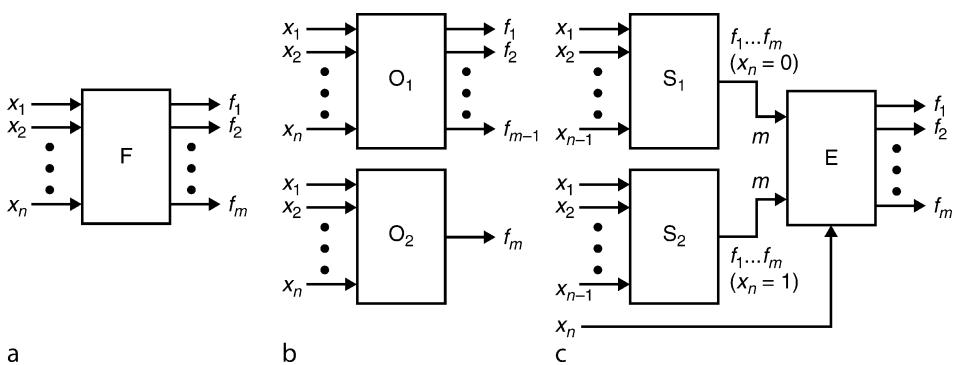

Table 2

Parameters of evolved polymorphic multipliers/sorters. Gates in “Gate set” are numbered as (1) NAND/NOR, (2) AND, (3) OR, (4) XOR, (5) NAND, (6) NOR, (7) NOT A, (8) NOT B, (9) MOV A, and (10) MOV B, where MOV denotes the identity operation. Population size is 15

Multiplier/sorter	$2b \times 2b/4b$	$3b \times 2b/5b$	$3b \times 3b/6b$	$4b \times 3b/7b$
$u \times v$	10×12	100×1	120×1	16×16
L-back	1	100	120	16
Mutation (genes)	1	2	4	4

Runs	10	10	10	10
Successful runs	10	10	9	3
Generations (average)	52,580	854,900	26,972,648	62,617,151
Min. # of gates	23	30	52	113

Fig. 10

(a) Original circuit, (b) input-oriented decomposition, (c) output-oriented decomposition.

decomposed either according to the inputs or outputs. Both decompositions can be applied recursively and thus they can yield subcircuits that can be evolved directly using CGP, for example. Advanced variants of the incremental evolution further optimize evolved modules in order to maximize the number of gates shared among them and so to reduce the total number of gates. The most complex circuits evolved by the gate-level incremental evolution were reported in Stomeo et al. (2006): 6-bit multipliers, 17-input parity circuits, and some MCNC benchmarks (such as the alu4 with 14 inputs and 8 outputs). Incremental evolution was also used to design classifiers directly in the FPGA (see ➤ Sect. 5.1.2).

4.4 Developmental Approaches

As developmental approaches employ indirect encoding, the chromosome contains a program which is executed in order to construct the target circuit. The program can be implemented as an L-system, cellular automaton, if-then-else rules or, in general, as a program.

Arbitrarily large multipliers were constructed using evolved programs working in a grid of programmable nodes (Bidlo and Skarvada 2008). However, no innovation is observable in evolved multipliers in comparison to conventional multipliers. A similar approach was proposed to create arbitrarily large sorting networks, which exhibit slightly better properties (in the number of components and delay) than sorting networks created using conventional construction algorithms (Sekanina and Bidlo 2005). Papers of Gordon and Bentley (2002), Tufte and Haddow (2005), Tempesti et al. (2007), and Zhan et al. (2008) present more biologically plausible models of development for digital circuits. Although these approaches do not lead to innovative circuit designs, they are useful for investigation of principles of development, genetic regulatory networks, environmental interactions, and fault tolerance that could be useful for evolution and adaptation of large-scale digital circuits in future.

4.5 Functional-Level Evolution

CGP can easily be modified to evolve larger circuits. Instead of gates and single-wire connections, application-specific functions and multiple-bit connections are employed. The advantage is that while the size of the chromosome is similar to the gate-level evolution, the size of the phenotype can be arbitrarily large, depending on the building blocks used. Filters, predictors, and classifiers are typical circuits designed at this level. Because of the size of the candidate circuits, it is impossible to evaluate circuit responses for all possible input vectors. Hence, candidate circuits are evaluated using a training set during evolution and validated using a test set at the end of evolution. The goal of the evolution is to minimize the difference between the response of a candidate circuit and the target response. ➤ Section 5.1 will demonstrate real-world applications of functional-level evolution accelerated in FPGAs.

4.5.1 Digital Filter Evolution

Digital filter optimization and design is one of the most common applications of evolutionary computation in the hardware field. Digital filters are traditionally modeled using discrete-time systems theory (Ifeachor and Jervis 2002). A *discrete-time* system is essentially a mathematical

algorithm that takes an input sequence, $x(n)$, and produces an output sequence, $y(n)$. A *digital filter* is an example of a discrete-time system. A discrete-time system may be linear or nonlinear, time invariant or time varying. *Linear time-invariant* (LTI) systems form an important class of systems used in digital signal processing. The input–output relationship of an LTI system is given by the convolution sum

$$y(n) = \sum_{k=-\infty}^{+\infty} h(k)x(n-k) \quad (7)$$

where $h(k)$ is the *impulse response* of the system. The values of $h(k)$ completely define the discrete-time system in the time domain. A general infinite impulse response (IIR) digital filter is described by the equation

$$y(n) = \sum_{k=0}^N b_k x(n-k) - \sum_{k=1}^M a_k y(n-k) \quad (8)$$

The output samples, $y(n)$, are derived from current and past input samples, $x(n)$, as well as from current and past output samples. The task of the designer is to propose the values of the coefficients a_k and b_k and the sizes of vectors N and M . In finite impulse response (FIR) filters (☞ Fig. 11), the current output sample, $y(n)$, is a function only of past and present values of the input, that is,

$$y(n) = \sum_{k=0}^N b_k x(n-k) \quad (9)$$

The stability and linear phase are the main advantages of FIR filters. On the other hand, in order to get a good filter, many coefficients have to be considered in contrast to IIR filters. In general, IIR filters are not stable (because of feedback). FIR filters are algebraically more difficult to synthesize.

Conventional design methods are well developed and represent the approach to digital filter design widely adopted by industry. Digital filters are usually implemented either on DSPs or as custom circuits. Their implementation is based on multiply-and-accumulate structures. The multiplier is the primary performance bottleneck when implementing filters in hardware as it is costly in terms of area, power, and signal delay. Hence, multiplierless filters were introduced in which multiplication is reduced to a series of bitshifts, additions, and subtractions.

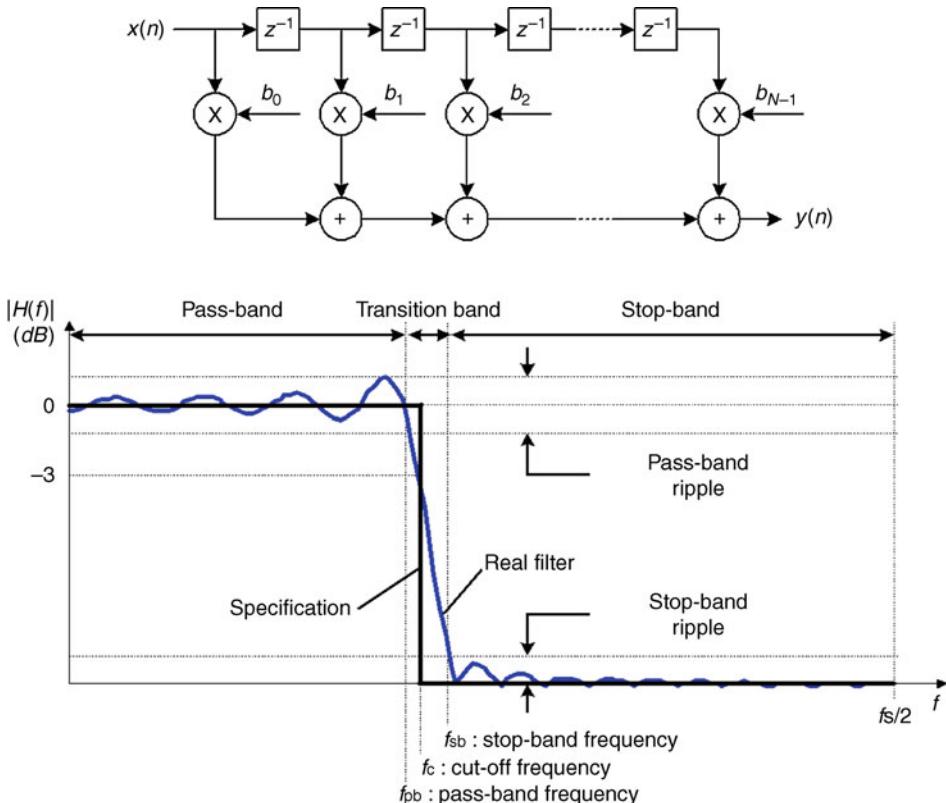

Evolutionary algorithms have been utilized either to optimize filter coefficients (Harris and Ifeachor 1995) or to design complete filter structures. In particular, structures of multiplierless filters were sought by many authors (Wade et al. 1994; Hounsell et al. 2004; Erba et al. 2001; Gwaltney and Dutton 2005). Regardless of filter representation, the fitness function is usually constructed in the frequency domain. Typically, a candidate's filter frequency characteristics are measured at k frequencies f_i (distributed logarithmically) and compared with target frequency characteristics that are derived from specification (☞ Fig. 11). The fitness value is calculated as

$$\text{fitness} = \sum_{i=0}^{k-1} [W(d(f_i), f_i) * d(f_i)] \quad (10)$$

where $d(x)$ is the absolute value of the difference between the target and observed values at frequency x , and $W(y, x)$ is the weighting for difference y at frequency x . The goal is to approximate the target characteristics as accurately as possible and better-than-conventional

Fig. 11

FIR filter structure (top) and frequency characteristics of a low pass filter: ideal vs. real (bottom).

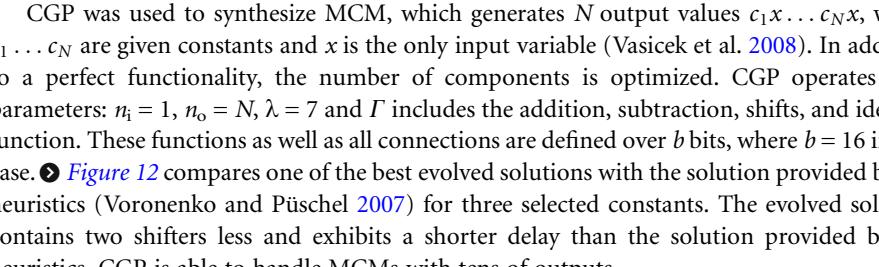

methods allow using the same resources. Additional objectives can be considered, for example, the circuit size or power consumption. The fitness calculation procedure is not trivial and can be time consuming.

4.5.2 Multiple Constant Multipliers

In digital filters, it is often required to multiply a single value x by N constants and so to generate N output products, that is, to implement a multiple constant multiplier (MCM). A multiplierless variant of MCM is such that it is composed of adders, subtractors, and shifters. Finding the optimal MCM, that is, the one with the fewest number of components is known to be NP-complete. A very efficient heuristic algorithm for the MCM problem was recently published (Voronenko and Püschel 2007).

Although MCMs are relatively complex circuits composed of high-level components, their interesting feature from the point of view of evolutionary design is that a candidate MCM can be perfectly evaluated by applying only one input vector (e.g., $x = 1$). The reason is that MCMs implement linear transforms. This feature is unique because it enables us to evolve very large circuits that are simultaneously perfectly evaluated. No training and test data sets are needed.

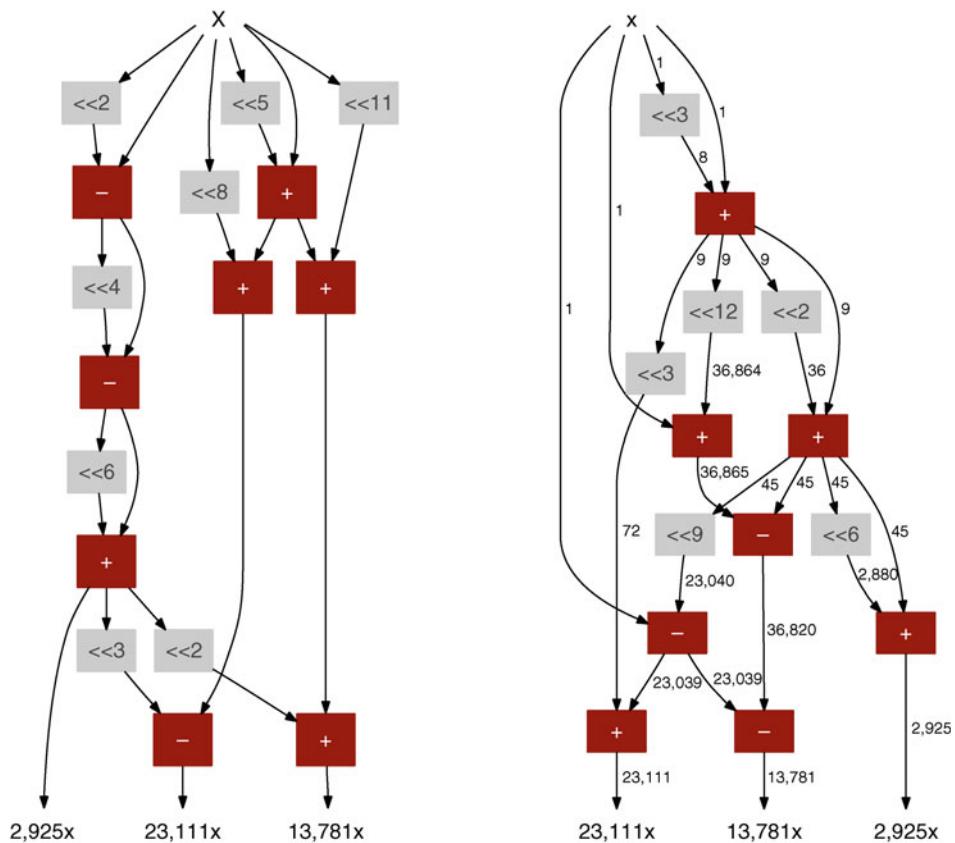

CGP was used to synthesize MCM, which generates N output values $c_1x \dots c_Nx$, where $c_1 \dots c_N$ are given constants and x is the only input variable (Vasicek et al. 2008). In addition to a perfect functionality, the number of components is optimized. CGP operates with parameters: $n_i = 1$, $n_o = N$, $\lambda = 7$ and Γ includes the addition, subtraction, shifts, and identity function. These functions as well as all connections are defined over b bits, where $b = 16$ in this case.  (Figure 12) compares one of the best evolved solutions with the solution provided by the heuristics (Voronenko and Püschel 2007) for three selected constants. The evolved solution contains two shifters less and exhibits a shorter delay than the solution provided by the heuristics. CGP is able to handle MCMs with tens of outputs.

4.6 Evolutionary Approaches in Diagnostics and Testing

Similarly to the circuit design, digital circuit diagnostics and testing have profited from *evolutionary optimization* for a long time. Among typical problems that were attempted in this area, we mention test vectors selection, test scheduling, scan-chain optimization, and test

 Fig. 12

MCM with three coefficients (2,925, 23,111, 13,781): according to Voronenko and Püschel (2007) (left), the best evolved solution (Vasicek et al. 2008) (right).

power consumption optimization under various constraints (Larsson 2005). Evolutionary design is applied in this area rarely. Two examples are briefly described below.

A method was described in Pecenka et al. (2008), which enables us to evolve large synthetic RTL benchmark circuits with a predefined structure and testability. These benchmark circuits are useful in a validation process of novel algorithms and tools in the area of digital-circuits testing. More specifically, as benchmark circuits are designed by means of the EA, they can contain constructions that do not usually appear in the circuits designed by classical design techniques. Thus, the use of evolved benchmark circuits in the process of evaluating new testability analysis tools can reveal problems of the tools that remain hidden when conventional benchmark circuits are used. With sizes up to 1.2 million gates, evolved benchmark circuits currently represent the most complex benchmark circuits with a known level of testability. Furthermore, these circuits are the largest that have ever been designed by means of evolutionary algorithms. This complexity was achieved because no requirement on the functionality was specified. Only some structural properties were measured in the fitness function that could be done in polynomial time.

Bernardi et al. presented a genetic programming-based approach to the construction of diagnosis-oriented software-based test sets for microprocessors (Bernardi et al. 2008). The methodology exploits existing manufacturing test sets designed for software-based self-test and improves them by using evolved test sets. Experimental results showed the feasibility, robustness, and effectiveness of the approach for diagnosing stuck-at faults on an Intel i8051 processor core. A similar approach was used to test peripheral cores.

4.7 Analog Circuits

Evolutionary algorithms can be used to optimize parameter values of circuit components in order to maximize circuit performance, reduce power consumption, or increase fabrication yield. However, in recent years, a lot of attention has been devoted in the evolvable hardware field to the evolutionary synthesis of complete structures of analog circuits. Analog circuits are evolved at various levels of description including passive circuits (composed of resistors, capacitors, and inductors), transistor-level circuits and circuits with operational amplifiers.

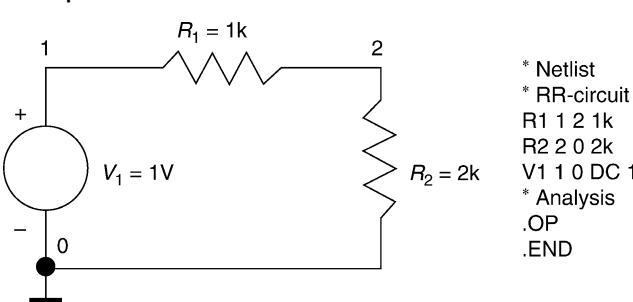

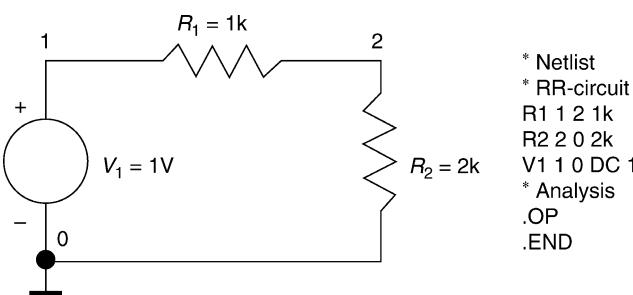

Candidate circuits are usually evaluated using the SPICE simulator, which is the most popular simulator for analog circuit designers.  Figure 13 shows a simple candidate circuit and its representation in a netlist – the input data format for SPICE. Before the circuit

Fig. 13

A circuit and its description in netlist.

evaluation can begin, the chromosome has to be transformed to a netlist and the input stimuli have to be specified. Then, the circuit is simulated using methods supported by SPICE, for example, DC analysis, AC analysis, transient analysis, or noise analysis can be performed. The results of the simulation are available in a text file. A typical fitness function takes the form of [Eq. 10](#), that is, the goal is to minimize the difference between the obtained signal and the target signal. The main disadvantage of the use of SPICE is that the fitness evaluation is relatively slow in comparison with measuring real circuits (several orders of magnitude reported in Stoica et al. (2002)).

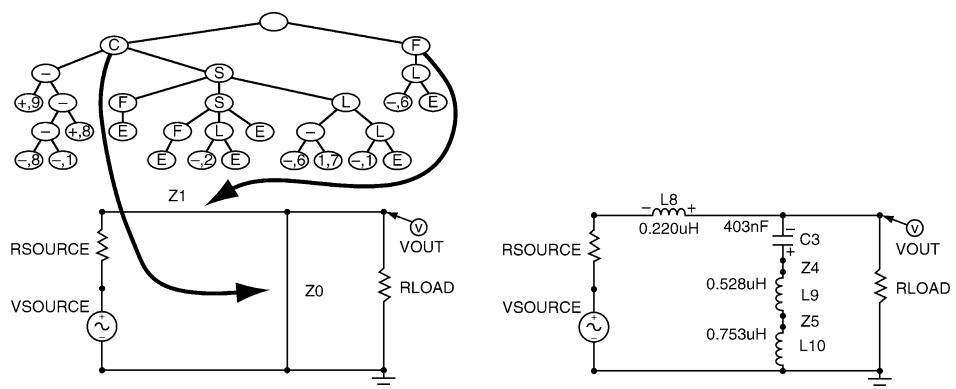

Analog circuits can be encoded in the chromosome either directly or indirectly. Direct encoding is similar to the structure of the netlist. For each component, parameters (e.g., resistances of the resistors) are given together with the description of its terminal connections. The chromosome is represented as a linear variable-length array of integers or real values (for parameter values).

Innovative implementations of analog circuits were obtained using indirect encoding, so-called *developmental genetic programming* introduced by Koza et al. (1999). In his method, a target circuit is subsequently constructed from a simple initial circuit (called the embryo) according to a program that is encoded in the chromosome. [Fig. 14](#) shows a typical embryonic circuit that contains fixed components (power supply, source resistor, and load resistor) and two modifiable wires Z0 and Z1. The developmental program ([Fig. 14](#)), which is encoded as a tree, contains two subtrees, each of them specifying the construction process for one of the modifiable wires. The functions used in the circuit-constructing program tree can be divided into five categories (Koza et al. 2003):

- Topology-modifying functions (e.g., series division (S), parallel division (P), and flip (F)) that modify the topology of the developing circuit
- Component-creating functions that insert components into the developing circuit (insert a capacitor (C), insert an inductor (L))
- Development-controlling functions that control the developmental process by which the embryo and its successors are converted into a fully developed circuit (e.g., the no-operation function, the end of construction function (E))

Fig. 14

Example of an embryonic circuit and a candidate program (left) used to create target circuit (right) (Koza et al. 1999).

- Arithmetic-performing functions that may appear in a value-setting subtree
- Automatically defined functions that enable certain substructures to be reused (including parameterized reuse)

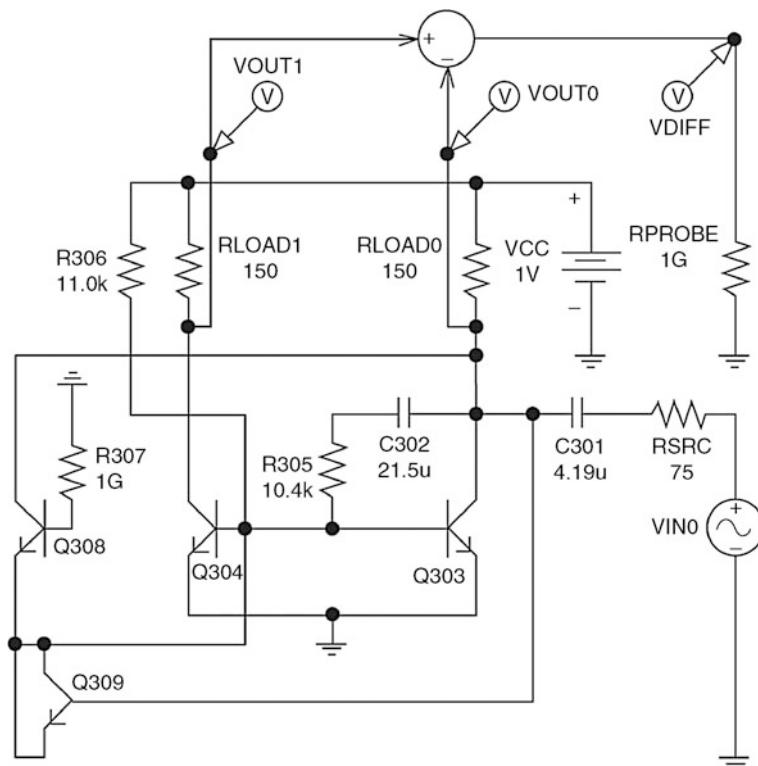

☞ *Figure 14* shows a fully developed circuit that was created from the embryo according to the given program. In order to obtain the fitness value of the circuit, this circuit has to be converted into a netlist and simulated.

Various books (Koza et al. 1999, 2003) present tens of circuits (passive analog circuits, circuits with transistors, circuits with operational amplifiers, controllers) evolved using the developmental genetic programming that can be classified as human-competitive designs, many times leading to rediscovering or even improving patented inventions. For example, an evolved analog circuit that duplicates the functionality of the low-voltage balun circuit (patented by Sang Gug Lee in 2001) is shown in ☞ *Fig. 15*. This design contains the key part of Lee's invention: a coupling capacitor that blocks DC (see capacitor C302 in ☞ *Fig. 15*).

Very high computational requirements are considered as the main disadvantage of the method. In contrast to CGP, it is typical for Koza's genetic programming that very large populations are used and only a few generations are produced. For example, Koza's team utilized two clusters of workstations, 1000 x Pentium II/350 MHz processor and 70 x DEC

▀ **Fig. 15**

Evolved analog circuit that duplicates the functionality of the low-voltage balun circuit that was patented by Sang Gug Lee in 2001 (according to Koza et al. 2003).

Alpha/533 MHz processor. For 36 tasks solved using GP on the clusters, the average population size is 3,350,000 individuals, 128.7 generations are produced on average and the average time to reaching a solution is 81.9 h (Koza et al. 2003).

Another criticism of Koza's genetic programming method for analog circuit synthesis comes from analog circuit designers who do not find evolved circuits trustworthy and suitable for fabrication. A solution to this problem was proposed by Gao, McConaghay, and Gielen who invented an analog circuit topology synthesis method called importance sampled circuit learning ensembles (ISCLEs). ISCLEs is a method that synthesizes circuit topologies that are novel in both functionality and topology, yet trustworthy, within reasonable CPU effort (Gao et al. 2008).

4.8 Antennas, Optical Systems, and MEMS

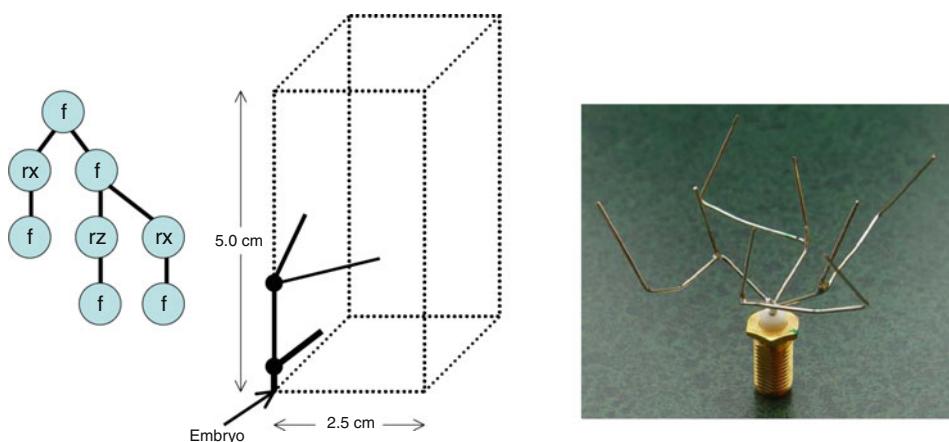

The evolutionary design of antennas, optical systems, MEMS, and other physical objects is strongly dependent on the existence of reliable simulators. With the increasing computer performance, sufficiently fast simulators have become available. These objects are usually evolved using generative encodings, similar to Koza's developmental genetic programming.

4.8.1 Antennas

Evolutionary optimization has been used in antenna design since the early 1990s (Linden 1997; Haupt and Werner 2007). Most of the work has been focused on optimizing parameters of a predetermined design as opposed to evolutionary design of the antenna's topology. One of the most famous examples of evolutionary design is the evolved antenna design for the flight hardware deployed on a NASA spacecraft for the Space Technology 5 (ST5) mission in 2006 (see Fig. 16). The antenna was evolved using generative encoding. The antenna's chromosome contains the instructions that control the construction of target shape. The process starts

Fig. 16

One of the candidate trees (left) that defines the process of antenna construction in a 3D space (middle) and evolved antenna ST5-3-10 (Hornby et al. 2006) (right).

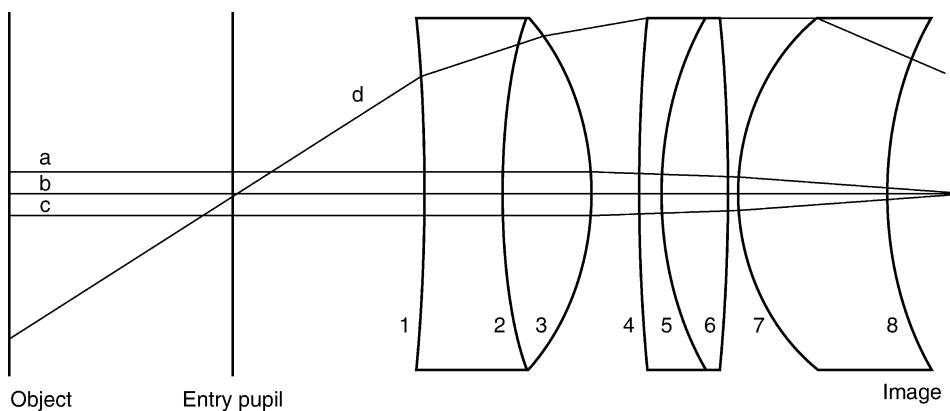

from a simple embryo – a small wire in this case. The instructions (such as F – move forward, R_i - rotate in direction i) can move and rotate the construction head in a 3D space of possible wire antennas. The paper by Hornby et al. (2006) explains that the fitness value of a candidate antenna is “the product of three scores involving the gain pattern, the VSWR, and pattern outliers. The gain pattern score compares the measured gain values across a range of elevation angles to the desired gain values and rewards antennas that exceed the requirements. VSWR is the ratio between the highest voltage and the lowest voltage in the signal envelope along a transmission line, with a ratio of 1 being ideal. The outlier score rewards antenna designs for having sample points with gains greater than zero.” Candidate antennas were simulated using NEC software. The evolved antenna has a number of advantages, in particular, low power consumption, short fabrication time, and good performance.

4.8.2 Optical Systems

Evolutionary algorithms have been used to optimize the parameters of optical systems with a prespecified layout and prespecified number of components. Koza has applied developmental genetic programming to create novel topologies for optical systems.  [Figure 17](#) shows one of the lens systems evolved using genetic programming that exhibits the same function as the patented solution of Koizumi and Watanabe, however its topology is different (Koza et al. 2005).

As the micron-meter resolution alignment of optical components usually takes a long time, to overcome this time problem the National Institute of Advanced Industrial Science and Technology in Japan (AIST) team proposed five systems that can automatically align the positions of optical components by evolutionary algorithms in very short times compared to conventional systems (Nosato et al. 2006): (1) an evolvable fiber alignment system, (2) an evolvable interferometer system, (3) an evolvable femtosecond laser system, (4) a wave-front correction system, and (5) a multiobjective adjustment system. In particular, the evolutionary algorithm was used to find positions of optical components that can be controlled by step motors. Proposed solutions have led to compacting the implementation of optical systems, reducing cost and lowering maintenance operations.

 **Fig. 17**
Evolved lens system according to Koza et al. (2005).

4.8.3 MEMS

Similarly to optical systems, evolutionary algorithms have been used to optimize parameters of MEMS, including the size, orientation, number of segments, etc. (Li and Antonsson 1998; Kamalian et al. 2002). Lohn, Kraus, and Hornby evolved a complete MEMS meandering resonator (i.e., topology and parameters) using a generative representation (Lohn et al. 2007). The JPL team has developed a tuning method for MEMS gyroscopes based on evolutionary computing to increase the accuracy of MEMS gyroscopes through electrostatic tuning. The method was successfully tested for the second generation of the JPL/Boeing post-resonator MEMS gyroscope (Keymeulen et al. 2006).

5 Intrinsic Evolution

This section surveys approaches to intrinsic evolution conducted directly in FPGAs, FPTAs, and FPAs. Evolution on unconventional devices is also discussed.

5.1 Evolvable FPGAs

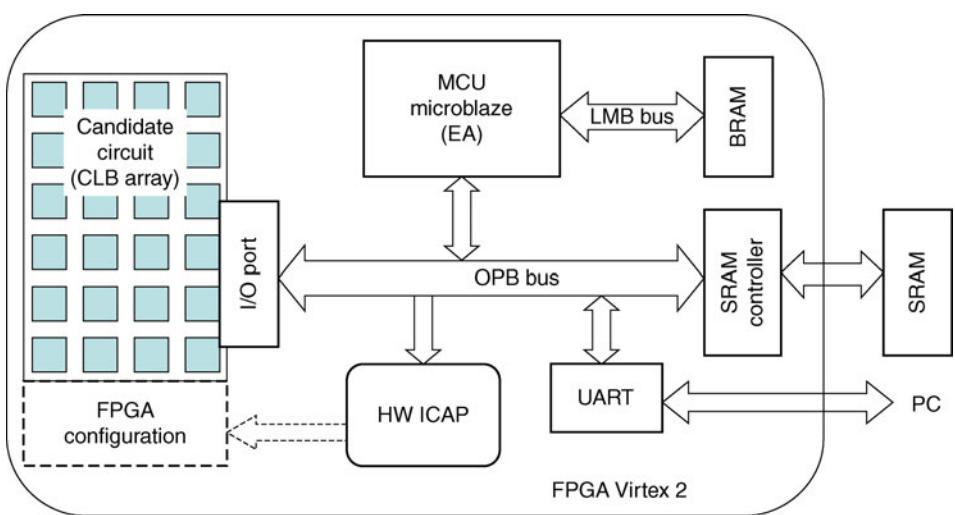

Nowadays, FPGAs are primarily used in the evolvable hardware field to accelerate circuit evolution. Most FPGA families can be configured only *externally*. The *internal reconfiguration* means that a circuit placed *inside* the FPGA can configure the programmable elements of the same FPGA. Although the internal configuration access port (ICAP) has been integrated into the recent Xilinx Virtex families (Virtex II, Virtex 4, Virtex 5) (Blodget et al. 2003), it is still too slow for many evolvable hardware applications.  Figure 18 shows a block diagram of an evolvable system implemented in an FPGA Virtex 2. The system includes an MCU microblaze (EA) connected to a BRAM via an LMB bus. The MCU is connected to an OPB bus. The OPB bus connects to an SRAM controller, which is connected to an SRAM. The SRAM controller is also connected to a PC. An I/O port is connected to the MCU and to an HW ICAP. The HW ICAP is connected to the FPGA configuration area of the Virtex 2. A Candidate circuit (CLB array) is also connected to the I/O port. The PC is connected to a UART, which is connected to the HW ICAP.

 Fig. 18

An evolvable system implemented in the FPGA using ICAP interface (Upegui 2006).

processor, reads a section of the configuration bitstream through ICAP, modifies the bitstream according to the genome currently evaluated in the MicroBlaze, sends the bitstream back through the ICAP for the partial reconfiguration of the FPGA, and evaluates the fitness of the current individual by interacting with the reconfigurable evolvable section through the standard OPB bus. The system was used to evolve the topology of Boolean networks (Upogui 2006).

In order to overcome the problem of slow reconfiguration, the concept of *virtual reconfigurable circuits* (VRC) was developed (Sekanina 2003, 2004). The VRC is, in fact, a second reconfiguration layer developed on top of the FPGA in order to obtain fast reconfiguration and application-specific programmable elements.  [Figure 19](#) shows that the VRC consists of a 2D array of programmable elements E_i . The routing circuits are created using multiplexers. The configuration memory of the VRC is typically implemented as a register array. All bits of the configuration memory are connected to multiplexers that control the routing and selecting of functions in programmable elements. Because the array of programmable elements, routing circuits, configuration memory, style of reconfiguration, and granularity of VRC can be designed exactly according to the requirements of a given application, designers can create an optimized application-specific reconfigurable device. If the structure of the chromosome corresponds to the configuration interface of the VRC then a very fast reconfiguration can be achieved (e.g., consuming a few clock cycles only).

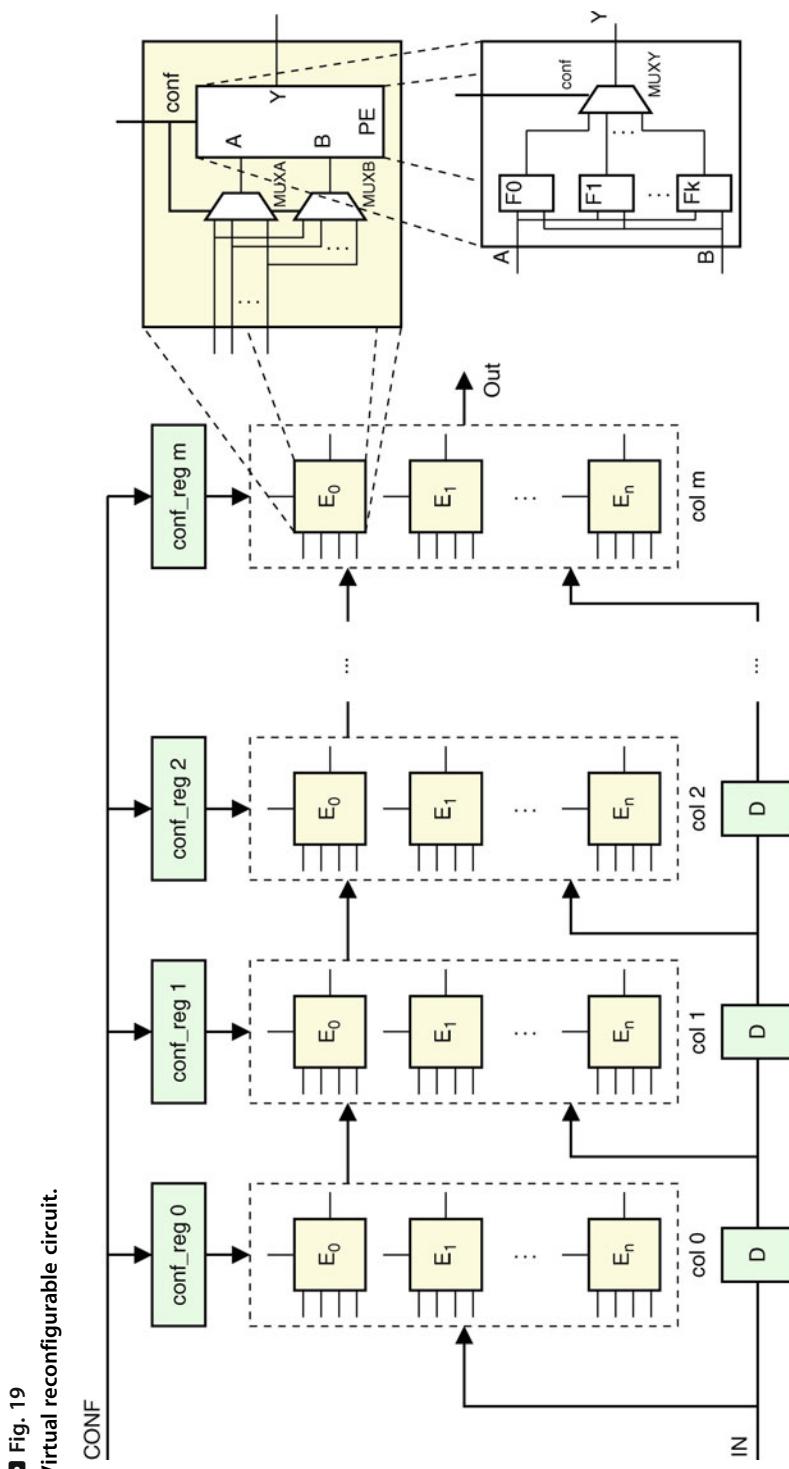

The FPGA-based implementations of evolvable hardware systems can be divided into two classes:

- *The FPGA serves in the fitness calculation only.* The evolutionary algorithm (which is usually executed on a personal computer) sends the configuration bitstreams representing candidate circuits to the FPGA in order to obtain their fitness values. The FPGA is configured externally. A typical example of this scenario is Thompson's experiment (see  [Sect. 3.2](#)).
- *The entire evolvable system is implemented in the FPGA.* The idea of the complete hardware evolution for FPGAs was initially demonstrated in Tufte and Haddow (2000); however, the paper provides only a simple example of the optimization of a few FIR filter coefficients stored in a register. Current FPGA implementations are capable of evolving circuit structures. They utilize either ICAP or VRC.

 [Table 3](#) surveys examples of FPGA implementations of digital evolvable systems. One can identify the following components in all systems: the array of reconfigurable elements, evolutionary algorithm, fitness calculation unit, and controller. The problem domain determines the type of reconfigurable elements. In some cases, the evolution is performed directly with reconfigurable cells of the FPGA; in other cases, a kind of VRC is utilized. An evolutionary optimization of coefficients stored in registers represents the simplest example. The EA and fitness calculation unit can be implemented either as an application-specific circuit or as a program. The program is running either in a personal computer or in an embedded processor, which is integrated into the FPGA.

5.1.1 Evolution of Image Filters

An FPGA-based evolvable image filter architecture was proposed to create novel implementations of image filters (Sekanina 2004; Vasicek and Sekanina 2007). The system consists of the

genetic unit, an array of reconfigurable elements (implemented as VRC), and a fitness calculation unit. While candidate filters are created and evaluated using user logic available on the FPGA, the genetic operations are carried out in the on-chip PowerPC processor. Every image operator is considered as a digital circuit of nine 8-bit inputs and a single 8-bit output, which processes gray-scaled (8-bit/pixel) images (see [Fig. 20](#)).

Table 3

Examples of FPGA implementations of evolvable digital systems

Reference	Application	Platform	EA	Fitness

Fig. 20

Image filter design problem.

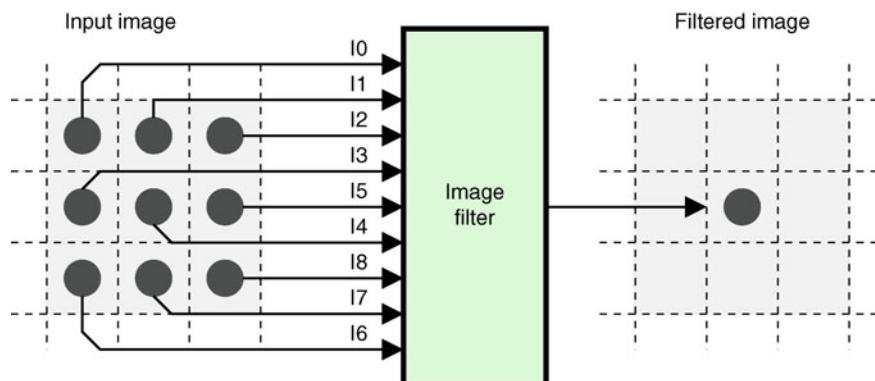

Figure 19 also shows a corresponding VRC, which consists of 2-input configurable functional blocks (CFBs), denoted as E_i , placed in a grid of eight columns and four rows. Any input of each CFB may be connected either to a primary circuit input or to the output of a CFB, which is placed anywhere in a preceding column. Every CFB can be programmed to implement one of the functions given in Table 4. All these functions operate with 8-bit operands and produce 8-bit results. The reconfiguration is performed column by column. The computation is pipelined; a column of CFBs represents a stage of the pipeline. The configuration bitstream of VRC, which is stored in a register array *conf_reg* consists of 384 bits. A single CFB is configured by 12 bits. The evolutionary algorithm directly operates with the configurations of the VRC.

The fitness calculation is carried out by the fitness unit (FU). The corrupted image, original image, and filtered image are stored in external SRAM memories, which are accessible via memory controllers implemented in the FPGA. The pixels of the corrupted image u are loaded from external SRAM1 memory and forwarded to the inputs of the VRC. The pixels of the filtered image v are sent back to the fitness unit, where they are compared with the pixels of the original image w that is stored in another external memory, SRAM2. The filtered image is simultaneously stored into the third external memory, SRAM3. The design objective is to minimize the difference between the filtered image and the original image, that is, the fitness value is calculated for an $M \times N$ -pixel image as

$$\text{fitness} = \sum_{i=1}^{M-2} \sum_{j=1}^{N-2} |v(i, j) - w(i, j)| \quad (11)$$

As Fig. 21 shows, the system is completely implemented in a single FPGA (except the SRAM memories). The program memory of the PowerPC as well as the population memory is implemented using on-chip Block RAM (BRAM) memories. The evaluation of the candidate configurations is pipelined in such manner as there are no idle clock cycles. Therefore, the time of evolution can be expressed as

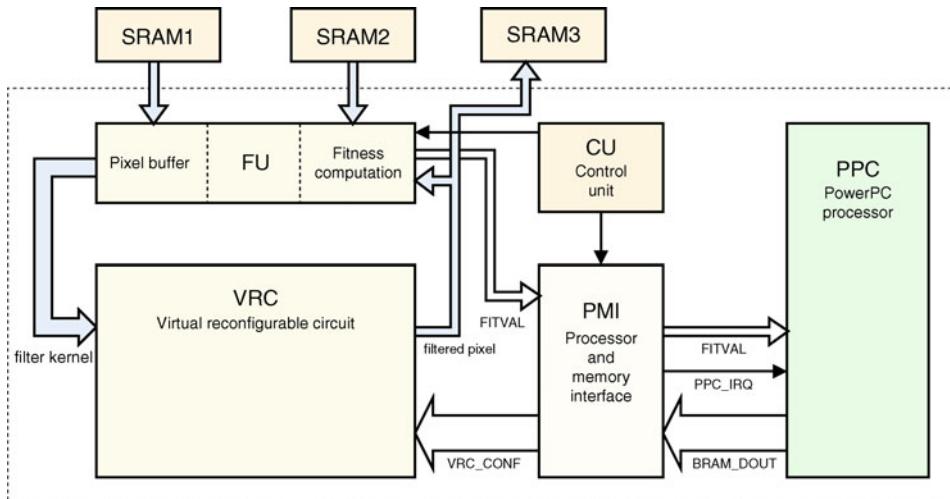

$$t_{\text{evol}} = Q(M - 2)(N - 2) \frac{1}{f}$$

where Q is the number of evaluations, $N \times M$ is the number of pixels (note that border pixels are ignored), and f is the operation frequency. The system was implemented in a COMBO6X

Table 4
List of functions implemented in each CFB

Code	Function	Description	Code	Function	Description
0	255	Constant	8	$x \gg 1$	Right shift by 1
1	x	Identity	9	$x \gg 2$	Right shift by 2
2	$255 - x$	Inversion	A	$\text{swap}(x, y)$	Swap nibbles

Fig. 21
System for image filter evolution in FPGA.

card, which is equipped with a Virtex-II Pro FPGA. It utilizes 20% slices. Experimental results show that approximately 6,000 candidate filters can be evaluated per second ($N = M = 128$), which is 44 times faster than the same algorithm running on a Celeron@2.4 GHz processor.

This platform was used to obtain the salt-and-pepper noise filters, Gaussian noise filters, edge detectors, and other image operators. By combining three evolved filters in a bank of filters, even better filtering properties can be obtained (Vasicek and Sekanina 2007).

Figure 22 compares evolved filters (a single filter and 3-band filter) with conventional solutions (median filters (MF) and adaptive median filters (AMF)) for 25 images corrupted by the salt-and-pepper noise of various intensities. In comparison to conventional filters, evolved filters exhibit better filtering quality and lower implementation cost.

Recent work of Harding (2008) shows how the same application can be accelerated using a modern graphical processing unit that comes as a standard component of conventional PCs.

5.1.2 Incremental and Run-Time Evolution of Classifiers

Glette and Torresen proposed an application-specific architecture for online incremental evolution of classifiers (Glette 2008; Glette et al. 2007). The architecture consists of three main parts – the classification module, the evaluation module, and the CPU (PowerPC or MicroBlaze IP core) where the genetic algorithm is carried out. The reconfigurable part of the system is implemented as a VRC.

The classifier system consists of K category detection modules (CDMs), one for each category C_i to be classified (see Fig. 23). The CDM with the highest output indicates the resulting class. The input data to be classified are presented to each CDM concurrently. A CDM consists of M “rules,” each of them is implemented using N functional units (FU) working concurrently over the input pattern (Fig. 24 left). The rule is activated when all outputs from the FUs are 1. The counter is used to count the number of activated FU rows. Figure 24

Fig. 22 Comparison of standard image filters (MF, AMF) and evolved filters (single filter, 3-bank) for the salt-and-pepper noise of various intensity. The implementation cost is given in FPGA slices.

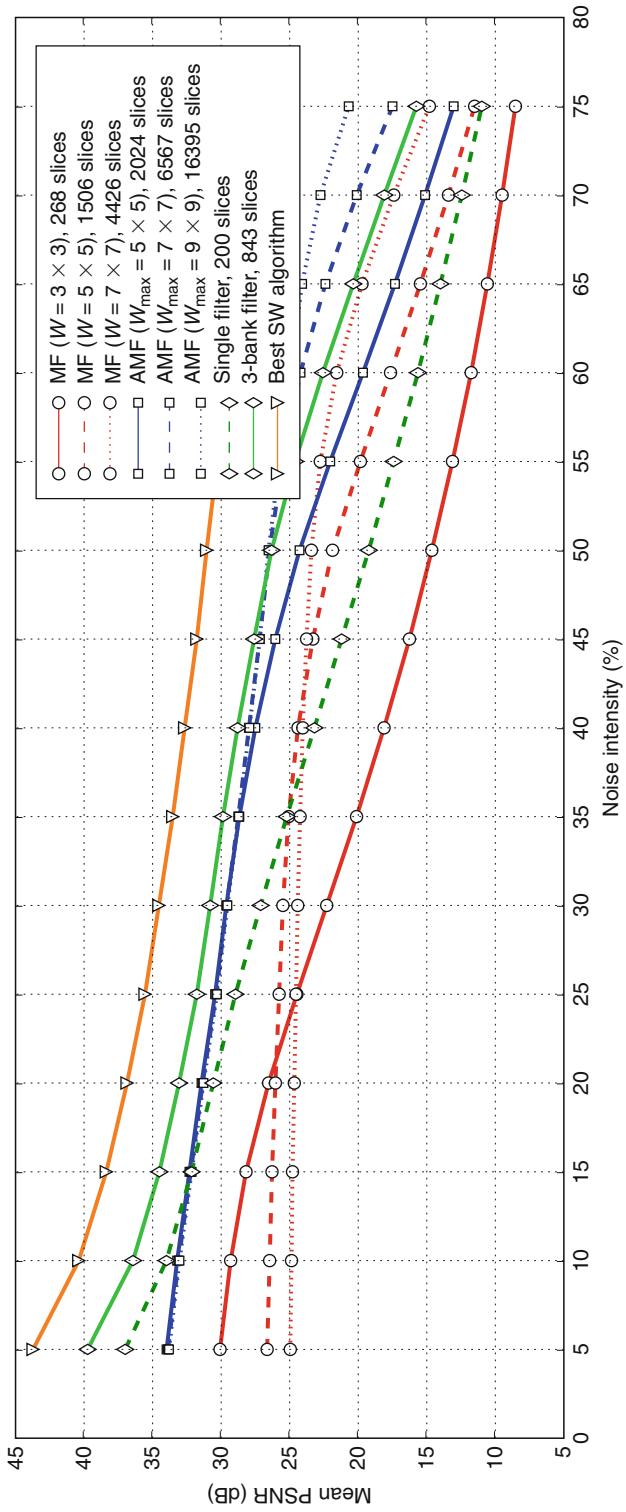

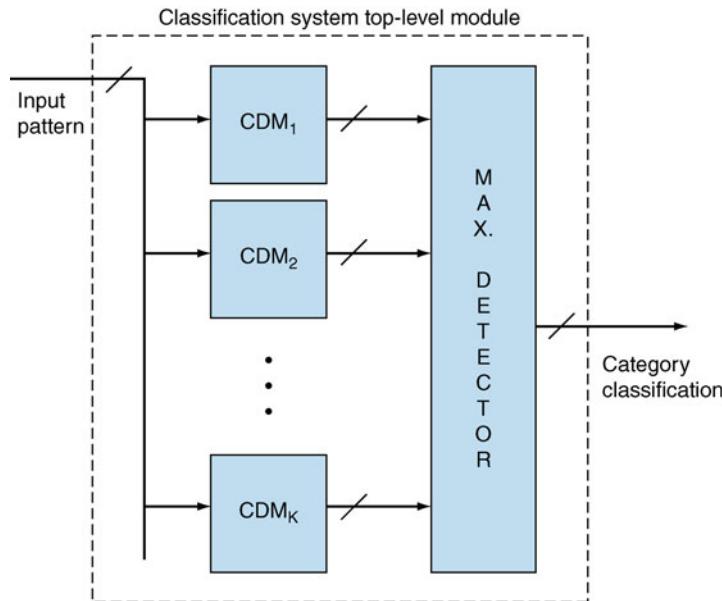

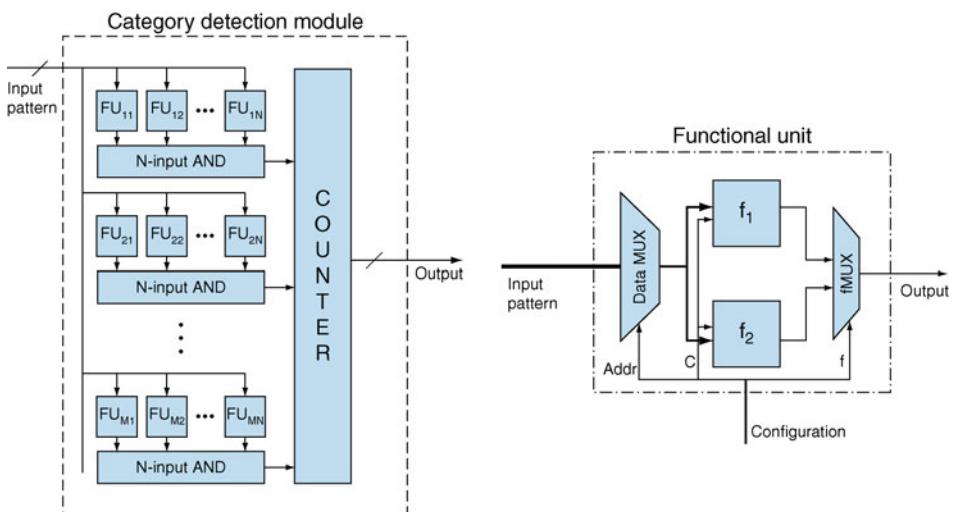

Fig. 23

Evolvable classifier system. The pattern to be classified is input to all of the category detection modules (according to Glette (2008)).

**Fig. 24**

Category detection module (left) and function unit (right) according to Glette (2008).

shows that each FU is controlled by configuration bits that determine some part of the input pattern to be processed by the FU, selection of function, and a constant value, C , which can be utilized for computations. This architecture is suitable for incremental evolution because each category detector, CDM_i , which is encoded using 100–200 bits, can be evolved separately.

According to Glette (2008), the fitness calculation is performed in the following way: Let V_t denote training vectors and V_v validation vectors utilized at the end of evolution. Each row of FUs is fed with the training vectors ($v \in V_t$), and fitness is based on the row's ability to give a positive (1) output for vectors v belonging to its own category ($C_v = C_i$), while giving a negative (0) output for the rest of the vectors ($C_v \neq C_i$). In the case of a positive output when $C_v = C_i$, the value A is added to the fitness sum. When $C_v \neq C_i$ and the row gives a negative output (value 0), 1 is added to the fitness sum. The other cases do not contribute to the fitness value. The fitness function F for a row can then be expressed in the following way, where o is the output of the FU row:

$$F = \sum_{v \in V_t} x_v \text{ where } x_v = \begin{cases} A \times o & \text{if } C_v = C_i \\ 1 - o & \text{if } C_v \neq C_i \end{cases} \quad (12)$$

The architecture was evaluated using nontrivial benchmark problems – face image recognition (Glette 2008), sonar spectrum classification (Glette et al. 2007) and electromyographic prosthetic hand control (Glette et al. 2008) – and compared with conventional as well as evolvable hardware approaches. The proposed solution exhibits fast classification and a short adaptation time. In comparison to existing evolvable hardware approaches, the quality of the classification is higher. In comparison to the state-of-the-art classification algorithms (such as support vector machines), the quality of classification is slightly worse.

5.2 Evolutionary Design in FPAA and FPTA

Although the previous section has dealt with the intrinsic approach, the goal of the presented applications was not to exploit the physical characteristics of FPGAs (as, e.g., Thompson et al. (1999)). The main objective was to make the evolutionary design faster. However, this is not always the case for analog circuits.

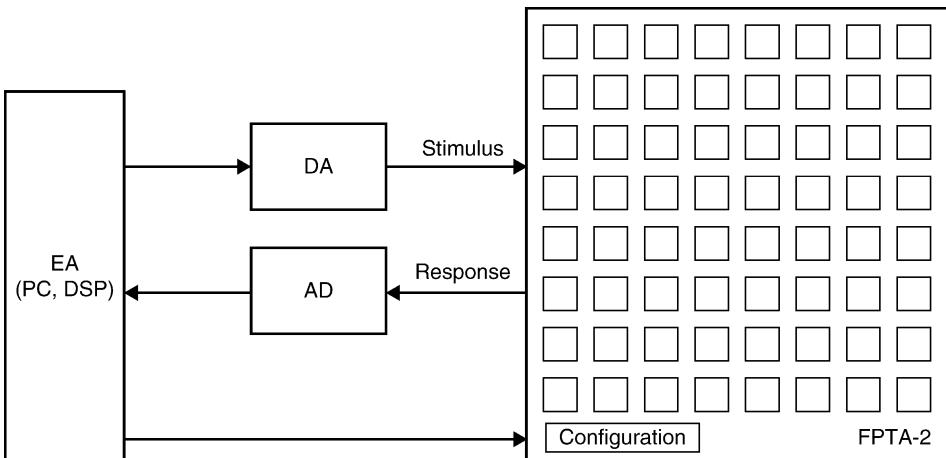

Full-custom design of analog circuits is time consuming and expensive. The aim of evolutionary design using FPTAs or FPAs is to obtain circuits working directly in a real environment. The intrinsic evolution should help to overcome the “simulator vs reality” gap, enable designers to immediately verify the structure and parameters setting of the circuit under design, and provide a working prototype in a relatively short time.

❸ *Figure 25* shows a typical setup for analog circuit evolution in FPTA (or FPAA). The EA runs in a PC (or DSP) that generates candidate circuits (configurations) for FPTA. The PC also generates test stimuli that are converted to analog signals using a DAC. Circuit responses are converted using an ADC on digital data that are compared with the required target signals. The objective is to minimize the differences between the obtained signals and target signals. Alternatively, the fitness calculation can be based on a comparison of the measured frequency characteristics and target frequency characteristics. This approach was used to evolve various circuits including rectifiers, amplifiers, oscillators, filters, DA converters, controllers, regulators, and primitive gates (Aggarwal et al. 2006; Greenwood and Tyrrell 2007; Henrici et al. 2007; Stoica et al. 2002, 2006).

As far as the reconfigurable device is analog, it is natural for evolution to exploit physical properties of transistors, configurable switches, and other components and the environment to find the required behavior. The evolutionary process can escape the space of conventional implementations (which designers are able to represent in advance) and produce circuits that are difficult to understand or even reconstruct in a circuit simulator.

Fig. 25

A typical setup for circuit evolution in FPTA.

It was recognized that intrinsic evolution of analog circuits can lead to some serious problems. Circuits highly ranked during evolution may obtain low fitness when reevaluated individually at the end of evolution. It can be due to the transient behavior, which describes a configuration that is not stable as a function of time. Or, the circuit can be dependent on a previous configuration of the chip because of various parasitic capacitors in the chip. In practice, the transient behavior can be resolved by reevaluating the individuals for a longer time period. The operational range of the evolved circuit in the frequency domain is another potential pitfall, since in principle the circuit behavior should be evaluated for the overall frequency domain in which it is expected to work. Similar problems may appear when loads different from those used during evaluation are connected. Various techniques were proposed to eliminate these undesirable effects (Stoica et al. 2000, 2004; Thompson et al. 1999). In summary, evolved circuits may not be stable after some time, they may not work correctly when uploaded on another chip (or even to another area of the same chip) or used in a different environment.

A promising application for the evolution of analog circuits is adaptation in extreme environments. Future NASA missions will face extreme environments, including environments with large temperature differences (from -233°C to 460°C) and high radiation levels, upto a 5 Mrad total ionizing dose (TID) (Stoica et al. 2006). Conventional approaches to extreme environment electronics include *hardening-by-process* (i.e., fabricating devices using materials and device designs with higher tolerance to extreme environment) and *hardening-by-design* (i.e., the use of special design/compensation schemes). Both of these hardening approaches are limited, in particular for analog electronics, by the fact that current designs are fixed and, as components are affected by extreme environments, these drifts alter functionality. A recent approach pioneered by JPL is to mitigate drifts, degradation, or damage on electronic devices in extreme environments by using reconfigurable devices and an adaptive self-reconfiguration of circuit topology. This new approach is referred to as *hardening-by-reconfiguration*. As the only investigator in this area, JPL's evolvable hardware group has demonstrated for simple circuits created in the FPTA-2 that evolutionary approach can

recover functionality lost (1) after a fault artificially injected into FPTA-2, (2) in extreme high and low temperatures (from -196°C to 320°C), and (3) in high radiation environments (up to 250 krad TID) (Keymeulen et al. 2000; Stoica et al. 2004, 2005, 2006; Zebulum et al. 2006).

5.3 Evolution on Unconventional Platforms

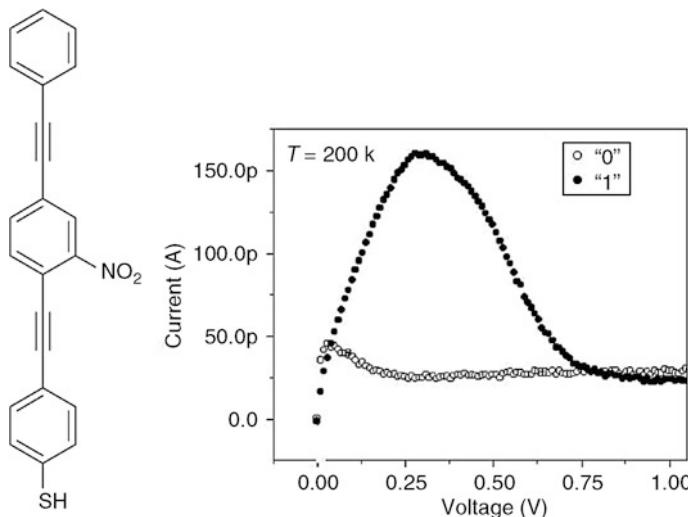

Inspired by Thompson's experiment, researchers began to use EAs to exploit physical properties of reconfigurable devices for computing. The aim was to obtain useful computations directly in materials, without formulating a mathematical model of the problem and without understanding "the rules of the game." In addition to common FPGAs and reconfigurable analog devices mentioned in previous sections, several platforms were proposed for these experiments, for example, an evolvable motherboard (Layzell 1998), RISA (Greensted and Tyrrell 2007) and REPOMO32 (Sekanina et al. 2009).

Recently, Miller has used the more general term, *evolvable matter*, to address the use of evolutionary algorithms for the design on any physical reconfigurable platform (e.g., chemical) in a real environment. The idea behind the concept is that applied voltages may induce physical changes that interact in unexpected ways with other distant voltage-induced configurations in a rich physical substrate. In other words, it should theoretically be possible to perform the evolution directly *in materio* if the platform is configurable in some way. Promising technology for evolution in materio was reviewed in (Harding et al. 2008). In particular, liquid crystals were used as a platform to evolve various circuits including primitive logic functions, signal discriminators, and robot controllers (Harding 2006).

Tour's group has presented another example – the Nanocell (Tour 2003). The nanocell is a 2D network of self-assembled metallic particles connected by molecular switches (Fig. 26). The nanocell is surrounded by a small number of lithographically defined access leads. The nanocell is not constructed as a specific logic gate – the logic is created in the nanocell by

Fig. 26

Molecular switch used in NanoCell and its V/I characteristics (from Tour 2003).

training it postfabrication by changing the states of the molecular switches. The training algorithm does not know the connections within the nanocell or the locations of the switches. However, the configuration can be changed by voltage pulses applied to the I/O pins. A genetic algorithm was utilized to generate these pulses in order to form the required logic gates.

Bartels et al. (2004) applied the evolutionary algorithm to configure a reconfigurable mirror used in a laser. The aim was to shape laser pulses in order to distort molecules in specific ways to catalyze chemical reactions, with the ultimate goal of manipulating large molecules, for example, proteins and enzymes. The method has also been used to create new quantum behaviors at the atomic level. Results completely unexpected from a physical point of view were reported. Evolved behaviors (such as anti-correlated attosecond harmonics in quantum systems) were not known to be physically possible. The ability to move beyond the nanoscale to the attoscale is considered as a major breakthrough. Potential applications of controlling the behavior of materials at the atomic level are enormous.

6 Adaptive Hardware

A promising approach to building adaptive hardware is to develop systems that combine a reconfigurable device with an intelligent mechanism for its reconfiguration. The reconfiguration mechanism is activated when the adaptation is needed. A straightforward solution for the adaptive system is to maintain a set of configurations designed a priori and use the most suitable one when the current configuration becomes unsatisfactory. An obvious weakness of this approach is that a suitable configuration may not be prepared. A more advanced approach, developed in the evolvable hardware field, tries to generate new configurations at run time using an evolutionary algorithm. A potential problem is that the EA is a stochastic algorithm. Nobody can guarantee that the resulting configuration really solves the problem. In addition, nobody can guarantee that the EA will provide an acceptable configuration on time. However, in many applications, a partial solution provided by the EA may be a very good result.

Examples of adaptive hardware systems will be presented according to the types of changes that usually lead to the requirement of system adaptation. These changes can be classified either as changes

- in the hardware platform itself (i.e., faults)
- in the input data characteristics, or
- in the specification

6.1 Self-repairing Hardware

The EA is used to recover the system function that was degraded/lost due to failure in the hardware platform (such as being stuck at zero, changes in the transistors' characteristics in extreme environments, etc.). Note that the requirement on the function remains unchanged and the input data are as expected. First of all, the failure has to be detected. Then, if no other mechanisms are capable of repairing the system, the EA is activated. In some cases, it is sufficient to tune only some circuit parameters (e.g., bias voltages) in order to repair the circuit. In more complicated cases, a new topology must be evolved.

6.1.1 SRAA

The self-reconfigurable analog array (SRAA) developed at NASA JPL provides the capability of *continual temperature compensation* (Stoica et al. 2008). The SRAA contains an array of 4×6 analog cells. Various specific circuits can be implemented in the SRAA for which mission-oriented ASICs were designed in the past. The SRAA cells are based on tunable OTAs used to compensate for the effects that come from temperature variations. A subset of cells, called reference cells, are continually compensated at the same time as other functional cells perform user operations. The result of compensation is then transferred to the main array. Elementary cells can be compensated for temperature-induced deviations within a -180°C to 120°C range. The EA is implemented as a digital circuit either in an FPGA or as ASIC.

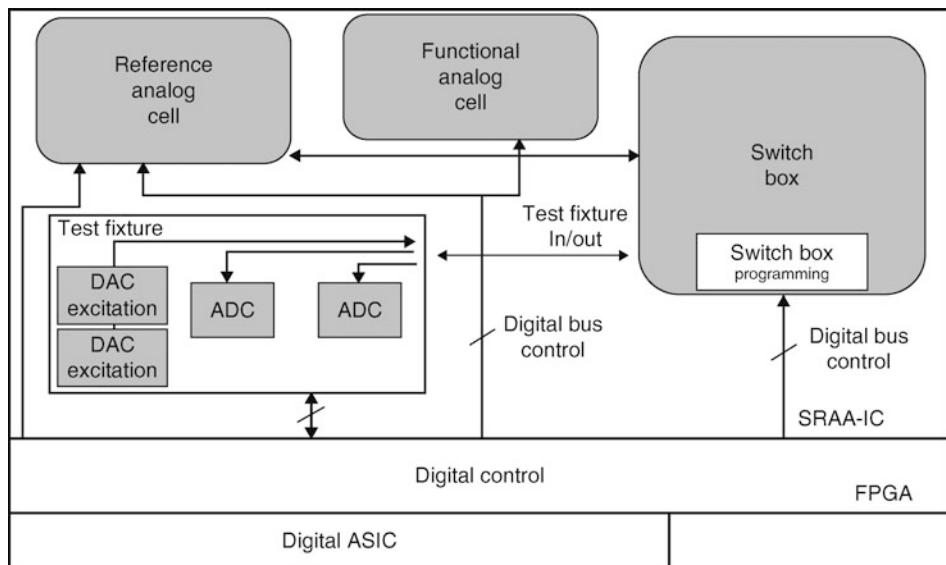

Figure 27 shows the SRAA chip that contains the array of cells divided into the functional and the reference analog arrays. The reference analog cells are individually probed to check for degradation. Both reference and functional cells include digital-to-analog converters (DACs) used to provide bias voltages or currents to tune the analog cell response. The switch box allows for the configuration of different functions in the functional analog array, as well as providing an interface between the reference analog cells and the test fixture. The SRAA contains 40 reconfiguration DACs for the 6×4 functional array.

The SRAA utilizes a hierarchical approach to calibration/compensation. First, a faulty configuration is replaced by a priori prepared configuration. If it fails, a second level takes place, which involves a less computationally expensive search algorithm. Finally, a third level is employed in case the previous levels do not succeed, and a global search is conducted using evolutionary algorithms.

Once an analog cell response goes out of specification (e.g., due to temperature or radiation effects), the FPGA will recalibrate the corresponding reference cell by reprogramming its

Fig. 27

Self-reconfigurable analog array (SRAA) according to Stoica et al. (2008).

respective reconfiguration DACs. Once new values are found that recover the behavior of the reference cell, the same are used to reprogram the configuration DACs of the associated functional cells. This tuning process assumes that for each type of cell, the functional and reference versions will exhibit the same behavior. This assumption usually holds when the SRAA chip is exposed to extreme temperatures. Since the chip is fabricated in a rad-hard process, the SRAA will tolerate permanent radiation effects (total ionization dose [TID]) up to 300 krad. The SRAA is designed to maintain a stable operation over a wide temperature range of more than 300°C, from -180°C to 125°C. Over this range, parameters of interest may vary with < 1–5% deviation from their 27°C value, depending on the circuit.

6.1.2 Self-repairing FPGAs

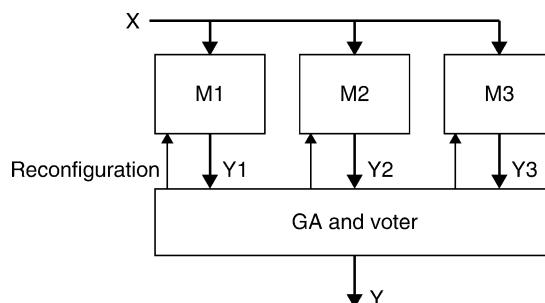

An interesting evolutionary-repair approach for FPGAs was introduced by Garvie (2005). He employed triple module redundancy (TMR), which is a conventional scheme used to mitigate faults. A TMR system has three copies of a module and uses a voting circuit on their outputs so that the final output is an agreement between at least two modules. A TMR extension, TMR+Scrubbing, in addition, provides fault tolerance to single event upsets (SEUs) in the FPGA configuration data by regular reprogramming of the FPGA. Garvie extended TMR +Scrubbing by “Jiggling” to repair also permanent damage by using the two healthy modules to repair the faulty one (Garvie 2005). He recognized that the two healthy modules can provide a reference signal (i.e., training vectors) for evolutionary design of the configuration of the third module. Once a Jiggling repair is complete three healthy modules are again available (☞ Fig. 28). Permanent faults can be repaired until spare resources are exhausted. The Jiggling repair evolutionary module is implemented on the same FPGA and requires a small additional area on the chip. Hence, it can be itself repairable by another Jiggler. Reliability analysis for small benchmark circuits shows the Jiggling system using 2.8 times the overhead per module can survive 17 times longer than a TMR/Simplex approach.

6.2 Changes in the Specification or Input Data Characteristics

Consider an image-recognition system in which an image filter is used to enhance the input images coming from a camera. If the type of noise is variable, the filter may have problems

Fig. 28

Triple module redundancy extended by a module repairing mechanism (Garvie 2005).

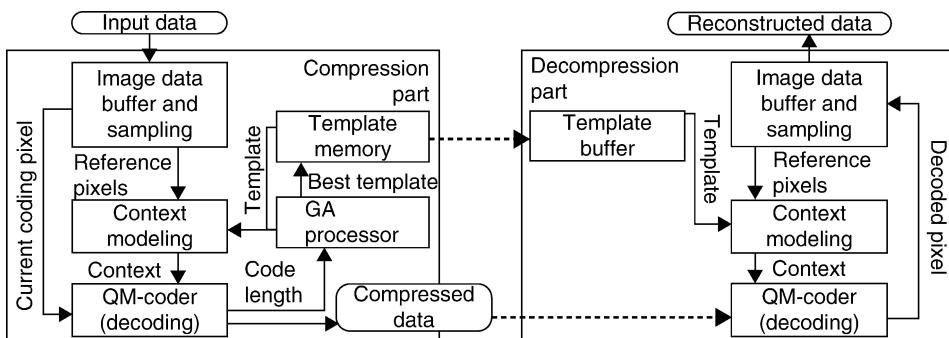

enhancing the images and the quality of recognition may decrease. Hence, the EA is employed to optimize the filter for a particular type of noise. In this case, the specification of the function remains unchanged; however, the system has to adapt because of changing environments. Also the specification can be changed either by an operator or autonomously, by the system itself which can, for example, continuously monitor its history and plan new actions (considered as circuit configurations). If the configuration that implements the required action is unknown in advance, the EA is activated to perform the adaptation. Several real-world applications developed in the AIST laboratory in Japan (Higuchi et al. 1999, 2006) in which this kind of adaptation has been employed will be shown.

6.2.1 Image Compression Chip

Adaptive image compression methods allow for modifying the compression algorithm according to the particular data that has to be compressed. In consequence, a higher compression ratio can be achieved. The AIST team has developed an evolvable chip for lossless image compression, which is suitable for electrophotographic printers (Fig. 29) (Sakanashi et al. 2001). As the size of a typical image printed using this printer goes from tens to hundreds of MBs, a compression algorithm must be used to reduce the image size as well as the time needed to read the images from a hard disk. The conventional algorithm (JBIG) is based on predicting the next pixel value using an MQ coder according to its (typically 16) neighbors. The positions of the neighbors are determined by a so-called template, which is invariable in the conventional algorithm. Since the evolvable chip is able to find the optimal positions of pixels in the template for each block of the image, the predictions are better than in the conventional implementation and hence the compression rate is higher. The EA is executed for each image block separately with the aim of maximizing the compression ratio for the block. The incoming blocks can in fact be viewed as a changing environment for the prediction algorithm. The developed chip operates at 133 MHz and is 7 times faster than the reference implementation running on a Pentium 4.2 GHz processor. The compression rate is 1.7 times better than that achieved by the standard JBIG2 algorithm (Sakanashi et al. 2001, 2006). This is a very good result for lossless compression.

□ Fig. 29

Image compression chip developed at AIST that adapts pixel positions for prediction (Sakanashi et al. 2001).

6.2.2 Adaptive Controllers

Another evolvable hardware chip from AIST was designed for a myoelectric prosthetic hand. The myoelectric hand is controlled by the signals generated with muscular movements (electromyography, EMG signals). It takes a long time, usually almost 1 month, before a disabled person is able to control a multifunction prosthetic hand freely using a fixed controller. This chip allows the myoelectric hand to adapt itself to the disabled person and thus significantly reduce the training period to several minutes (☞ Fig. 30).

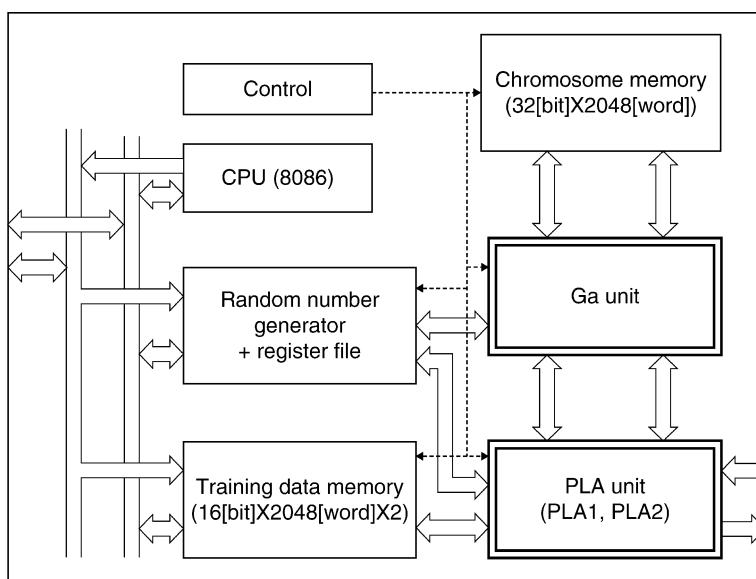

The myoelectric hand described in Kajitani et al. (2001, 2006) is able to perform the six actions, which are paired (open–grasp, supination–pronation, and flexion–extension), with a separate motor control for each pair. The task for the evolvable hardware is to synthesize a circuit that can map input patterns (feature vectors extracted from EMG signals) to the desired actions of the hand.

The training procedure is as follows: First, training pattern data is obtained in an online mode, where the hand user makes one of the six actions from which ten EMG signal patterns are measured. For all six actions, a set of 60 signals is obtained as training data. Then, based on this obtained training data, a classifier is evolved in the PLA (16-bit input/6-bit output), which is available in the chip. GA is implemented on the same chip (partly in an on-chip processor and partly as a special circuit). The same chip was also used for an adaptive robot controller (Keymeulen et al. 1997).

First implementations of the chip achieved 81% classification accuracy. An experienced user is able to achieve 98% accuracy on the recent version of the chip, which uses more complex data preprocessing. The classifier evolution in hardware is 40 times faster than a 1.2 GHz Athlon processor (Kajitani et al. 2006). An incremental evolution-based scheme for

■ Fig. 30

AIST evolvable hardware chip used to implement adaptive controllers and classifiers (according to Kajitani et al. 1998).

EMG signal classification achieving even a higher classification accuracy was also proposed (Glette et al. 2008).

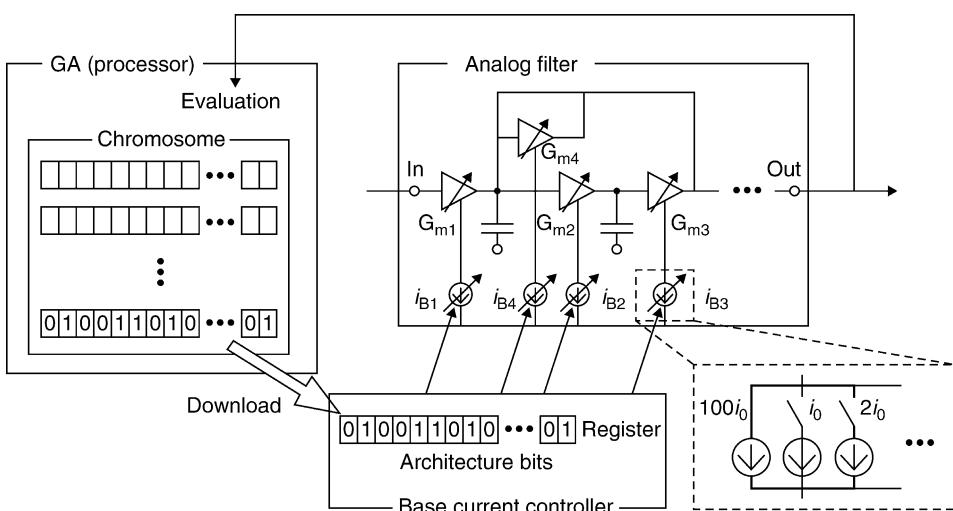

6.2.3 Post-fabrication Adaptation

Post-fabrication calibration of ASICs can also be considered as a kind of hardware adaptation. Fabrication variance in the manufacture of chips can cause problems in some high-performance applications, especially when a cutting-edge manufacturing technology is employed. In other words, only some of the fabricated chips really meet the specification. Hence, an EA is used to tune selected circuit parameters with the aim of obtaining required circuit function even for the chips that do not work because of variance of the fabrication process. Although some area of the chip has to be used for implementing the reconfiguration logic and controller, the overall benefits are significant: It is possible to fabricate simpler, smaller, and low-power designs that do not contain large circuits needed to compensate fabrication variances, and thus increase the yield.

A typical chip in which the post-fabrication tuning was successfully applied is an intermediate filter (IF), commonly found in mobile telephones (Murakawa et al. 1998). In this case, a 1% discrepancy from the center frequency (455 kHz) is unacceptable. Chips that do not meet this requirement must be discarded lowering the yield. The AIST team used GA to control 18 OTAs that properly tune currents to compensate for the errors introduced by fabrication variances (see Fig. 31). The GA operates with a 20-member population and 234-bit chromosomes. The tuning is usually complete after 100 generations, which takes a few seconds. In the experiment, 29 out of 30 fabricated chips were successfully tuned. The method allowed us to reduce the area by 9% and the power consumption by 26%. The recent generation of the chip reduces the area by 49% (with respect to existing commercial designs) (Murakawa et al. 2006).

Fig. 31

Tunable intermediate filter composed of programmable OTAs (from Murakawa et al. 1998).

The same concept was used to compensate for out-of-specification timing delays between circuits, or “clock skew.” AIST devised a clock timing adjustment architecture to eliminate the clock skew problem by using a genetic algorithm to make the clock timings perform within the intended design specifications. Simulation results showed yields rising from 2.9% to 51.1% using evolved clock-timing circuits (Takahashi et al. 2006).

A similar approach was applied to tune signal transmitters (of USB/IEEE 1394 standards) in order to compensate signal distortions at the end of the cable (Kasai et al. 2005). For a particular cable and its placement, the GA-based tuning of the transmitter has successfully achieved a transmission speed of 1.6 GHz, which is four times faster than the current IEEE1394 standard (400 MHz), and a cable length of 21 m, which is four times longer than the current USB standard (5 m).

The evolvable data-compression chip, evolvable controller, as well as the chips that enable post-fabrication parameters tuning were commercialized in Japan. The post-fabrication tuning seems to be the most attractive application of evolvable hardware from the commercial point of view.

7 Other Areas

Evolutionary design has been applied in many hardware-oriented areas, significantly extending the original intention of the evolvable hardware research – electronic circuit evolution and adaptation. For example, in evolutionary robotics, robot controllers are evolved together with robot physical bodies (Lipson and Pollack 2000). The specialized evolutionary robotics literature provides more details, for example, Nofli and Floreano (2000) and Gross et al. (2006). Evolving physical designs have become popular in the aerospace industry (Terrile et al. 2005). Other evolutionary design applications are well covered in Bentley (1999) and Bentley and Corne (2002).

Several research teams have developed adaptive and fault-tolerant research platforms inspired by embryonic processes (Durbeck and Macias 2001; Mange et al. 2000; Moreno et al. 2005; Tufte and Haddow 2005). These platforms implement arrays of artificial cells, which are able to divide (i.e., copy the configuration to neighboring cells) and differentiate (i.e., interpret the configuration according to, for example, location of the cell). These platforms contain various mechanisms for fault detection, localization, and repair. Circuit recovery is implemented using reconfiguration of spare cells and bridging over faulty cells. Fault-tolerance mechanisms are implemented hierarchically providing thus a really robust solution for digital circuits. These approaches will be useful for the massively parallel architectures that we expect in future with the progress in nanotechnology. However, the circuit overhead connected with the implementation of fault-tolerant mechanisms is impractically huge for current technology.

Finally, research is concentrated on the biological aspects and possibilities offered by modeling biological systems in hardware. This includes building biologically inspired structures such as virtual cells, artificial immune systems, and artificial brains using evolvable hardware. Research in this area focuses primarily on biological mechanisms, which can eventually lead to techniques for improved hardware design. Haddow speculates that modeling biological networks can be a killer-application for evolvable hardware (Haddow 2008).

8 Conclusions

The field of evolvable hardware has been surveyed. The status of its main subareas can be now summarized.

Digital circuits evolved so far contain from several gates to millions of gates. It is typical for the evolution of small circuits that all possible input vectors are used in the fitness function and the aim is to improve circuit parameters (area, delay) with respect to existing designs. Evolved mid-size circuits such as image filters or classifiers contain thousands of gates. As the training set has to be used in the fitness function, candidate circuits are evaluated imperfectly, that is, they may not work perfectly for some of the unseen input patterns. For million-component circuits evolved so far, requirements neither on function nor on size were specified; only some structural properties of circuits were evaluated. It can be stated that in all the circuit classes, the chromosomes have similar size, typically around one or two thousand bits. It seems that larger search spaces cannot be sought effectively using existing search algorithms and computational resources. In order to evolve a circuit larger than a small multiplier, a domain knowledge method has to be employed to define suitable components, possibilities of interconnection, and fitness function. Real-world circuits are usually evolved using function-level representation or incremental evolution. Although many developmental encodings were proposed and investigated to overcome the scalability problem, no really innovative designs have been obtained using developmental schemes so far.

In contrast to digital circuit design, analog circuit design requires more experience and intuition. Despite this fact, John Koza and his team have demonstrated high competitiveness of evolutionary algorithms (in particular, genetic programming) in the area of analog circuit synthesis. An important step toward evolving really trustworthy analog designs was done by McConaghy. Evolutionary design is particularly good at exploiting properties of physical systems in order to achieve target behaviors. This unique feature is important for fast tuning of analog circuits that are implemented in reconfigurable devices and operated in a real environment. Successful results were demonstrated for FPTAs running in various environments and FPAs working as controllers. Similarly, it was demonstrated that design for other reconfigurable devices (e.g., antennas, optical systems, and nanosystems, including unconventional platforms such as liquid crystals and nanoparticles) can significantly benefit from the evolutionary approach.

The main contribution of the evolutionary hardware design can be seen in the areas where it is impossible to provide a perfect specification for target implementations, and conventional design methods are based on experience and intuition rather than on a fully automated methodology. Then, the EA can explore the “dark corners” of design spaces that humans have left unexplored. Also, the existence of a fast simulator for a particular domain is important for successful evolutionary designs.

Only few systems exist in which autonomous hardware adaptation is achieved using evolutionary computation. The reason is that there are some crucial problems associated with the use of EAs in these applications, namely, a solution is not always obtained in real-time, the quality of a solution may not be acceptable, and it is difficult/impossible for many applications to obtain training data during system operation. A typical adaptive/evolvable system uses an EA to optimize only a few parameters. In comparison to evolutionary circuit design, chromosomes are relatively short and the task is not difficult for EA (since the EA has to provide a sufficient solution almost anytime). However, with the development of

reconfigurable technology, we can expect a boom in adaptive systems that will be tuned for a particular location, user, or time of operation. The evolutionary approach seems to be very promising in achieving the adaptive behavior.

Finally, evolvable hardware has an impact on the theory of computation. The evolved computational devices represent a distinct class of devices that exhibits a specific combination of properties, not visible and studied in the scope of all computational devices till now. Devices that belong to this class show the required behavior; however, in general, we do not understand how and why they perform the required computation. The reason is that the evolution can utilize, in addition to the “understandable composition of elementary components,” material-dependent constructions and properties of environment (such as temperature, electromagnetic field, etc.) and, furthermore, unknown physical behaviors to establish the required functionality. Therefore, nothing is known about the mapping between an abstract computational model and its physical implementation. The standard notion of computation and implementation developed in computer science as well as in cognitive science has become very problematic with the existence of evolved computational devices (Sekanina 2007).

It can be concluded that evolvable hardware as a field is maturing. Real-world applications of evolutionary hardware synthesis as well as evolutionary-based adaptive hardware exist and bring advantages when compared to conventional solutions.

Abstract

The field of natural computing (NC) has advanced rapidly over the past decade. One significant offshoot of this progress has been the application of NC methods in finance. This chapter provides an introduction to a wide range of financial problems to which NC methods have been usefully applied. The chapter also identifies open issues and suggests future directions for the application of NC methods in finance.

1 Introduction

Recent years have seen the application of multiple natural computing (NC) algorithms (defined in this chapter as computer algorithms whose design draws inspiration from phenomena in the natural world) for the purposes of financial modeling (Brabazon and O'Neill 2006). Particular features of financial markets including their dynamic and interconnected characteristics bear parallel with processes in the natural world and, *prima facie*, this makes NC methods “interesting” for financial modeling applications. Another feature of both natural and financial environments is the phenomenon of emergence, or the activities of multiple individual agents combining to coevolve their own environment.

The scale of NC applications in finance is illustrated by Chen and Kuo (2002) who list nearly 400 papers that had been published by 2001 on the use of evolutionary computation alone in computational economics and finance. Since then several hundred additional papers have been published underscoring the continued growth in this application area (see also Barbazon and O'Neill 2008, 2009; Chen 2002; Tsang and Martinez-Jaramillo 2004 and Wong et al. 2000 for additional examples of NC applications in finance).

Some of the major areas of financial applications using NC methods are: forecasting, algorithmic trading, portfolio management, risk management, derivatives modeling and market modeling. This chapter describes the utility of NC methods within each of these areas wherein their usage can be broadly categorized as optimization, model induction, and agent-based modeling.

1.1 Optimization

A wide variety of NC methodologies including genetic algorithms, evolutionary strategies, differential evolution, and particle swarm optimization have been applied for optimization purposes in finance. A particular advantage of these methodologies is that, if applied properly, they can cope with “difficult” search spaces. Examples of the use of optimization techniques in finance include optimal asset allocation, stock selection, risk management, pricing and hedging of options, and asset liability management (Zenios 2008).

1.2 Model Induction

While optimization applications of natural computing are important, the underlying model or data-generating process is not known in many real-world financial applications. Hence, the task is often to “recover” or discover an underlying model from a dataset. This is usually a difficult task as both the model structure and associated parameters must be uncovered.

Financial markets are affected by a myriad of interacting economic, political, and social events. The relationship between these factors and financial asset prices is not well understood and, moreover, is not stationary over time. Most theoretical financial asset pricing models are based on strong assumptions which are often not met in real-world asset markets. This offers opportunities for the application of model induction methodologies in order to recover the underlying data-generating processes. These methods can be applied, for example, to financial forecasting, credit risk assessment, and derivatives pricing.

1.3 Agent-Based Modeling

Agent-based modeling (ABM) has become a fruitful area of financial and economic research in recent years. ABM allows the simulation of markets which consist of heterogeneous agents, with differing risk attitudes and differing expectations to future outcomes, in contrast to traditional assumptions of investor homogeneity and rational expectations. ABM attempts to explain market behavior, replicate documented features of real-world markets, and allows one to gain insight into the likely outcomes of different regulatory policy choices.

A growing community of researchers are engaged in the application of natural computing methodologies in finance as illustrated by the number of conferences, workshops, and special sessions in this area. Examples of these include the annual track on Evolutionary Computation in Finance and Economics at the IEEE Congress on Evolutionary Computation, the IEEE Symposium on Computational Intelligence for Financial Engineering (CIFEr), the annual International Conference on Computational Intelligence in Economics & Finance (CIEF), and the European Workshop on Evolutionary Computation in Finance (EvoFIN) held annually as part of Evo*.

1.4 Structure of the Chapter

The rest of this chapter is organized as follows: [Section 2](#) provides a concise overview of a number of key families of natural computing methods. [Section 3](#) introduces various financial applications of natural computing methods and shows how these methodologies can add value in those applications. [Section 4](#) concludes this chapter, suggesting multiple avenues of future work at the intersection of finance and natural computing.

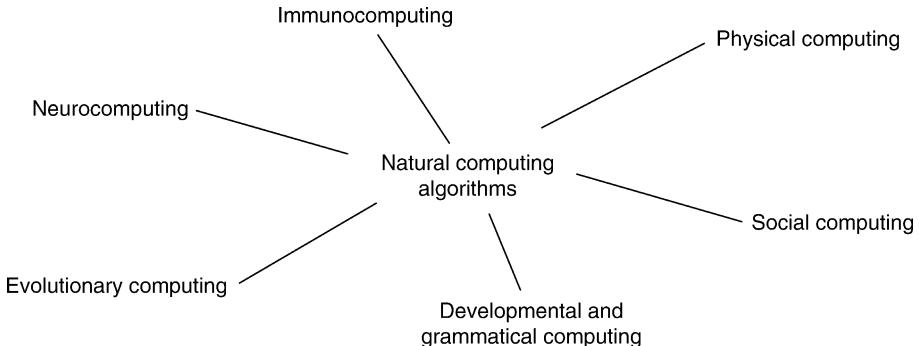

2 Natural Computing

NC algorithms can be clustered into different groups depending on the aspects of the natural world upon which they are based. The main clusters that are relevant for finance applications illustrated in this chapter are neurocomputing, evolutionary computing, social computing, immunocomputing, physical computing, and developmental and grammatical computing (see [Fig. 1](#)).

Neurocomputing (or neural networks, NNs) typically draws inspiration from simplified models of the workings of the human brain or the nervous system. From a design perspective, neural networks can be characterized by a set of neurons (or nodes), the network structure which describes the pattern of connectivity between neurons, and the learning (or training)

Fig. 1

An overview of natural computing algorithms.

approach used. The predominant neurocomputing paradigms include *feedforward networks*, *recurrent networks*, *self-organizing networks*, *radial basis function networks*, *support vector machines* (Vapnik 1995; Cristianini and Shawe-Taylor 2000), etc. Financial firms worldwide are employing NNs to tackle difficult tasks involving intuitive judgment or requiring the detection of data patterns which elude conventional analytic techniques. For example, NNs are already being used to trade the securities markets, to forecast the economy, and to analyze credit risk. NNs were among the earliest NC methodologies to see widespread applications in finance (see, for example, Trippi and Turban 1993) but they do suffer from the practical drawback that their black-box nature makes their internal workings opaque to the user.

Evolutionary Computation (EC) is based upon neo-Darwinian principles of evolution. A population-based search process is used, whereby better (fitter) members of the population are preferentially selected for reproduction and modification, leading to a new population of individuals increasingly adapted to their environment. The main streams of EC are *genetic algorithms* (GA), *evolution strategies* (ES), *evolutionary programming* (EP), and *genetic programming* (GP). These methods have broad applications for optimization and model induction purposes. Recent extensions of the literature on EC to encompass dynamic, multi-objective, and constrained optimization problems has greatly increased the practical utility of these algorithms in finance.

Social Computing adopts a swarm metaphor and includes algorithms inspired by the flocking and schooling behavior of birds and fish. It also includes algorithms inspired by behaviors observed in social insects such as ants. These social systems exhibit a number of characteristics facilitating self-organization, flexibility, robustness, and direct or indirect communication among members of the population. Some examples of social computing include *ant colony*, *particle swarm*, and *bacterial foraging* algorithms. These algorithms are population-based like their evolutionary computation counterparts, and they operate by allowing the population of problem-solvers to communicate their relative success in solving the problem to each other, thereby biasing the future actions of the individuals in the population.

Immunocomputing encompasses a family of algorithms, which turn to the complex and adaptive biological immune system of vertebrates to inspire their design. The natural immune system represents an intricate network of specialized chemicals, cells, tissues, and organs with the ability to recognize, destroy, and remember an almost unlimited number of foreign bodies,

and to protect the organism from misbehaving cells in the body. These properties are especially useful for tasks such as classification and optimization. Practical applications of immuno-computing include financial pattern-recognition such as the identification of potentially fraudulent credit card transactions, the identification of financially at-risk companies, and the identification of market “state.”

Physical Computing draws inspiration from the physical processes of the natural world to design computational algorithms. These algorithms draw inspiration from phenomena such as simulated annealing and quantum mechanics. A claimed benefit of the quantum-inspired algorithms is that, because they use a quantum representation, they can maintain a good balance between exploration and exploitation. It is also suggested that they offer computational efficiencies, as use of a quantum representation can allow the use of smaller population sizes than typical evolutionary algorithms. Computational efficiency is important in many financial applications such as real-time trading where systems have to deal with large data flows and a dynamic environment. Consequently, there is a continuing demand for optimization algorithms, which can potentially offer efficiency gains.

Developmental and Grammatical Computing borrows from both a developmental and a grammar metaphor. Grammatical computing refers to algorithms, which adopt concepts from linguistic grammars and are dominated by the generative form of grammars. Generative grammars are used to construct a “sentence” in the language specified by the grammar, and this generative process is metaphorically similar to the developmental process in biology in which “rules” govern the production of a complex, multicellular organism from a single embryonic cell. Generative grammars have been used in natural computing as a convenient representation by which developmental systems can be realized *in-silico*. The implementations of developmental and grammatical computing, such as *grammatical evolution* (GE) (O’Neill and Ryan 2001, 2003) (a grammatical variant of GP) may also embed an evolutionary algorithm typically used to drive the search process. GE has been already successfully applied to financial forecasting, credit rating assessment, and other financial applications.

These families of NC algorithms provide a rich set of tools for the development of quality optimization, model induction, and agent-based modeling applications, and all have seen application in finance. Readers requiring detailed information on these algorithms are referred to earlier chapters in this book. A review of these methods can also be found in Brabazon and O’Neill (2006), de Castro (2007), and Kari and Rozenberg (2008).

3 Financial Applications

This section introduces the application of NC methods across a range of financial areas including forecasting, algorithmic trading, portfolio management, risk management, derivatives modeling, and agent-based market modeling.

3.1 Forecasting

Financial forecasting applications may involve the prediction of future values of macroeconomic variables, individual stock market indices, commodity futures, the volatility of some financial products, etc. From an optimization perspective, NC methods can be applied either for variable identification or for parameter estimation (optimization). For example, NC

methods can be used to select the explanatory variables from a large pool of candidates, which are then incorporated into the forecasting model. Even where the modeler knows the appropriate set of explanatory variables and model form, the selection of appropriate model parameters (coefficients) can be a difficult task, particularly for complex, nonlinear model structures. In the more difficult problem where the model form is not known, model induction methodologies such as GP or NNs can be used. This is potentially of considerable importance in financial applications, as many theoretical forecasting models are based on assumptions which are not met in real-world financial markets. This offers opportunities for the application of NC methods as model induction tools in order to “recover” the underlying data-generating processes directly from the data.

One family of NC methods which has seen extensive application for financial forecasting is NNs (e.g., Wong and Selvi 1998; Kaastra and Boyd 1996; Aiken 2000; Cao and Tay 2003a Edelman 2007). They offer particular advantages due to their ability to identify nonlinear models, handle noisy data, and embed a memory (recurrent NNs). A simple case of index prediction using a basic feedforward multilayer perceptrons (MLP) to construct a financial prediction model is illustrated in Brabazon and O’Neill (2006), where the MLP model is employed to predict the 5-day percentage change in the value of the FTSE 100 index. Ten inputs selected from a range of technical, fundamental, and intermarket data were included in the final model:

1. 5-Day lagged percentage change of the FTSE 100 index
2. 20-Day lagged percentage change of the FTSE 100 index
3. Ratio of the 10 vs 5-day moving average of the FTSE 100 index
4. Ratio of the 20 vs 10-day moving average of the FTSE 100 index
5. Bank of England Sterling index
6. S&P 500 composite index_{(t) – (t-5)}
7. LIBOR 1-month deposit rate
8. LIBOR 1-year deposit rate
9. Aluminum (\$ per tonne)
10. Oil (\$ per barrel)

In developing the final MLP models, a 11:6:1 structure was utilized, as illustrated in Fig. 2

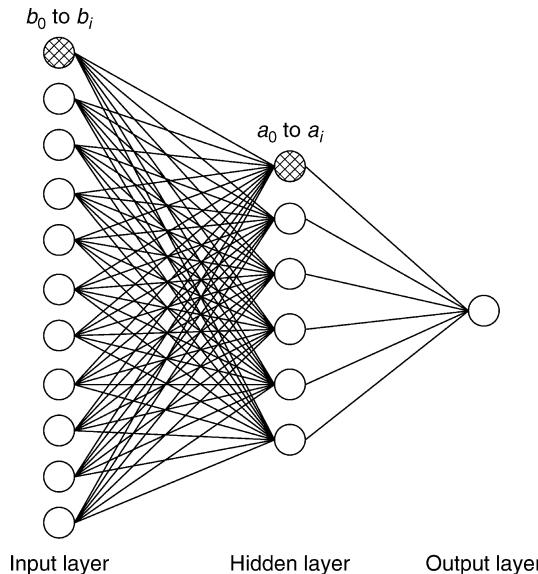

$$y_t = L \left(\sum_{j=0}^5 w_j L \left(\sum_{i=0}^{10} b_i w_{ij} \right) \right)$$

where b_i represents *input_i* (b_0 is a bias node), w_{ij} represents the weight between input node_i and hidden node_j, w_j represents the weight between hidden node_j and the output node, and L represents the hyperbolic tangent function. Generally, NNs are developed through a trial-and-error approach guided by heuristics, the process is time consuming, and there is no guarantee that the final network structure is optimal. One approach is to automate the construction of the NN using evolutionary approaches (e.g., Aiken and Bsat 1999; Armano et al. 2005; and Cao and Tay 2003b).

GP can also be applied for forecasting. One of the best-known examples, EDDIE (which stands for *Evolutionary Dynamic Data Investment Evaluator*), was developed as an interactive decision tool (Tsang and Lee (2002); Li (2001)). It is a *genetic-programming*-based system for channeling expert knowledge into forecasting. Given a set of variables, EDDIE attempts to find interactions among variables and discover nonlinear functions.

Fig. 2

Index prediction using MLP model, with 11 input nodes, six hidden nodes, and a single output node.

Other examples of forecasting in the financial literature include the prediction of takeover targets (Harris et al. 1982; Belkaoui 1978; Palepu 1986; Rege 1984; Hickey et al. 2006), the prediction of auditor qualification of the financial statements of a company (Mutchler 1985; Dopuch et al. 1987; Thompson et al. 2007), the prediction of earnings and the prediction of IPO underpricing. In earnings prediction, Trigueros (1999) uses a GA to select explanatory variables from financial statements in order to predict corporate earnings. In the prediction of IPO underpricing, Quintana et al. (2005) employs GA for rule-based prediction. A less common, but nonetheless important, application in the literature is the prediction of volatility. Neely and Weller (2002) use GP to predict exchange rate volatility, where GP is applied for producing forecasting rules of the out-of-sample daily volatility in the foreign exchange market.

Typically, studies applying NNs, GA, or GP methods, for financial time series forecasting, use measures of goodness of fit drawn from statistics such as *mean squared error*, *sum of squared error*, *mean absolute percentage error*, etc., as their error (or fitness) function. The aim is to uncover or train a model using historical data, which “fits” that data well. Unsurprisingly, the choice of fitness function usually has a critical impact on the behavior of resulting model, hence a model constructed using one fitness metric would not necessarily perform well on another. While many forecasting studies applying NC methods to financial data indicate that models could be constructed to fit historic data fairly well, a common finding is that the quality of the forecasts diminishes, over time, out of sample.

3.2 Algorithmic Trading

Algorithmic trading is defined here as the use of computer programs to assist with any aspect of the trading of financial assets. It can therefore encompass systems which decide on certain

aspects of the order such as the timing, price, or even the final quantity of the order. Hence, algorithmic trading can be combined with any investment strategy. A few related processes of algorithmic trading where NC methods can be applied, namely, investment analysis, arbitrage, and trade execution, are illustrated below.

3.2.1 Investment Analysis

Financial trading has seen a large number of applications of NC methods. Typically, these studies take one of two approaches of investment analysis, using either fundamental data (*fundamental analysis*) or market data, primarily price and volume (*technical analysis*).

Fundamental Analysis

Taking the example of investing in stocks, fundamental investment concentrates on the use of accounting information about the company, as well as industry and macroeconomic data, in order to identify companies which are mispriced by the market. In other words, the objective is to identify stocks which are good value (underpriced by the market), or stocks which are overpriced by the market (and therefore are candidates for “shorting”). In this approach, the investor needs to develop stock screening rules in order to decide which stocks to invest in. These rules were formulated manually in decades before computers. With a natural computing algorithm such as the GA, a large range of stock filter rules can be searched efficiently in order to find the highest-quality rules. In this approach, each individual in the population corresponds to a potential stock filter rule. The utility of these rules are tested using historical data, with the best rule (or set of rules) then being used for investment purposes (☞ Fig. 3). More generally, GP methods can be applied to evolve the structure of the filter rules.

Technical Analysis

In contrast to investors using a fundamental investment approach, technical analysts attempt to identify imbalances in the supply and demand for a financial asset using information from the time-series of the asset’s trading (such as historical price, volume, and volatility data). Usually, investors who adopt a technical analysis approach look to combine technical indicators (preprocessed price and volume time series data about a financial asset), in order to produce a “trading signal”. For example, a “technical indicator” could be the *moving average convergence-divergence* (MACD) oscillator, calculated by taking the difference of a short-run and a long-run moving average. If the difference is positive, it may indicate that the market is

Fig. 3

String encoding of a number of fundamental indicators. Each indicator can be coded as a 0 (no) or 1 (yes).

High sales growth relative to industry average?	High debt level relative to industry average?	High level of cash flow from operations relative to industry average?	High level of liquidity relative to industry average?	High profit level relative to industry average?
---	---	---	---	---

trending upward. For example, a buy signal could be generated when the shorter moving average crosses the longer moving average in an upward direction. A sell signal could be generated in a reverse case. Hence, a sample MACD trading rule could be:

IF x -day MA of price \geq y -day MA of price
THEN Go Long ELSE Go Short

where $x < y$. The optimal value of x and y can be evolved through a genetic algorithm, in order to maximize the trading profit (the fitness measure). A candidate solution encoded as a binary string of length 8 is illustrated below.

$$\begin{array}{r} x: \quad 0 \quad 0 \quad 0 \quad 0 \quad 1 \quad 0 \quad 1 \quad 0 \\ \hline y: \quad 0 \quad 0 \quad 1 \quad 1 \quad 0 \quad 0 \quad 1 \quad 0 \end{array}$$

This solution indicates that $x = 10$ and $y = 50$. The MACD oscillator is a crude band-pass filter, removing both high-frequency price movements and certain low-frequency price movements, depending on the precise moving average lags selected. In essence, the choice of the two lags produces a filter, which is sensitive to particular price-change frequencies. In a recursive fashion, more complex combinations of moving averages of values calculated from an MACD oscillator can themselves be used to generate trading rules. In the past decades, the search for apparently useful technical indicators (or combinations of these) was undertaken manually by investors who back tested various indicators on historical financial data. GP allows the automation of this process with the concurrent vast expansion of the search space, which can be feasibly searched (Dempster and Jones 2001).

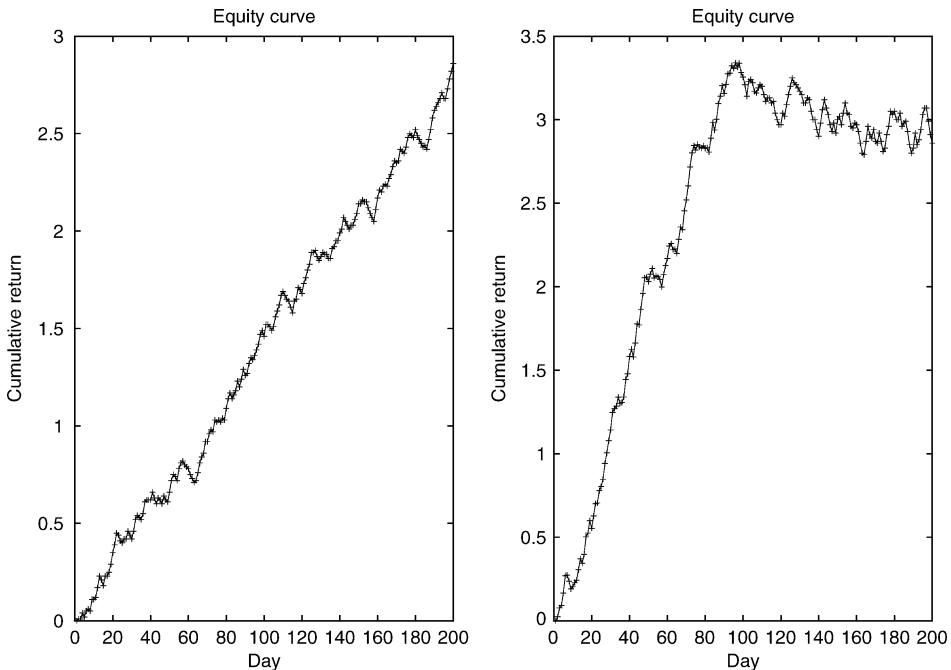

A trading rule should specify the entry, profit-taking, and stop-loss or exit strategy. NC methods can be used for rule optimization (to find optimal parameters for a fixed rule) or rule induction (to find optimal combination of diversified rules). Early applications of EC to uncover trading rules include Bauer (1994), Mutchler (1985), Allen and Karjalainen (1999), and Fyfe et al. (1999). The flexibility to implement different fitness functions is one particular advantage of EC approaches. However, there are also some issues related to the fitness functions as to include transaction cost and to consider different types of risks (Pavlidis et al. 2007). While markets exhibit periods in which a static trading rule can work, it is hard to find evidence of rules which are successful over long time periods. Of course, as financial markets comprise a dynamic system, the utility of any static trading system can be expected to degrade over time (Dempsey et al. 2009). One basic way of examining the characteristics of a trading system is to use an equity curve (Fig. 4). The use of an adaptive trading strategy seems more plausible (Ghandar et al. 2008; da Costa Pereira and Tettamanzi 2008).

Recent work has seen a broadening of the information sources used as inputs in trading models. Instead of typical data drawn from the market, financial statements or macroeconomic data, for example, Thomas and Sycara (2002) and Larkin and Ryan (2008), used text data drawn from either internet message boards/the financial press in the creation of trading rules.

A wide range of forecasting approaches have also been employed to support making trade decisions, such as support vector machines (Edelman and Davy 2004), and hybrid methods like neuro-fuzzy hybrids (Zaiyi et al. 2006), neuro-genetic hybrids, geno-fuzzy (Ghandar et al. 2008) and ensemble methods (combining multiple models) (Kwon and Moon 2004).

Fig. 4

Sample equity curves showing cumulative returns on the y axis and time on the x axis. The left-hand graph exhibits gradual return accumulation, whereas the right-hand graph suggests that the model is working less well on the second half of the time period.

3.2.2 Arbitrage

Arbitrage trading can be defined in a variety of ways, but, broadly speaking, these trades seek to make profits by exploiting price differences of identical or similar financial instruments, on different markets or in different forms (e.g., buying a share at \$23.78 on one exchange, and selling it immediately on another for \$23.82, thereby exploiting a pricing difference for the same asset between the two exchanges). As would be expected, arbitrage opportunities tend to be closed very quickly and transaction cost can negate apparent arbitrage possibilities.

A simple example of an arbitrage play based on *Put-Call Parity* is illustrated in Tung and Quek (2005). In essence, the concept underlying this trade is that the price of a “long” position on an asset and an associated put option (the right to sell that asset in the future at a specified price, see [Sect. 3.5](#) for a detailed description of options) must be equal to the price of a long call option on the same asset and a long position in a risk-free bond. Specifically, for example, for a European option:

$$S_0 + P_E(S_0, T, K) = C_E(S_0, T, K) + K(1 + r)^{-T}$$

where S_0 is the current price of the underlying asset, P_E is the current price of a European put, C_E is the current price of a European call, r is the risk free rate of return, K is the strike price for both options, and T is the time to maturity of the options. If either the put or call option are

mispriced, the investor can, in theory, make a risk-free gain by constructing a portfolio of the four financial instruments.

The above example describes an arbitrage opportunity between the cash market (for the asset) and the option market. More generally, arbitrage opportunities can also exist between cash and future markets and between future and options markets. In its purest form, arbitrage is a risk-free transaction but in reality, most arbitrage trades are exposed to some risk such as liquidity risk or credit risk, and more significantly, execution risk where prices move before all elements of the trade can be completed.

An alternative approach that wait for arbitrage opportunities to emerge and then try to trade on them, is to anticipate or forecast opportunities in advance of the actual mispricing occurring. Markose et al. (2002) adopted this approach and developed a GP model to predict arbitrage opportunities between the FTSE 100 index futures and options market up to 10 min in advance of the arbitrage opportunity arising. Another example of the application of computational intelligence for uncovering arbitrage opportunities is provided in Tung and Quek (2005) who used self-organising, fuzzy NNs to identify mispriced American style currency options between the USD and the GBP, and then use a Delta hedge trading strategy to execute the arbitrage play.

3.2.3 Trade Execution

An important issue in trading financial assets is the efficient execution of large institutional size orders, and applications of EC for this task have begun to emerge in recent years. Typically, orders to buy or sell a stock can be either *market orders* (the transaction is undertaken immediately in the market at current prices) or limit orders (the purchase/sale must occur at a price which is no greater than/or less than a specific price). When a market order is placed, the customer does not have control over the final price, and in a limit order, while the customer has some price control, there is no guarantee that the order will actually be executed. So for example, if a customer places a limit order to buy a stock at \$25 per share, the transaction will only take place if the market price falls to \$25 or less.

Over the last number of years, trading algorithms have been executing an ever-increasing number of trades on markets. In the USA their rise has been brought about through a series of technological and regulatory changes. Since 2001, with the move to decimalization of the US equity markets and the widespread acceptance of electronic market places, the average trade size has declined from 1,200 shares per transaction in 2000 to 300 shares in 2008 (NYSE Euronext). This in turn has led to an explosion in the number of trades executed and a narrowing of spreads, with large institutional orders taking longer to execute. As a result, investors wishing to trade large blocks face trade-offs in balancing the risk of tipping their hand and providing information to the marketplace, thereby suffering market risk as the trade is executed. Trading algorithms seek to optimally execute these orders, using the vast amounts of data produced by the market place and submitting appropriately sized smaller orders to various destinations with the aim of achieving best execution. In reaching this goal, an entire ecology of different trading algorithms have been designed to perform under different market conditions, with recent innovations intelligently switching between these algorithms depending on current market conditions.

When trading shares, particularly when an investor is looking to buy or sell a large quantity of stock, the problem of *market impact* arises. Market impact occurs when the actions of an investor start to move the price adversely against themselves. Hence, market impact is the

difference between a transaction price and what the market price would have been in the absence of the transaction. For example, the order may be executed as quickly as possible through sweeping any orders posted to the limit-order book, however, this would incur significant cost and drive the price of the stock against the investor. In this case, the investor avoids market risk but, by demanding instantaneous liquidity, incurs significant market impact costs. The obvious strategy to minimize market impact is to break the order into smaller lots and spread it over several purchases. While this will reduce the market impact, it incurs the risk of suffering *opportunity cost*, that market prices may start moving against investor during the multiple purchases. Added to this, the steady flow of small orders over time will inform other market participants of the presence of a large institutional order and so encourage competitors to run ahead of the investor. Hence, the design of trade execution strategies is intended to balance out the total cost of market impact and opportunity cost while maintaining a tight control over information leakage.

In selecting a trade execution strategy, the investor must not only balance her preferences but must also be prepared to adapt and change strategy as market conditions evolve. NC techniques provide ample scope to assist in uncovering information that can help optimize trading algorithm selection and/or adaptation. Various rules and heuristics can be evolved and adapted using (for example) GAs that can provide a trading strategy with predictive capability (Stephens and Sukumar 2006) with the aim of selecting best trading tactic under current market conditions. For institutional sized orders, which can be on the order of millions of shares, the reduction in average price by a couple of pennies can lead to significant savings.

Despite the importance of optimizing trade execution, there has been relatively little attention paid in the literature to the application of evolutionary methodologies for this task. One interesting exception is Lim and Coggins (2005) who used a GA to evolve a trading strategy in order to optimize trade execution performance using order book data from the Australian Stock Exchange. In this study, the approach taken was to initially split each trade into a series of N equal sized orders, and the objective was to evolve the timing strategy for the execution of each of these N orders during a single trading day. Each order was submitted as a limit order at the best ask or bid prevailing at the time the order was submitted, depending on whether the investor was seeking to buy or sell shares. A simple traditional trading strategy could be to submit one of these orders every 10 min. However, there is no guarantee that a 10-min order spacing would produce good results in terms of minimizing market impact. Lim and Coggins (2005) used a GA to uncover good quality timings for each order by evolving a chromosome of N genes, where each gene encoded the maximum lifetime that the order would remain on the order book (if it had not already been executed) before it was automatically ticked over the spread (e.g., a limit buy order being repriced to the current ask) to close out the trade. Any uncompleted trade at the end of the day were closed out the same way. Hence, the GA evolved the maximum time that each order would be exposed to the market before being crossed over the spread.

A variety of fitness functions could be designed to drive the evolution of the trading strategy but a common metric of trade execution performance is its *volume weighted average price* (VWAP):

$$\text{VWAP} = \frac{\sum(\text{Price} \cdot \text{Volume})}{\sum(\text{Volume})}$$

The VWAP of a strategy can be calculated and benchmarked against (for example) the overall VWAP for that share during the period of the trading strategy's execution. The aim is to evolve a strategy which produces as competitive a VWAP as possible.

In the above approach, the basic structure of the execution rule is determined in advance (number of trades, etc.) and the task of GA is to parameterize the rule. Another approach which could be applied is to use GP to evolve the structure of the execution rule, as well as its parameters.

In real-world trading, a number of interesting additional issues arise. While the order book provides an indication of the current state of supply and demand for a share, it does not always present a true reflection of the investor's trading intentions. For example, market participants can attempt to "game" the order book by placing limit orders which are subsequently canceled or amended, and (as described above) the order book may contain *iceberg orders* (a large order which has been split into several smaller orders in order to disguise the investor's trading intent). The dynamic nature of the order book suggests that an agent-based modeling approach could be used in order to uncover robust trade execution strategies.

3.3 Portfolio Management

In finance, a *portfolio* refers to a basket of financial assets such as stocks, bonds, and cash equivalents. Portfolio management involves the art and science of making decisions about investment mix and policy, matching investments to objectives, asset allocation, and balancing risk and return. An overview of the portfolio management process is illustrated in Fig. 5. For a portfolio manager, the first and foremost part of the investment process is understanding the client's needs, the client's tax status and his or her risk preferences. The next part of the process is the actual construction of the portfolio, which involves asset class allocation and security selection decisions. Asset class allocation refers to the allocation of the portfolio across different asset classes defined broadly as equities, fixed income securities, and real assets (such as real estate, commodities, and other assets). The security selection decision refers to the selection of specific securities under each asset class. The final component of portfolio management is trade execution, the efficient purchase or sale of the relevant assets in the marketplace. An important and open question is how best to measure the performance of the resulting portfolio.

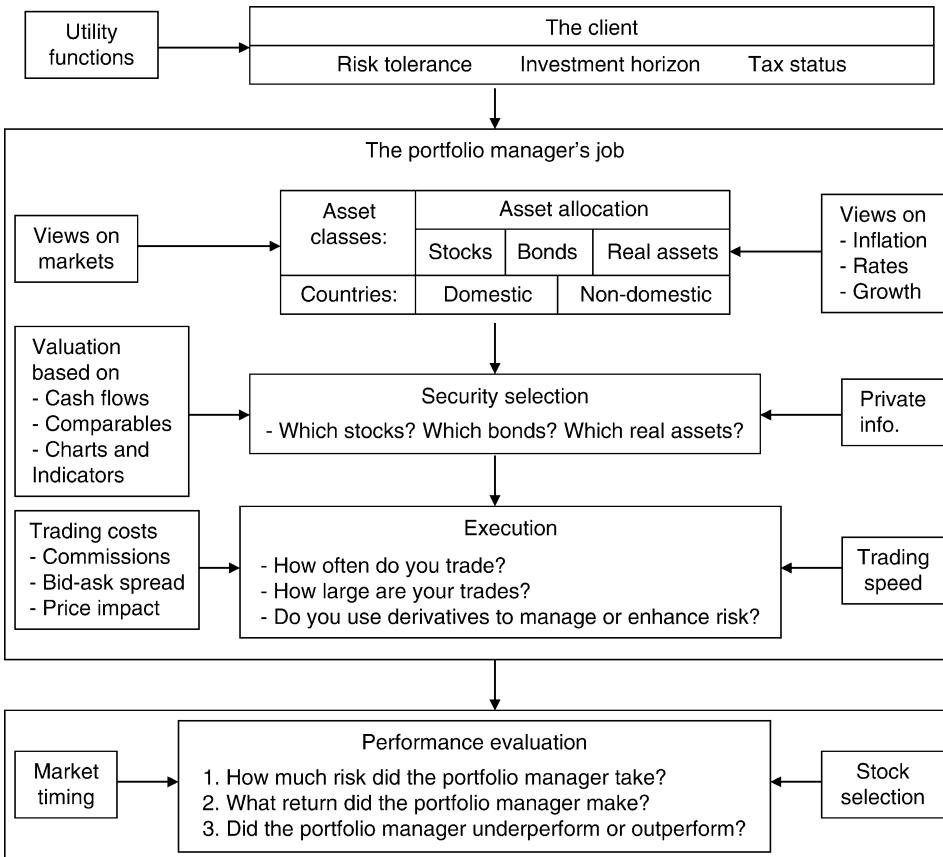

"Optimization is the engineering part of portfolio construction," as mentioned by Fabozzi et al. (2007) in their recent survey for quantitative equity portfolio management: "*Most portfolio construction problems can be cast in an optimization framework, where optimization is applied to obtain the desired optimal risk-return profile.*" Multiple elements of the portfolio management process, such as asset allocation, security selection, index tracking, etc., where optimization is crucial, are amenable to NC methodologies. Applications of NC methods for the purpose of asset allocation and index tracking are illustrated below.

3.3.1 Asset Allocation

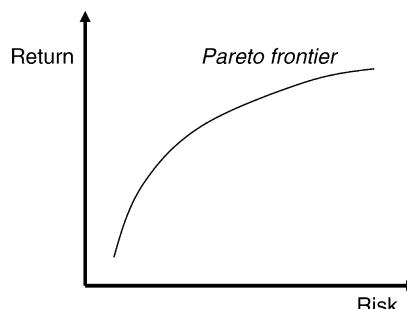

Asset allocation is the selection of a portfolio of investments where each component is an asset class rather than an individual security. The aim of asset allocation is to invest a fixed amount of money in a diverse set of assets so as to maximize return while minimizing a risk measure. The solution to this is a Pareto frontier (usually referred to as the *efficient frontier*) shown in Fig. 6, as for a given level of risk, there should not be a portfolio with a higher rate of return, or for a given level of return, there should not be a portfolio with a lower level of risk.

Fig. 5

An overview of the portfolio management process (from Damodaran (2003)).

**Fig. 6**

Pareto frontier. The points that correspond to the risk-return of the set of portfolios that are Pareto optimal.

Once the frontier is uncovered, the final choice of portfolio is determined by the individual investor's risk preference.

A classical approach used for asset allocation is the Markowitz mean-variance model (Markowitz 1952, 1959). It assumes that investors wish to maximize their return (measured as mean or expected return) and minimize their risk (measured as variance or the standard deviation of their return). This produces the risk-return trade-off. The goal of the Markowitz model is therefore to find an optimal portfolio p of N assets, each with a weighting w_i (in percentage), such that the return E_p is maximized:

$$E_p = \sum_{i=1}^N w_i \cdot \mu_i$$

while minimizing the variance of the return:

$$V_p = \sum_{i=1}^N \sum_{\substack{j=1 \\ i \neq j}}^N w_i \cdot w_j \cdot \sigma_{ij}$$

subject to

$$\begin{aligned} \sum_{j=1}^N w_i &= 1 \\ w_i &\geq 0; i = 1, \dots, N \end{aligned}$$

where σ_{ij} is the covariance of return between asset i and j , the constraints are used to ensure that all the money is invested and all investments are positive (assuming that short selling is not allowed). It produces a multi-objective optimization problem (maximize return, minimize risk) and there are two equivalent formulations which are the dual of each other (first, fix a value of expected return and find the portfolio that minimizes the risk, second, select a level of risk and find the portfolio that maximizes the expected return). Either of the formulations produces a quadratic programming problem and several algorithms exist, which can be applied to uncover good-quality portfolios.

Adding Real-World Constraints

Quadratic programming relies on a number of assumptions, including a single quadratic objective function, linear constraints, and the existence of a positive definite covariance matrix between the asset returns. However, these assumptions are typically breached in the real world. For example, the constraints can include *cardinality constraints* (a limit on the number of assets which can be held in the portfolio), i.e., $\sum_{i=1}^N sign(w_i) = K$, or there may be *threshold limits* on the amount of investment in any single asset, i.e., $w_i \leq m_i$, $i = 1, \dots, N$, where m_i is the threshold amount for asset i . Other constraints may include industry or sector (or *concentration*) holding constraints, round lot constraints, and transaction cost may have both fixed and nonlinear variable cost elements. These constraints can lead to non-convex, non-differential models. In addition, some constraints may be hard and others may be soft. Hence, real-world portfolio selection can present a difficult, high-dimensional, constrained optimization problem, which is beyond the capabilities of traditional optimization methods. In this setting, heuristic approaches such as evolutionary computing methods are of particular interest, because of their ability to find good solutions, even if optimality is not assured.

MOEA and Portfolio Selection

An extensive literature on multi-objective evolutionary algorithms (MOEA) has developed over the past 20 years (see Schaffer 1984; Deb 2001; Coello et al. 2002 for a detailed review). MOEA have an advantage of maintaining a population of solutions and therefore offer the potential to uncover multiple points on the Pareto frontier. A wide range of approaches have been offered to deal with different types of constraints including penalty function approaches, repair mechanisms, the design of appropriate representations, and diversity-generation operators. A stream of literature also exists which has used hybrid evolutionary algorithms or local search techniques for MOEA. Many of these approaches have been applied for portfolio selection.

The earliest papers to apply EAs for portfolio selection include Arone et al. (1993), Loraschi et al. (1995), Shoaf and Foster (1998), and Vedarajan et al. (1997). In the case of Arone et al. (1993) multiple GA populations were used to identify the Pareto frontier. Rather than use the standard Markowitz model, the authors used a downside risk measure. The multi-objective problem was converted into a single objective using a trade-off function, with each population using a different trade-off coefficient and therefore producing a different portion of the Pareto frontier. The formulation of the portfolio problem includes cardinality and buy-in constraints, and a repair mechanism was applied in order to ensure that generated solutions were feasible. The utility of differing crossover operators and differing genotypic representations for the portfolio selection problem was examined by Streichert et al. (2004a, b), and the application of EC hybrids was examined by Subbu et al. (2005) and Streichert et al. (2006). The impact of cardinality constraints was examined in Fieldsend et al. (2004) and Moral-Escudero et al. (2006) (the latter also adopted an EC hybrid approach). A number of other applications including stock ranking, and credit portfolio optimization have been reported in the literature (see Castillo Tapia and Coella (2007) and Schlottmann and Seese (2004) for a review of MOEA applications in finance).

In practical settings, investment managers are concerned with a variety of risk and return measures, not just expected return and its variance. For example, *value at risk* (VaR), the risk that a portfolio could lose a significant amount of its value over a defined time window (more precisely, VaR at level $(1-\alpha)$ is the α -quantile of the loss distribution), has gained importance especially for regulatory purposes. VaR is typically nonlinear and non-convex, making optimization in models, which use this metric difficult. More generally, a portfolio manager may be concerned with more than one risk constraint. A variety of papers have applied MOEA to non-Markowitz risk metrics, including Lipski (2008) which uses a compound risk metric. Hochreiter (2008) introduces an evolutionary stochastic portfolio optimization methodology and illustrates its application using a set of structurally different risk measures, which include, standard deviation, mean-absolute downside semi deviation, value-at-risk, and expected shortfall. Recent work has also seen the application of coevolutionary MOEAs for portfolio optimization (Dreżewski and Siwik 2008).

3.3.2 Index Tracking

There are two common types of portfolio management strategies: passive and active. Active portfolio management consists of picking assets which are expected to outperform the market. In contrast, passive management simply tracks a market index, where the objective is to form a portfolio that replicates the performance of an index as closely as possible.

Passive portfolio management strategies have become very common in recent decades. Just like general portfolio optimization, the construction of an index tracking portfolio is a constrained optimization problem, where the objective is to minimize a measure of *tracking error* (or difference between the return to the portfolio and the return to the index), subject to a variety of constraints, similar to those in the general portfolio optimization problem. The solution space is non-convex suggesting a useful role for population-based, global optimization heuristics.

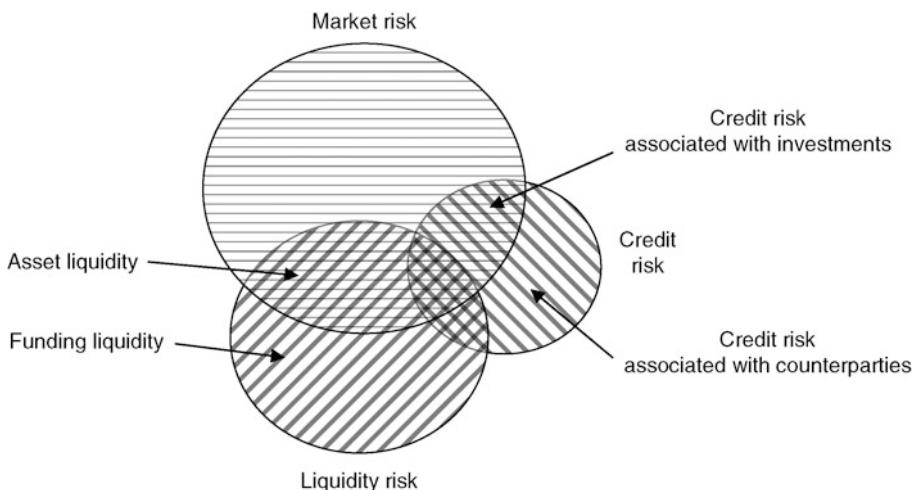

At first glance, the construction of an index tracking portfolio appears trivial, merely requiring the purchase of the same basket of assets that make up the index, using the same weight that each asset has in the index. However, the creation of a perfect replica portfolio is difficult for several reasons including a requirement for frequent portfolio rebalancing (with associated transactions costs), integer constraints on asset purchases, mandate limits on the maximum holding in any individual asset, etc. Another practical issue is that not all assets making up market indices have equal liquidity. Hence, there may be good reason to seek to track the performance of a broad market index using a portfolio which comprises of a subset (rather than all) of the assets making up the index. Another feature of this problem is that the investor's risk attitudes to tracking errors are not symmetric. While investors will not wish to underperform the index, they will not object if the portfolio outperforms the index. EC applications to the index tracking problem include Shapcott (1992), Streichert and Tanaka-Yamawaki (2006), Orito et al. (2007), and Maringer (2008) who also examine the impact of investor loss-aversion preferences on tracking portfolio construction.

3.4 Risk Management

Risk management is a critical aspect of investing. Some of the main types of risks faced by investors are illustrated in Fig. 7 below.

Fig. 7

Risk illustration (from Sound Practices for Hedge Fund Managers (2000)).

3.4.1 Market Risk Computation

Market risk refers to the risk faced by an investor arising from changes in financial market prices. The degree of risk of loss faced by an investor will vary depending on the price volatility of the assets they hold. Not all assets will have the same degree of volatility. There are various techniques to measure market risk (Marrison 2002), applications of NC methodology include the calculation of value-at-risk (VaR) and the sensitivities. The VaR approach measures the worst expected loss under normal market conditions over a specific time interval. The loss distribution is usually assumed to be normal when calculating VaR. Evolutionary algorithms do not need to embed this assumption and can incorporate any preferred loss distribution type (Uludag et al. 2007). NNs have also been used for other market risk measures, such as conditional VaR estimates (Lee et al. 2005), and expected shortfall (Diagne 2002). The sensitivity analysis approach measures how much the portfolio's (or a specific financial instrument's) value is expected to change, if there is a small change in one of the market-risk factors, such as interest rates, equity prices, commodity prices, etc. The sensitivities are the so-called *greeks* for derivatives; *duration* and *convexity* for fixed income products. Keber and Schuster (2001) has used GP to calculate greeks of the American-type put options (see  Sect. 3.5 for an explanation of derivative products).

3.4.2 Credit Risk Assessment

Credit risk assessment is an important component of the lending decision of financial institutions and other commercial companies. Examples of decisions of where credit scoring could be useful include, decisions such as should a loan be extended to a firm or to an individual, should a customer be allowed to purchase goods on credit, or what credit limit should be offered to a customer on their credit card?

Over the past several decades, an extensive literature has amassed on modeling creditworthiness and default risk. Traditional statistical methods including linear discriminant analysis (Altman 1968) and logit (Ohlson 1980) have been applied. In all of these applications, the objective is to develop a model, which will provide a metric of creditworthiness from a series of explanatory variables. Typically, in assessing corporate creditworthiness, explanatory variables can include numbers drawn from the financial statements of the firm, from financial markets, general macroeconomic variables, and nonfinancial, firm-specific information). In assessing personal consumer creditworthiness, explanatory variables can include income, age, occupation, current employment status, past borrowing record, etc. (West 2000; Yobas et al. 2000; Leung et al. 2007). Closely associated streams of academic literature include corporate failure or bankruptcy prediction (Altman 1968), and the reverse engineering of the bond-rating models used by rating firms such as Standard & Poor's (S&P), Moody's, Fitch's, or Dominion Bond Rating Service (Ederington 1985; Dutta and Shekhar 1988; Gentry et al. 1988). Assessments of credit default probability could also form a useful input into a stock- or bond-trading model. A practical problem in constructing risk-assessment models is that there is no clear theoretical framework for guiding the choice of explanatory variables or model form. In the absence of an underlying theory, most published work on credit rating employs a data-inductive modeling approach. This produces a high-dimensional combinatorial

problem, as the modeler is attempting to uncover a good set of explanatory variables and model form.

An illustration of an early credit risk assessment model is provided by Altman's (1968) classic study in which five ratios were combined to produce a linear discriminant classification model for corporate bankruptcy. A Z score was calculated for each company, and this value determined whether the company was classified as bankrupt or solvent:

$$Z = 0.012X_1 + 0.014X_2 + 0.033X_3 + 0.006X_4 + 0.999X_5$$

where

X_1 = working capital to total assets

X_2 = retained earnings to total assets

X_3 = earnings before interest and taxes to total assets

X_4 = market value of equity to book value of total debt

X_5 = sales to total assets

As the range of NC techniques have expanded over the past 20 years, each new technique has been applied to credit scoring and corporate failure prediction. Examples include feedforward NNs (Wilson et al. 1995; Atiya 2001), self-organizing maps (Serrano-Cina 1996; Kiviluoto and Bergius 1998), GAs (Kumar et al. 1997; Varetto 1998), Ant models (Wang et al. 2004; Brabazon and O'Neill 2006), GP and GE (McKee and Lensberg 2002; Brabazon and O'Neill 2006; O'Neill and Ryan 2001; Alfaro-Cid et al. 2008). The domain offers particular potential for evolutionary automatic programing methodologies such as GP or GE as these methods can produce human-readable credit decision rules. This can be important in some countries where lenders can be required to justify decisions not to grant loans. Another advantage of GP and GE is that the rule-evolution process can be seeded using domain knowledge.

Another closely related application is the prediction of bank failure (Lee et al. 2006), with many regulatory authorities using risk models in order to assess which financial institutions require the closest scrutiny. Obviously, for these applications it is important that the regulatory authority can verify the correctness of the underlying prediction model, hence, methodologies which can incorporate expert knowledge and produce interpretable decision rules, such as fuzzy systems and GP, are of particular interest.

Of course, there are other types of risks which need to be quantified in practice, such as liquidity risk and operational risk (arising due to poor or inadequate management control systems or due to human error). However, as yet, there is little literature concerning the application of NC methods in these areas.

3.5 Derivatives Modeling

Derivatives are contracts whose value is derived from the value of the underlying assets, such as equities, interest rates, currencies, market indices, commodities, etc. Two of the best known forms of derivatives are futures and options. A futures contract is an agreement to buy or sell goods, currency or securities on an agreed future date and for a price fixed in advance. An option is a financial instrument that simply gives the holder (buyer) the right, but not the obligation, to buy (a call option), or sell (a put option), a specified underlying asset at

a pre-agreed price on or before a given date. A European style option refers to an option that may only be exercised on expiration; while an American style option can be exercised on any trading day on or before expiration.

The key issue for investors wishing to trade in derivatives is the determination of the fair price for the derivative. For some standard derivatives (based on specific assumptions such as continuous time finance theory), closed-form pricing equations have been determined (e.g., the Black–Scholes model (Black and Scholes 1973; Merton 1973) for pricing European options, the Cox et al. (1979) binomial model, etc.). The traditional approach to pricing a derivative is (Noe and Wang 2002):

- Specify a stochastic process for the underlying asset(s)
- Derive the pricing equation for the derivative (using a no-arbitrage argument) and
- Price the derivative by solving the pricing equation

Of course, this approach can be difficult to implement, as the relevant stochastic process may be imperfectly understood, and the pricing equation may be too difficult to solve analytically. In the latter case, there is scope to use tools such as Monte Carlo (MC) simulation to estimate the expected payoff and the associated payoff risk for the derivative. In valuing a complex derivative using MC, the typical approach is to randomly generate a set of independent price paths for each security underpinning the derivative, then compute the present value of the payoff to the derivative under each set of these price paths. The simulation process is repeated multiple times and the distribution of the payoffs is considered to characterize the derivative. An example of this approach is illustrated in Kim and Byun (2005). A critical issue in applying an MC approach is the correct design of the theoretical pricing model.

There have been two main avenues of application of NC methods in pricing financial derivatives, namely,

- Model calibration and
- Model induction

In model calibration, the objective is to estimate the parameters of (or “calibrate”) a theoretical pricing model. The parameters are estimated by fitting the model to the relevant return time series. Typically, the pricing model will have a complex, nonlinear structure with multiple parameters. Hence, global search heuristics such as the genetic algorithm can have utility in uncovering a high-quality set of parameters. Examples of the use of NC algorithms for model calibration include Dang et al. (2008) and Fan et al. (2007).

In model induction, NC approaches such as GP would have particular utility when little is known about the underlying asset-pricing dynamics as both the structure and the parameters of the pricing model are estimated directly from the data, thereby extracting the pricing model implicitly. Even where theory does exist, model induction methodologies allow one to investigate whether other plausible theories may exist to explain observed prices. Applications of such methods include NNs (Malliaris and Salchenberger 1993; Hutchinson et al. 1994; White 1998), self-organizing, fuzzy NNs (Tung and Quek 2005), or GP (Chen et al. 1999; Chidambaran et al. 1998; Keber 2000; Chidambaran 2003; Yin et al. 2007) to recover a proxy for the price-generating model directly from the data.

An example of using GP to generate an option pricing model is illustrated below. One advantage noted by Chidambaran (2003) is that the GP process can be seeded with the Black–Scholes equation, with the final resulting model being an adaptation of the Black–Scholes equation for conditions which violate its underlying assumptions. For example, in the

Black–Scholes setting for a non-dividend-paying European call option, there are five factors that affect the price of the option (assuming no dividends):

1. S_0 – the underlying asset price
2. K – the exercise price of the option
3. T – the time to maturity (of the option)
4. r – the risk free rate of return (of the underlying asset)
5. σ – the expected volatility of the asset price

Items 1 and 2 can be combined to give ($S_0 - K$) or a measure of the *moneyness* of the option. An option is said to be “in the money” when this value is greater than zero, and “out of the money” when it is less than zero. In developing a pricing model for options from these factors, the Black–Scholes model embeds several critical assumptions. It is assumed that the stock price undergoes a diffusion process that is lognormally distributed, with an instantaneous drift and volatility given by μ and σ , respectively. The volatility σ and the risk-free rate r are also assumed to be constant during option’s life. This implies that:

$$\ln \frac{S_T}{S_0} \sim N\left(\left(\mu - \frac{\sigma^2}{2}\right)T, \sigma\sqrt{T}\right)$$

and in turn this leads to:

$$S_T = S_0 e^{\eta T}, \eta \sim N\left(\left(\mu - \frac{\sigma^2}{2}\right), \frac{\sigma}{\sqrt{T}}\right)$$

where μ is the instantaneous expected return on the stock, σ is the instantaneous volatility of stock price return, S_T is the stock price at a future time T , S_0 is the stock price at time zero, $N(m, s)$ denotes the normal density function with mean m and standard deviation s and η is defined as the continuously compounded rate of return per annum realized between time zero and T . The Black–Scholes formula for the price at time zero of an European call option on a non-dividend-paying stock is therefore:

$$C_0 = S_0 N(d_1) - K e^{-rT} N(d_2)$$

where

$$d_1 = \frac{\ln(S_0/K) + (r + \sigma^2/2)T}{\sigma\sqrt{T}}$$

$$d_2 = d_1 - \sigma\sqrt{T}$$

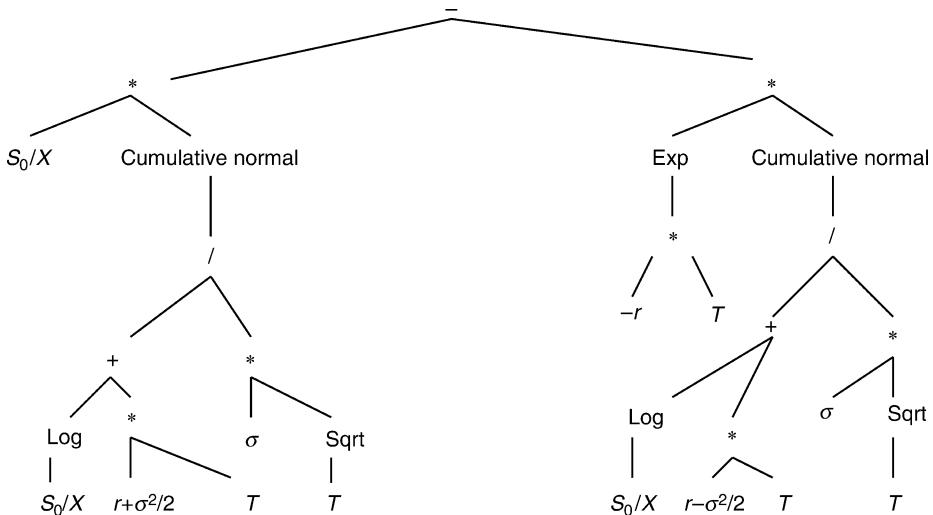

$N(\chi)$ is the cumulative probability distribution function for a standardized normal distribution, C_0 is the price of the European call option at time 0.

Of course, assuming that the Black–Scholes model did precisely value options, model induction techniques such as neural networks or GP could be used to recover the structure of the option pricing model directly from a historical time series of option prices (C_0) and the five factors that influence option prices.  [Figure 8](#) illustrates a tree representation of the Black–Scholes Model which could (potentially) be recovered by GP.

In reality, some of the key assumptions in the Black–Scholes model do not hold in real-world option markets, and hence the model does not explain observed option prices correctly. For example, prices can experience discontinuous jumps, the distribution of price changes has fatter tails than those implied by a lognormal distribution, and asset price volatility changes over time. (There is a long line of literature which examines alternative (non-normal) stock

Fig. 8

Stylized illustration of a tree representation of the Black–Scholes model (not all sub-trees are shown).

return models including Poisson jump-diffusion return processes and GARCH processes. However, closed-form solutions for the option price cannot be obtained for all these models.) The latter issue can be easily seen if market prices are substituted into the Black–Scholes model, in order to calculate the “implied volatility” for that option. If the assumptions underlying the Black–Scholes option pricing model were correct, the implied volatilities for options on the same underlying asset would be constant for different strike prices and maturities. However, in practice, the Black–Scholes implied volatilities are varying over strike price and maturity. Keber (2002) has used GP to generate formulae for determining the implied volatility based on American put options.

3.6 Agent-Based Market Modeling

The essence of agent-based modeling (ABM) lies in the notion of autonomous agents whose behavior evolves endogenously leading to complex, emergent, system dynamics, which are not predictable from the properties of the individual agents. ABM is an exciting new tool for exploring behavior in financial markets that are far from traditional notions of equilibrium, and where agents exhibit behavior that is less than fully rational at times. Financial markets are particularly appealing applications for agent-based methods especially considering the following: issues of price and information aggregation tend to be sharper in financial settings where agent objectives tend to be clearer; financial markets are rich in data sets (such as price and volume data) at many different frequencies, that can be used for testing and calibrating agent-based models; financial markets are well organized, centralized, and trade homogeneous products in a generally efficient fashion relative to markets for other goods and services; there are continuing developments in the area of experimental financial markets, which give carefully controlled environments that can be compared with agent-based experiments; the

key debates in finance about market efficiency and rationality are still unresolved; many puzzles of the financial time series (such as the volatility persistence) are still not well understood. In designing ABMs of financial markets, modelers face a daunting list of design choices which can critically impact on the system's behavior. Important design questions include:

- Representation and structure of the actual trading agents. Agents can vary from simple budget constrained *zero intelligence agents* (refers to a type of trader that randomly makes price bids (offers to buy) and/or price asks (offers to sell) subject only to a budget constraint), as in Gode and Sunder (1993), to sophisticated learning agents as in Chen and Yeh (2001).
- The actual mechanism that governs the trading of assets. Ways of designing this include assuming a simple price response to excess demand, building the market, such that a kind of local equilibrium price can be found easily, or explicitly modeling the dynamics of trading to mimic the continuous trading of real-world markets.
- Types of securities to be incorporated into the agent-based market model, where typically simple securities (such as stocks) are considered.

In designing agent-based models (ABMs) of financial markets, NC methods can be used to model the information processing and storage by agents, the process of adaptive learning by agents, or to model the trading mechanism. One example of the use of ABM to simulate a financial market is provided by LeBaron (2002) in building the well-known Santa Fe Artificial Stock Market. This model simulates price generation and trading in a market made up of artificial adaptive agents. This is a prototype example of a complex system and is thought to illustrate the benefits of simulation modeling. The Santa Fe Artificial Stock Market consists of a central computational market and a number of artificially intelligent agents. The agents choose between investing in a stock and leaving their money in the bank, which pays a fixed interest rate. The stock pays a stochastic dividend and has a price which fluctuates according to agent demand. The agents make their investment decisions by attempting to forecast the future return on the stock, using GA to generate, test, and evolve predictive rules. Other applications of ABM include the simulation of a foreign exchange market (Izumi 1999), the modeling of an artificial stock option market (Ecca et al. 2008) and the modeling of an artificial payment card market (Alexandrova-Kabadjova 2008).

A key output from the ABM literature on financial markets is that it illustrates that complex market behavior can arise from the interaction of quite simple agents. Carefully constructed, ABM can help increase one's understanding of market processes and can potentially provide insights for policy makers and regulators, where, unlike laboratory sciences, one cannot rerun a real market under different regulations "to see what would happen." Of course, issues of model validation are important in all ABM applications, including those in financial markets.

4 The Future

Though a plethora of academic literature on NC applications in finance exists, it is notable that many papers have been concerned with proof of concept rather than robust, industry-strength, applications. While NC methods offer potential in multiple areas in finance, the maturing of their application requires future work focusing on complex real-world problems. This will require the construction of multidisciplinary research teams, drawing academic

expertise as necessary from finance, computer science, mathematics, biology, etc., and combining this with industrial collaborators. For example, quality work on trading systems requires deep knowledge of market microstructure, the regulatory environment, available financial instruments, and the technology available to traders. Indicated below are some promising future directions for research at the nexus of natural computing and finance.

- **Forecasting:** While forecasting models applying NC methods can typically be constructed to fit historical data fairly well, a common finding is that the quality of the out-of-sample forecasts degrades over time. Hence, one can expect to see increased use of sophisticated methods for preprocessing the raw time-series inputs, and for the adaptation of the resulting models in response to changing environmental conditions. Another area of growing interest is the incorporation of information from text mining (e.g., from the financial press) into forecasting models.
- **Algorithmic Trading:** While many published works have focused on the development of simplified trading systems, successful real-world applications have often focused on the support of specific elements of the investment process. In the medium term, one can expect to see a notable increase in the rigor of the published works in this area as computer scientists form teams with finance academics and practitioners, incorporating realistic models of market microstructure. The area of trade execution has seen relatively little published application of NC methodologies, despite its real-world significance. Model induction tools such as GP offer interesting potential here, as do agent-based modeling approaches. The latter could be used to uncover robust trade execution strategies.
- **Portfolio Optimization:** There has already been an extensive application of NC methods for portfolio optimization, but there is still a need for further systematic investigation of portfolio constraints for special sub-application areas including hedge funds, pension funds, and insurance. The extension of dynamic portfolio optimization needs further development, which may involve the simulation or forecasting of extreme market situations, and the solution of multistage constraint optimization problems.
- **Risk Management:** Recent events on the financial markets have underscored the importance of risk management, and the weakness of existing theoretical models in this area. It is interesting to note that applications of NC methods in risk management have not attracted as much attention as might be expected in the literature and this remains an open research area. For example, NC methods could be applied to assist in the development of enterprise-wide risk management systems, and to improve the flexibility and efficiency of large-scale multistage *asset liability management* (ALM) models.
- **Derivatives Modeling:** In spite of the vast array of derivative products available, and the weakness of financial theory, once one moves beyond vanilla products there have only been a relatively limited number of applications of NC for model calibration or induction in this area. Possibilities also exist to hybridize NC methods with traditional numerical methods, and to develop dynamic derivative pricing models.
- **Agent-Based Market Modeling:** The field of ABM is attracting significant attention with the increasing questioning of agent homogeneity which underlies classical financial economics. ABM allows one to examine the effect of the differing forms of market structure on market behavior. Doubtless, the next few years will see increased focus on this, given the failures of market regulation during the recent financial crisis. The coevolutionary element of markets lends itself well to NC approaches in terms of modeling of agent behavior and strategy adaptation.

A practical issue that arises in the application of NC to finance is that the underlying algorithms are themselves undergoing a process of maturation. Recent years have seen extensive research in order to extend canonical NC algorithms into high-dimensional environments (enhancing algorithmic scalability), to develop efficient algorithms for constrained optimization, and to develop practical application of the algorithms in dynamic problem environments. Meanwhile, we have also seen developments in computer hardware, and in our ability to implement parallel versions of NC algorithms (e.g., using *graphics processing unit* (GPU) implementations). These two strands of development are creating an ever more powerful toolbox of NC algorithms for financial modelers.

Abstract

In this chapter we will discuss a selection of application areas in which natural computation shows its value in real-world enterprises. For the purposes of demonstrating the significant impact and potential of natural computation in practice, there is certainly no shortage of documented examples that could be selected. We present just ten applications, ranging from specific problems to specific domains, and ranging from cases familiar to the authors to highlights known well in the general natural computation community. Each displays the proven promise or great potential of nature-inspired computation in high-profile and important real-world applications, and we hope that these applications inspire both students and practitioners.

1 Introduction

The study of natural computation has borne several fruits for science, industry, and commerce. By providing exemplary strategies for designing complex biological organisms, nature has suggested ways in which design spaces can be explored and developed into innovative new products. By exhibiting examples of effective cooperation among organisms, nature has hinted at new ideas for search and control engineering. By showing how highly interconnected networks of simple biological processing units can learn and adapt, nature has paved the way for the development of computational systems that can discriminate between complex patterns and improve their abilities over time. And the list goes on.

It is instructive to note that the methods used that have been inspired by nature are far more than simply “alternative approaches” to the problems and applications that they address. In many domains, nature-inspired methods have broken through barriers in the erstwhile achievements and capabilities of “classical” computing. In many cases, the role of natural inspiration in such breakthroughs can be viewed as that of a strategic pointer, or a kind of “tiebreaker.” For example, there are many, many ways that one might build complex multiparameter statistical models for general use in classification or prediction; however, nature has extensive experience in a particular area of this design space, namely neural networks – this inspiration has guided much of the machine learning and pattern recognition community toward exploiting a particular style of statistical approach that has proved extremely successful. Similar can be said of the use of immune system metaphors to underpin the design of techniques that detect anomalous patterns in systems, or of evolutionary methods for design.

Moreover, it seems clear that natural inspiration has in some cases led to the exploration of algorithms that would not necessarily have been adopted, but have nevertheless proven significantly more successful than alternative techniques. Particle swarm optimization, for example, has been found enormously successful on a range of optimization problems, despite its natural inspiration having little to do with solving an optimization problem. Meanwhile, evolutionary computation, in its earliest days, was subjected to much skepticism and general lack of attention – why should a method be viable for real-world problems when that method, in nature, seems to take millions of years to achieve its ends? What need is there for slow methods that rely on random mutation, when classical optimization has a mature battery of sophisticated techniques with sound mathematical bases? Nevertheless, evolutionary methods are now firmly established, thanks to a long series of successful applications in which their performance is unmatched by classical techniques.

The idea of this chapter is to present and discuss a collection of exemplars of the claims made in this introduction. A handful of selected applications of natural computation will be looked at, each chosen for a subset of reasons, such as level of general interest, or impact. Some classic applications will be considered, which still serve as inspirational to current practitioners, and some newer areas will be looked at, with exciting or profound prospects for the future.

The applications are loosely clustered into four themes as follows. The first theme deals with applications under the banner of “Strategies,” where three examples in which natural computing methods have been used to produce novel and useful strategies for different enterprises are studied in detail. These include an evolutionary/neural hybrid method that led to the generation of an expert checkers player, the use of genetic programming (GP) to discover rules for financial trading, and the exploitation of a learning classifier system to generate novel strategies for fighter pilots. The next theme is “science and engineering” where applications that have wider significance for progress in one or more areas of science and engineering, in areas (or in ways) that may not be traditionally associated with natural computing, are considered. The two exemplars in this area are the use of multi-objective evolutionary computation for a range of areas (often in the bio and analytical sciences) for *closed-loop* optimization, and the concept of *innovization*, which exploits multi-objective evolutionary computation in a way that leads to generic design insights for mechanical engineering (and other) problems. The next theme, “logistics,” exemplifies how natural computing (largely, learning classifier systems and evolutionary computation) has provided us with successful ways to address difficult logistics problems (the case of a real-world truck scheduling problem is looked at), as well as a way to design new fast *algorithms* for a range of logistics and combinatorial problems, via approaches referred to as “super-heuristics” and/or “hyper-heuristics.” Finally, the theme of “Design” is considered and three quite contrasting examples are discussed. These are, in turn, antenna design, Batik pattern design, and the emerging area of software design using natural computing methods.

2 Strategies: Generating Expert Pilots, Players, and Traders

Many problems in science and industry can be formulated as an attempt to find a good strategy. A strategy is, for practical purposes, a set of rules (or an algorithm, or a decision tree, and so forth) that sets out what to do in a variety of situations. Expert game players are experts, presumably, because they use good strategies. Similar is true for good pilots, and successful stock market traders, as well as myriad other professionals who are experts in their particular domains. It may well come as a surprise to some that humans do not have the last word on good strategy – strategies can be discovered by software, which, in some cases, can outperform most or even all human experts in particular fields. In this section, three examples of applications in which strategies have been developed via natural computing techniques, respectively, for piloting fighter aircraft, for playing expert-level checkers, and for trading on the stock market will be looked at.

2.1 Discovery of Novel Combat Maneuvers

In the early 1990s and beyond, building on funding support from NASA and the USAF, a diverse group of academics and engineers collaborated to explore the automated development of

strategies for piloting fighter aircraft. A broad account of this work (as well as herein) is available in Smith et al. (2002). The natural computing technology employed is termed “genetics-based machine learning” (GBML), the most common manifestation of which is the *learning classifier system* – essentially a rule-based system that adapts over time, with an evolutionary process central to the rule adaptation strategy. In this work, such an adaptive rule-based system takes the role of a test pilot. In the remainder of this section, some of the background and motivation for this application are covered, the computational techniques used are explained, and some of the interesting and novel results that emerged from this work are presented.

2.1.1 Background: New Aircraft and Novel Maneuvers

As explained in Smith et al. (2002), a standard approach, when developing a new fighter aircraft, is to make a prototype for experimentation by test pilots, who then explore the performance of the new aircraft and, importantly, are then able to develop combat maneuver strategies in simulated combat scenarios. Without such testing, it is almost impossible to understand how a new aircraft will actually perform in action, which in turn depends, of course, on how it will be flown by experienced pilots. In particular, it is very important that pilots are able to develop effective and innovative combat strategies that exploit the technology in the new craft. Following such testing, issues in performance are then fed back into the design process, and perhaps the prototype will need to be reengineered, and so forth. This testing process is obviously very expensive – costing the price of at least one prototype craft, and the time of highly skilled pilots. One way to cut this cost includes using a real pilot, but to “fly” a simulation of the new craft; another is to resort to entirely analytical methods; however, both of these approaches are problematic for different reasons (Smith et al. 2002). The idea of Smith et al.’s research is to explore a third approach, in which a machine learning system takes the place of a test pilot and operates in the context of sophisticated flight simulations.

To help better understand the motivation for this work and grasp the importance of developing novel maneuvers, it will be useful to recount some background in fighter aircraft piloting. This is adapted next from Smith et al. (2002), while a comprehensive account is in Shaw (1998). A relatively new aspect of modern fighter aircraft is the use of post-stall technology (PST). This refers to systems that enable the pilot to fly at extremely high angles of attack (the angle between the aircraft’s velocity and its nose–tail axis). Pilots have developed a range of combat maneuvers associated with PST flight, including, for example, the Herbst Maneuver, in which the aircraft quickly reverses direction via a combination of rolling and a high angle of attack. In another example, the Cobra Maneuver, the aircraft makes a very quick pitch-up from horizontal to 30° past vertical; the pilot then pitches the aircraft’s nose down and resumes normal flight angles. This causes dramatic deceleration, meaning that a pursuing fighter will overshoot. The technologies that allow PST flight have led to the invention of these and several other maneuvers, as well as the prevalence of tactics that involve “out-of-plane” maneuvering, where the attacking aircraft flies in a continually changing maneuvering plane, invariably different from the plane of the target craft. This link between new technologies and new maneuvers is critical in the design and deployment of new aircraft and is the focus of Smith et al.’s work. The results that are described later involve experiments in which the attacking craft was an X-31 experimental fighter plane, with sophisticated PST capability, and where the target craft in the simulations was an F-18.

2.1.2 Learning Classifier Systems

Learning classifier systems (LCSs: Holland et al. 1986; Grefenstette 1988; Goldberg 1989; Holland 1992) use a collection of rules called *classifiers* in the form of state/action pairs. Each such pair indicates an action to take if the environment currently matches the “state” part of the rule. An LCS operates in an environment according to its current set of classifiers, and uses reinforcement learning and other adaptation methods, in particular, including genetic algorithms (GAs) to gradually adapt the rules over time. Classically, a classifier in an LCS represents states and actions as binary strings, but states may also contain “don’t care” characters (#s). For example, the string: “0 1 0 # 1/0 1 0” is a classifier with the meaning: “If the environment is in state 0 1 0 0 1 or state 0 1 0 1 1, then perform action 0 1 0.”

In a typical LCS, each cycle begins with a message representing the state of the environment (as will be seen, the environment in the fighter plane combat context is simply a characterization of the relative positions and velocities of the aircraft in the simulation). The LCS then sees which of its classifiers match this environmental message. There may of course be several, and some form of conflict resolution method must then be invoked to decide which classifier’s action will be executed. The action eventually chosen is then performed. This action may lead to a reward – that is, some aspect of the environment becomes (more) favorable, and the classifier that led to this action receives an increment to its “fitness” score. In some classifier systems, sophisticated credit allocation systems are in place to ensure that the most recent action does not necessarily receive all of the credit. After some specified number of cycles, the genetic algorithm is invoked. The GA population is formed from a subset of the classifiers focusing on those with higher fitness. New classifiers are produced by standard genetic operations on selected classifiers (where, naturally, selection is biased by fitness), and these are then incorporated into the LCS, overwriting some of the less fit existing classifiers. Clearly, an LCS operates in a way that attempts to find – via the GA, which is in turn informed by the fitnesses of classifiers, which in turn are informed by experience in the environment – a good set of classifiers that achieves continual rewards in its environment.

2.1.3 Implementation, Experimentation Details, and Results

The way that LCS technology has been used, with considerable and long-established success in the domain of combat maneuver discovery (Smith and Dike 1995; Smith et al. 2002), is basically as follows. The task faced by the LCS is (typically) a one-on-one engagement for a specific amount of time, such as 30 s. There is a specified initial configuration of positions and velocities, and the period is divided into periods of 0.1 s (i.e., each action of the classifier pilot must last for at least 0.1 s before another action can be performed). At each of the (typically) 300 timesteps during a simulation, each aircraft observes the current configuration, and decides on an action. At the end of an engagement, a score can be calculated based on the relative probabilities of the two aircrafts having damaged their opponents.

All Smith et al.’s experiments employed AASPEM, the Air-to-Air System Performance Evaluation Model developed by the U.S. Government for computer simulation of air-to-air combat. The encoding of the state/action parts of a classifier were as follows. The state part of a classifier comprised 20 bits: six bits were used to encode the two “aspect angles” that gave the current relative positions of the aircraft in terms of their lines of sight. The remaining 14 bits were used to encode seven parameters (hence, each discretized into four bins), namely: range,

speed, delta speed, altitude, delta altitude, climb angle, and opponent's climb angle. The action part of a classifier comprised eight bits, encoding three parameters: a relative bank angle (three bits), an angle of attack (three bits), and a speed (two bits). Speed, for example, was either 100 knots (00), 200 knots (01), 350 knots (10), or 480 knots (11). The meaning of an action that specified, for example, relative bank angle of 30° and speed of 200 knots, was to aim for these as desired targets. In all cases, the simulation environment (i.e., the AASPEM system) would automatically interpret these aims into realistic actions.

A set of such classifiers, therefore, represents a general strategy, and subsets of related classifiers can potentially encode entire novel maneuvers. During a simulated engagement, the classifiers are run for 300 cycles, as described; when no classifier matches the current environmental configuration, a default action for straight, level flight is used. When more than one classifier is matched, the fittest one is chosen as the provider of the action. At the end of the 300 cycles, a fitness measure is calculated. Following experiment with various approaches, the most promising fitness measurement was found to be based on the difference between the self and the opponents' "aspect angles." This basically gives a score that is a linear function along the continuum from: *self is aiming directly at opponent's tail* to *opponent is aiming directly at self's tail*, with the former obviously preferred. The fitness assigned after an engagement was based on the average of this value over the entire engagement, and is assigned to every individual classifier that was active at any point during the engagement.

Following a full engagement, the GA then operates over the whole population of classifiers. Using a moderate selection pressure for parents, and standard crossover and mutation operations, a collection of new classifiers is generated. The fitness assigned to a new classifier is simply the average of its parents' fitnesses. Typically, about half of the classifiers in a population were replaced with new classifiers. A learning run would continue with repeated such engagements (perhaps ~ 500), each resulting in fitness assignment and operation of the GA, leading to a revised set of classifiers for use in the next engagement. The starting configuration for all engagements in a single run was always one from the small set of tactically interesting situations shown in [Fig. 1](#).

The conditions in [Fig. 1](#) were designed to generate X-31 tactics results for a balanced set of relevant situations.

The early experiments described in Smith and Dike (1995) were quite similar, involving one-on-one combat, in which the LCS attempted to find novel maneuvers for the X-31, but the opponent F/A-18 aircraft used a fixed (although suitably reactive and challenging) set of standard maneuvers embedded in AASPEM. In short, the opponent would always attempt to execute the fastest possible turn that would leave it pointing directly at its opponent, at the same time attempting to match the opponent's altitude.

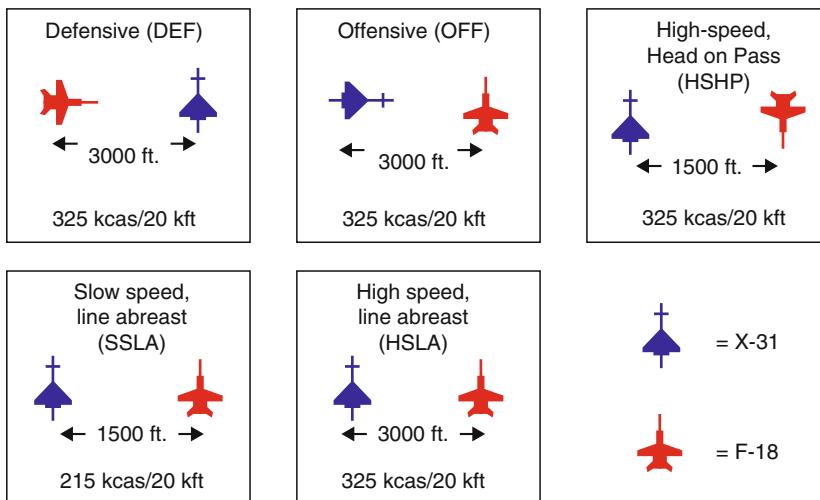

As reported, in considerably more detail, in Smith and Dike (1995), this setup led to the discovery of a wide variety of new and novel fighter maneuvers, which were evaluated in positive terms by real fighter test pilots. An example of such a maneuver is shown in [Fig. 2](#).

The strategy discovered by the LCS in [Fig. 2](#) involves pitching upward sharply, stalling, tipping over, and then engaging the opponent with a favorable relative position. This turns out to be a variation on the "Herbst maneuver" mentioned earlier – in fact it was common for the LCS to rediscover existing maneuvers, as well as discover novel variations.

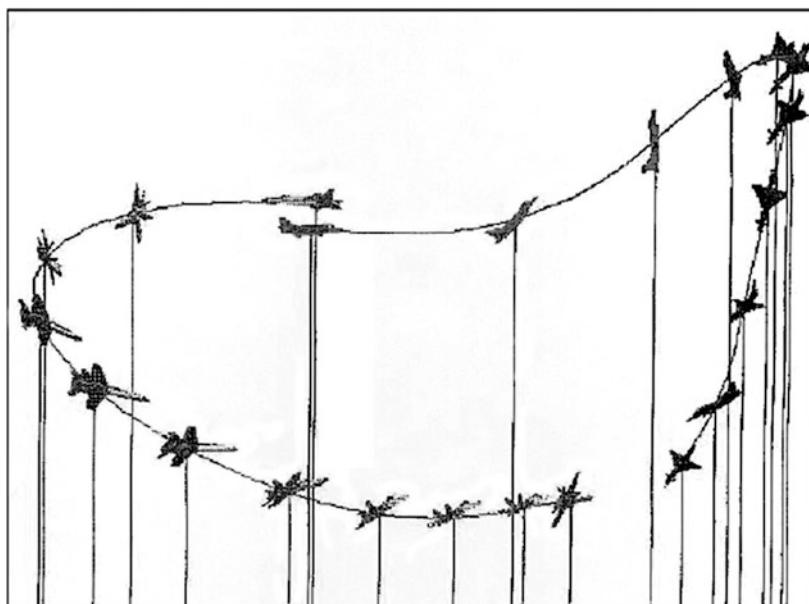

In a later work (Smith et al. 2000), both opponents were controlled by a separate LCS. As Smith et al. (2002) describe, in this scenario, reminiscent of the continuous iterated prisoners' dilemma (IPD), the resulting dynamic system has four potential attractors, the most attractive of which is an "arms race" dynamic, in which each pilot continuously improves his or her

**Fig. 2**

An example of a novel maneuver evolved by the learning classifier system under the HSHP starting condition (see Fig. 1). The aircraft on the *left* is following a fixed, but reactive strategy; the aircraft on the *right* is following a strategy evolved by the LCS, which in turn is a new variation on the Herbst maneuver. Reprinted from Smith et al. (2002), with permission from Elsevier.

strategies. Smith et al. (2000) explored various setups and indeed found that an arms race effect reliably occurs under some conditions.

2.1.4 Findings and Impact

Smith and Dike (1995) and Smith et al. (2000) contain and discuss several more examples of discovered maneuvers, including some revealing expositions of arms races that develop under the conditions of two LCSs in combat with each other. One clear result of this (still ongoing) work is the real impact it has had on its industrial collaborators. In general, the aerodynamics of a new aircraft can be understood before the first prototype is flown; but, the complexities of piloting and combat, and consequently any real knowledge about the potential combat performance with skilled pilots, are much more difficult to predict. Discovering successful combat maneuvers in the way described has many advantages – in particular, without the cost of test pilot time or prototype construction, LCS experiments generate rich sources of information on combat advantages (or disadvantages) that can be fed back to designers, pilots, and customers. The system described briefly here, and more fully in Smith et al. (2000, 2002), and Smith and Dike (1995), has resulted in several novel strategies that have been approved by test fighter pilots and continue to provide useful results in a highly complex, real-world domain.

2.2 Developing an Expert Checkers Player

The next example comes from the area of “computational intelligence.” The term “computational intelligence” has come to be associated largely with the major fruits of nature-inspired computing, particularly, evolutionary, neural, and fuzzy techniques. This is not to be confused with the older, more well-established term “artificial intelligence,” which stands for the much wider enterprise of, by whatever means, designing algorithms and systems that perform functions that can be called “intelligent.” Artificial intelligence (AI) includes classic areas and techniques such as expert systems, heuristic tree search, machine vision, natural language processing, planning, and so forth, as well as the growing range of nature-inspired techniques. AI is concerned with everything from full-scale intelligent systems, through to the details of appropriate heuristics for edge detection in images from a narrow domain.

Basically, almost any activity, other than those that are “easy” for computers to handle with standard techniques, can be labeled with the adjective “intelligent.” However, via natural computing, achievements have been made that will seem genuinely surprising to many people. It is no great surprise, for example, that computers can design, more successfully than humans, effective production schedules for factories with thousands of jobs per day. However, it perhaps is surprising that one can produce a software that plays checkers at the level of an expert, without encoding any expert knowledge of the game.

2.2.1 Blondie24

In 1999, on an Internet gaming site called “The Zone,” an online checkers player with the screen name *Blondie24* regularly played against a pool of 165 human opponents, and achieved

a rating of 2,048, placing it well into the top half a percent of checkers players using that site. Blondie24 learned to play well at checkers, as did all of the good human players using that site (or otherwise). However, “she” was (and still is) a computer program.

In common with many successful artificial intelligence game playing programs, Blondie24 (Chellapilla and Fogel 1999a, b, 2001; Fogel 2002) incorporates a minimax algorithm (Russell and Norvig 2003) to traverse the game tree induced by the available moves from the current position. However, individual nodes in the tree are evaluated by an artificial neural network (ANN). The input to this ANN is a specialized representation of the current state of the game, and the output is a single value that is then used by the minimax algorithm. So far so clear – one can perhaps imagine that a well-trained or well-designed ANN could be capable of returning values in this context that would translate to competent checkers playing. But how can one design, or train, such an ANN? In Blondie24’s case, training was accomplished by using an evolutionary algorithm. A population of such ANNs played against each other, accumulating points over many games. The result of a game between two such ANNs comes down to a single value (per ANN) – either 1 (win), 0 (draw), or -2 (lose) – and the overarching evolutionary algorithm operates by regarding the fitness of an ANN as its total score after a number of games. In each “generation” of this evolutionary algorithm, the ANNs with the lowest scores are eliminated, and new ones are generated by making mutant copies of the better performers, and so it continues.

For several reasons, Blondie24’s design and its success are both surprising and significant. Its prowess at checkers does not rely on tuition by human experts. Instead, it emerges from the evolutionary algorithm process, guided only by the bare, raw total of points earned after playing several games. If an individual had a fitness of six, for example, it was considered better (and hence had more chance for selection as a parent) than an individual with fitness four. However, this takes no account of the distribution of wins, losses, and draws. The individual with fitness six may have won six games and drawn four, while the individual with fitness four may have won eight games and lost two.

Guided only by this summary measure of performance, an evolutionary algorithm was able to traverse the space of checkers-playing ANNs (or, more correctly, ANNs for evaluating game positions in the context of minimax search) and emerge with expert-level players. It is worth covering in more detail the approach taken to generate Blondie24, which is done next, following the treatment provided in Chellapilla and Fogel (2001).

2.2.2 Checkers: The Game

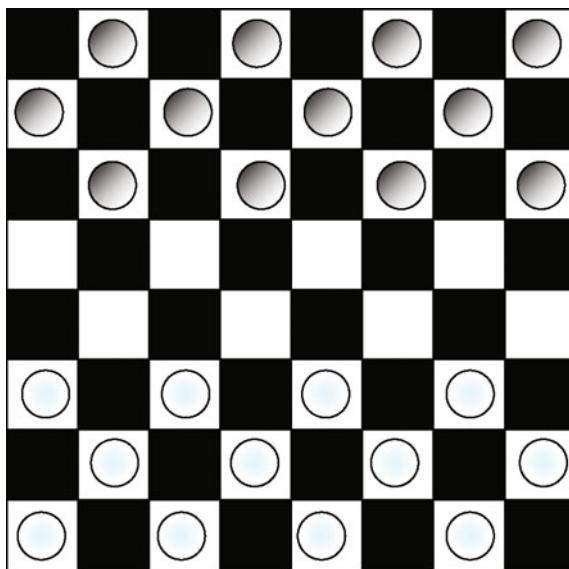

Checkers, known in some countries as “draughts,” involves an eight-by-eight board with squares of alternating colors, equivalent to a chessboard. Each player has 12 identical pieces, and the initial game position is as detailed in Fig. 3.

When it is a player’s turn to move, the allowed moves are as follows: an individual piece can move diagonally forward by one square; or an individual may jump over an opponent’s checker into an empty square. Such a “jump” is only allowed if it takes two diagonal steps in the same direction, the first such step is occupied by an opponent’s piece, and the second step is currently empty. After a jump, the opponent’s piece is removed from play.

If one or more jump moves are available, then it is mandatory for the player to make such a move. If an opponent manages to find itself in the final row (from their side’s viewpoint), it becomes a “king” piece. It is then able to move either forward or backward, but otherwise

Fig. 3

The initial position in a game of checkers. The White player moves upward, and the Black player moves downward.

follow the same rules. The object of the game is to reach a position in which the opponent has no possible moves – a common way in which this happens is for the opponent’s pieces to all have been removed.

2.2.3 Representing the Board and Evaluating Moves

Chellapilla and Fogel (2001) used a straightforward and sensible approach to encoding a board position. The current state of the game is simply represented by a vector of 32 numbers, one for each board position. The numbers in a position are either $-K$, -1 , 0 , 1 , or K , where K represents a value assigned to a king. From the viewpoint of a given player, a 1 or a K at a given board position represent, respectively, either a standard piece or a king at that position, while the negative values are used to represent the opponent’s pieces, and 0 indicates an empty position. In Chellapilla and Fogel’s work, K was not preset. Rather than bias the process toward giving a king any particular relative value over an ordinary piece, the value of K was itself subject to evolution.

When a move is to be made, Blondie24 operates by evaluating, in turn, each of its possible moves. Any such move leads to a future board position, and this future board position is evaluated by the ANN. The input to the ANN is therefore this 32-dimensional vector. As is well known from ANN theory, any reasonable ANN architecture (in terms of the number of hidden layers and the numbers of nodes in each layer) might suffice in being capable of then performing the appropriate mapping from input vector to appropriate, useful output. The difficulty, as ever, is in choosing an appropriate training regime, which promotes learning of suitable features and components of the problem state that are useful guides toward a proper

evaluation. After initial experiments with a more straightforward neural network architecture (which did not encapsulate the spatial information that human players take for granted), Chellapilla and Fogel designed the architecture of the ANN in a way that highlighted potentially appropriate features. This was done as follows.

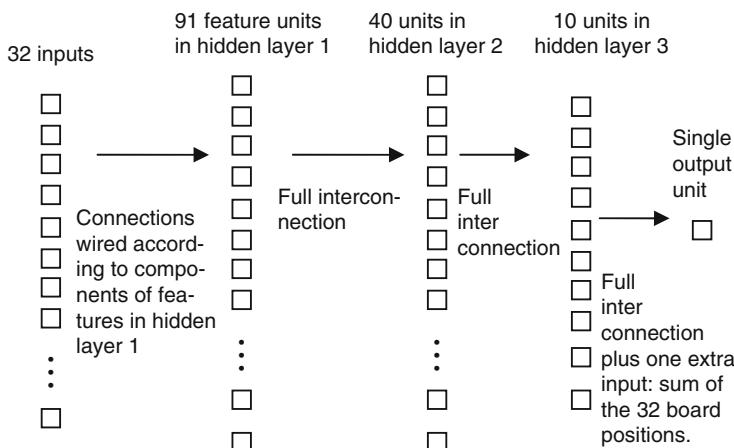

Each 3×3 block on the board was represented by its own unit in the first hidden layer. That is, given any specific 3×3 block, one of the units in the first hidden layer received incoming connections from that specific set of nine inputs from the input layer (from the nine parts of the vector corresponding to the component positions of that 3×3 block), and had no incoming connections from any of the other units. In this way, a specific signal emerging from this unit, for later processing in subsequent layers, summarizes the state of play in that specific 3×3 block. The first hidden layer contained such a unit for each of the 36 different 3×3 blocks on the board. In just the same way, each 4×4 block, 5×5 block, 6×6 block, 7×7 block, and 8×8 block (of which there was of course just one) was represented in the first hidden layer by its own unit. This resulted in a set of 91 units which comprised the first hidden layer.

The complete picture of the ANN's architecture is given in [Fig. 4](#). Between the input layer, which simply carries 32 units, one per board position, and the first hidden layer, the connections are arranged according to the specific feature encoded by each of the units in hidden layer 1. Between the pairs of layers, the connections are all complete – for example, each unit in hidden layer 1 has a feedforward connection to each unit in hidden layer 2, and similarly for hidden layers 2 and 3, while every unit in hidden layer 3 is connected to the single output unit. The output unit receives an additional input, which is the sum of the 32 board positions.

In total, including bias weights, there are 5,046 connections in this network, each of which is a real-valued weight subject to the evolution process. In addition, every hidden layer unit has a bias input, which means an additional weight to be evolved. Each unit in the hidden layers operates in the standard way, common in most ANN applications, by calculating the weighted sum of its inputs and applying the hyperbolic tangent function, resulting in an output signal

Fig. 4

The architecture of the Blondie24 artificial neural network.

strictly between -1 and 1 . From the perspective of the ANN “player,” this ultimate scalar value is directly used as an estimate of the value of this board position: the closer it is to 1 , the better for the ANN. However, where the board position was actually a win for the ANN, the value was taken to be precisely 1 , and if it was a win for the opponent, the value was taken to be -1 .

2.2.4 Evolving Checkers Players

The process begins with a population of 15 such ANNs, which are initialized randomly. Every connection weight and bias value is given a value chosen uniformly at random from the interval $[-0.2, 0.2]$, and with K set initially at 2.0 . In common with the practice of evolutionary programming and evolution strategies, each individual in the population also contained a vector of step-size parameters. For every connection weight, and every corresponding bias unit, there was also a step-size parameter governing the range of mutations that would be applied to that parameter. That is, when a weight or bias parameter was mutated, this was done by adding a Gaussian perturbation whose mean was 0 and whose variance was provided by the associated step-size parameter in the chromosome. The step-sizes were initially all set at 0.05 , and then subject to evolution along with the other parameters.

Whenever an ANN was selected as a parent, its offspring was generated as follows: first, each of the step-size parameters was mutated, by multiplying it with a random number from a specific exponential distribution, and every weight and bias parameter was mutated by adding a Gaussian perturbation whose step size was the associated step-size parameter, as indicated. Finally, recall that each individual also carries its own value for K , which is also subject to evolution. This was mutated by adding a perturbation chosen uniformly at random from the set $\{-0.1, 0, 0.1\}$, but was protected from moving below 1 or above 3 .

During the evolution process, each ANN played one game each against five opponents, selected uniformly from the population. With the scoring for individual games as indicated, the ANN would therefore accumulate a score over these five games ranging from ten (all losses) to five (all wins). A game was declared as a draw (zero points) if it lasted for 100 moves. Essentially, in each generation, each ANN took part in around ten games, and the top 15 (in terms of points received) became parents for the next generation. Each individual game was played using a minimax alpha–beta search set to four-ply (with extended ply in a number of special cases). After 840 generations in which evolving ANNs played against each other, the best-resulting ANN was then harvested and recruited to play against human opponents on the Internet gaming site “The Zone.” The next subsection summarizes the surprising and remarkable resulting performance of this ANN.

2.2.5 Humans Versus Evolved ANNs

Over a 2-month period, the evolved ANN, eventually named “Blondie24” (which was successful in attracting opponents) played 165 games against human opponents at “The Zone,” although opponents were not aware they were playing against a computer program. In these games, the ANN used an eight-ply search, and faced a variety of opponents. The ANN’s performance placed it at better than 99.6% of all the (rated) players using the site. On one occasion, the ANN beat an expert-level player (with a rating of 2,173, just below the master level of 2,200) who was ranked 98th of over 80,000 registered players.

Chellapilla and Fogel (2001) performed some comprehensive control experiments, which showed that the evolved ANN operated with a clear advantage over a system that simply used the piece differential as the basis for choosing moves in an eight-play approach. In particular, they compared the ANN with a piece-differential-based player, on the basis of using equal CPU time in their look-ahead search at each move; this disadvantages the ANN, since it has over 5,000 weight parameters involved in its heuristic calculation, so the piece-differential player can look further ahead in the time available. These experiments showed conclusively that the evolved ANN was a significantly better player in both equal-ply and equal CPU-time conditions.

The achievement of Blondie24 is remarkable from many viewpoints: particularly the essential simplicity of its approach, the fact that the search landscape for the evolutionary algorithm was so huge, and the fact that fitness assessment was a relatively coarse measure of a network's performance. A straightforward assessment of Blondie24's "message" is that it exemplifies the flexibility and potential of evolutionary search, even when this is recruited to search a coarse-grained 10,000-dimensional landscape (the evolution strategy that was employed optimized both a weight and a step-size parameter for each connection). Achieving expert-level performance (over 2,000 points) is considerably superior to most humans. Perhaps not surprisingly, this is also certainly superior to a simpler (but seminal) approach in this area by Samuel (1959), which attempted to derive, by an iterative learning process, a polynomial board rating function. Chellapilla and Fogel (2001) note that this was considered to rate below 1,600 in the opinion of the American Checkers Federation games editor.

The world champion checkers program, Chinook (Schaeffer et al. 1996), is rated at over 2,800, over 100 points above its closest human competitors (Schaeffer 1996). In fact, it is now known that Chinook can never be defeated in "go-as-you-please" checkers, in which there are no restrictions on the initial moves. The chief difference between Blondie24 and Chinook is the amount of built-in specialized knowledge. In Chinook, the level of such knowledge is very substantial indeed; in Blondie24, it is virtually none. Along with many other elements informed by careful expert knowledge and tuning, Chinook incorporates a database of games from previous grand masters and a complete endgame database for *all* cases that start from ten pieces or fewer. Blondie24 and Chinook represent entirely different artificial intelligence approaches to designing a game-playing program. It is not difficult to argue that the approach taken by Blondie24 is the more interesting and impactful – from no prior knowledge, other than a built-in awareness of the rules of the game, an expert-level player emerged from the evolutionary process, providing a very tough, usually insurmountable challenge to all but a very small percentage of human players.

Finally, since the checkers research, Chellapilla and Fogel's approach was extended to address chess, by combining the coevolutionary spatial neural network approach with domain-specific knowledge (Fogel et al. 2004, 2006). The result was an evolved chess player that earned wins over Fritz 8, which was the fifth best computer program in the world at that time.

2.3 Discovering Financial Trading Rules

Financial markets are complex and ever-changing environments in which groups of individuals, companies, and other investors are always competing for profit. There are many

opportunities in this area for machine learning and optimization methods, and consequently a variety of natural computation approaches to be exploited, and a chapter in this volume is indeed devoted to this topic. This section focuses on one specific thread of research in this area – which has a simply grasped approach and a straightforward task to solve. This is the use of GP to discover new and valuable rules for financial trading.

It is now common to see applications of evolutionary computation applied to the financial markets (Brabazon and O'Neill 2005, this volume). GP (Koza 1992; Angeline 1996; Banzhaf et al. 1998) is particularly prominent in terms of the degree to which it has recently been applied in finance (Chen and Yeh 1996; Fyfe et al. 1999; Allen and Karjalainen 1999; Marney et al. 2001; Chen 2002; Cheng and Khai 2002; Farnsworth et al. 2004; Potvin et al. 2004). This section focuses on the specific area in finance known as *technical analysis* (Pring 1980; Ruggiero 1997; Murphy 1999; Lo et al. 2000). Technical analysis is a set of techniques that forecast the future direction of stock prices via the study of historical data. Many different methods and tools are used, all of which rely on the principle that price patterns and trends exist in markets, and that these can be identified and exploited.

Common tools in technical analysis include indicators such as moving averages (the mean value of the price for a given stock or index over a given recent time period), relative strength indicators (a function of the ratio of recent upward movements to recent downward movements). There have been a number of attempts to use GP in technical analysis for learning technical trading rules, and a typical strategy is for such a GP-produced rule to be a combination of technical indicator “primitives” with other mathematical operations. Such a rule is often called a “signal.” For example, GP may be employed to find both a good buy signal and a good sell signal – that is, one rule that, if its output is above 0, indicates that it is a good time to buy, and a different rule indicates when it is a good time to sell.

Early attempts to use GP in technical trading analysis were by Chen and Yeh (1996) and Allen and Karjalainen (1999). However, although GP could produce profitable rules for the stock exchange markets, their performance did not show any benefit when compared to the standard buy-and-hold approach. “Buy-and-hold” simply means, for a given period, buying the stock at the beginning of the period, and selling at the end – hence, always a good idea in a market that generally moves up during the period.

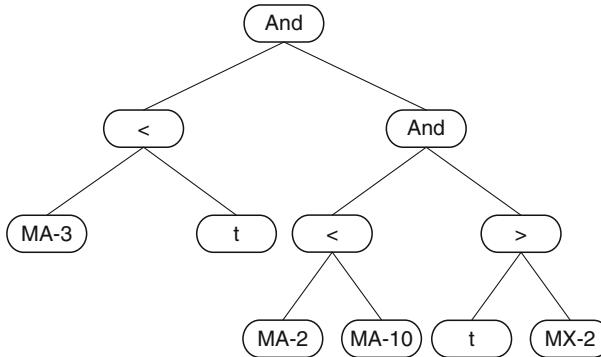

More recent applications of GP in this context have been more encouraging (Marney et al. 2000, 2001; Neely 2001). Becker and Seshadri’s (2003a, b, c) work is looked at in particular, which found GP-evolved technical trading rules that outperformed buy-and-hold (at least if dividends are excluded from stock returns). In turn, their approach was founded in Allen and Karjalainen (1999), with various modifications. After giving some detail of the overall approach, further experiments from Lohpetchi and Corne (2009, 2010), which probed certain boundaries of the technique and examined its robustness, are summarized.

2.3.1 Becker and Seshadri’s Approach to Evolving Trading Rules

Becker and Seshadri (2003a, b, c), based on Allen and Karjelainen (1999), used a fairly standard GP approach and found rules that significantly outperformed buy-and-hold on average over a 12-year test period of trading with the Standard & Poors (S&P 500) index. Their GP’s function set contained the standard arithmetic, Boolean, and relational operators, and the terminal set included some basic technical indicators. An example of a specific rule found by their method is in  Fig. 5.

Fig. 5

Example of a trading rule found by Becker and Seshadri's GP approach.

The rule in Fig. 5 has the following basic interpretation “the 3-month moving average (MA-3) is less than the lower trend line (t) and the 2-month moving average (MA-2) is less than the 10-month moving average (MA-10) and the lower trend line (t) is greater than the second previous 3-month moving average maxima (MX-2).” This signals trading behavior in the following way: If the trader is currently out of the market (no stocks invested in the S&P 500), and the rule evaluates to *true*, then *buy*; if the trader is currently in the market, and the rule becomes *false*, then *sell*. This procedure assumes a fixed amount to invest (e.g., \$1,000) whenever there is a buy signal.

The remainder of this subsection explains the approach in more detail, and tries to emphasize the key points that are necessary to replicate similar performance. In passing, the main ways in which Becker and Seshadri modified the original approach of Allen and Karjelainen are noted. These were: monthly trading decisions rather than daily trading; a reduced function set in the GP approach; a larger terminal set in the GP approach (with more technical indicators); the use of a complexity-penalizing element to avoid over-fitting; and finally, modifying fitness function to consider the number of periods with well-performing returns, rather than just the total return over the test period. In combination, these methods enabled Becker and Seshadri to find rules that outperformed buy and hold for the period they tested, when trading on the S&P 500 index. It is an open question as to which modifications were most important to this achievement; however, Lohpetchi and Corne (2010) begin to answer that question, as will be seen, by showing (as is intuitively the case) that it is increasingly easier to find good rules as one changes the trading interval from daily to weekly, and then to monthly.

In the following, we exclusively use S&P 500 data (as did Allen and Karjelainen 1999 and Becker and Seshadri 2003a, b, c); so, the “portfolio” is the fixed set of 500 stocks in the S&P 500 index, which aggregate to provide daily price indicators.

2.3.2 Function and Terminal Sets Used by Becker and Seshadri

In Becker and Seshadri's GP approach, the function set comprises simply the Boolean operators and, or, and not, and the relational operators $>$ and $<$. The terminal set comprises

the following, in which “period” was always *month* in Becker and Seshadri’s work, but later Lohpetch and Corne (2010) will be discussed in which it could be day, week, or month in different experiments.

- Opening, closing, high and low prices for the current period;
- 2-, 3-, 5-, and 10-period moving averages;
- Rate of change indicator: 3-period and 12-period;
- Price Resistance indicators: the two previous 3-period moving average minima, and the two previous 3-period moving average maxima;
- Trend Line indicators: a lower resistance line based on the slope of the two previous minima; an upper resistance line based on the slope of the two previous maxima.

The n -period moving average at period m is the mean of the closing prices of the n previous months (included m). The n -period rate of change indicator measured at period m is: $(c(m) - c(m - (n - 1))) \times 100 / c(m - (n - 1))$, where $c(x)$ indicates the closing price for period x . Previous maxima MX1 and MX2 are obtained by considering the 3-period moving averages at each point in the previous 12 periods. Of the two highest values, that closest in time to the current period is MX1, and the other is MX2. The two previous minima are similarly defined. Finally, to identify trend line indicators, the two previous maxima are used to define a line in the obvious way, and the extrapolation of that line from the current period becomes the upper trend line indicator; the lower trend line indicator is defined similarly, using the two previous minima.

2.3.3 Becker and Seshadri’s Fitness Function

The fitness function has three main elements. First is the so-called “excess return,” indicating how much would have been earned by using the trading rule, in excess of the return that would have been obtained from a buy-and-hold strategy. The other elements of the fitness function were introduced by Becker and Seshadri to avoid over-fitting. These were as follows: a factor that promoted fitness for trading rules that were less complex (e.g., with reference to [Fig. 5](#), a less complex rule is one in which the tree has smaller depth); and, a factor that considered “performance consistency” (PC), favoring rules that generally were used often, each time providing a good return, rather than rules that were very fortunate in only brief periods.

In more detail, the excess return is simply $E = r - r_{bh}$, where r is the return on an investment of \$1,000, and r_{bh} is the corresponding return that would have been achieved using a buy-and-hold strategy. To calculate r , Allen and Karjeleinen (1999) and Becker and Seshadri (2003a, b, c) used:

$$r = \sum_{t=1}^T r_t I_b(t) + \sum_{t=1}^T r_f(t) I_s(t) + n \ln \left(\frac{1-c}{1+c} \right)$$

in which: $r_t = \log P_t - \log P_{t-1}$, indicating the continuously compounded return, where P_t is the price at time t . The term $I_b(t)$ is the buy signal, either 1 (the rule indicates *buy* at time t) or 0. The sell signal, $I_s(t)$, is analogously defined. So, the first component gives the return on investment from the times when the investor is in the market, and the second component, $r_f(t)$, indicates the risk-free return which would otherwise be available, which is taken for any

particular day t from the published US Treasury bill data (these data are available from <http://research.stlouisfed.org/fred/data/irates/tb3ms>). The second component therefore represents time out of the market, in which it is assumed that the investor's funds are earning a standard risk-free interest. Finally, the third component is a correction for transaction costs, estimating the compounded loss from the expenditure on transactions; a single transaction is assumed to cost 0.25% of the traded volume – for example, \$2.50 for a transaction of volume \$1,000. The number of transactions sanctioned during the period by the rule is n .

The second main part of the fitness function, r_{bh} , is calculated as:

$$r_{bh} = \sum r_t + \ln\left(\frac{1-c}{1+c}\right)$$

in which r_t is as indicated above. This calculates the return over the period from risk-free investment in US Treasury bills, involving a single buy transaction.

Becker and Seshadri's complexity-penalizing adjustment works as follows: Given a rule that has *depth* and fitness value (excess return) f , the adjusted fitness becomes $5f/\max(5, \text{depth})$. This involves the constant 5 as a relatively arbitrary desired maximal depth, and in the trading rule evolution context, there has been little parametric investigation around this value so far. The other of Becker and Seshadri's modification to the excess return fitness function, PC works as follows. The excess return E is calculated for each successive group of K windows of a certain length covering the entire test period.

The value returned is simply the number of these periods for which E was greater than both the corresponding buy-and-hold return (from investing in the index over that period) and the risk-free return during that period. For example, if the rule is evaluated over a 5-year test period, the PC version of the fitness function might use 12-month windows. Clearly, there are five such windows in the test period, and the fitness value returned will simply be an integer between 0 (the rule did not outperform buy-and-hold and risk-free investment in any of the five windows) and 5 (the rule was more successful than both buy-and-hold and risk-free returns in all of the windows).

At last, the above background enables one to state the fitness function used (with minor variations in each case) in Becker and Seshadri (2003a, b, c) and Lohpetch and Corne (2009, 2010). The fitness of a GP tree of depth d in these studies was the performance-consistency-based fitness (i.e., a number from 0 to X , where there were X windows covering the test data period) adjusted to penalize undue complexity by $5f/\max(5, d)$, in which f is the number of the X windows in which both the corresponding buy-and-hold return and the risk-free return were outperformed by the rule.

2.3.4 Some Illustrative Results

Reported here are some results that show how this approach performs on various windows of time when trading with the S&P 500 index. The results shown are some of those from Lohpetch and Corne (2010), and the subset of those that were obtained under the same test conditions as used by Becker and Seshadri (i.e., monthly trading for a specific training and test window) are quite indicative of Becker and Seshadri's own results. However, it is worth first discussing some further details of the way that the GP method was set up for the experiments.

Although perhaps not always the case, it seems that the precise choice of mutation and crossover methods makes little real difference in this application; the chance of evolving

effective trading rules seems clearly related to a good choice of function and terminal sets for the expression trees, as well as a wise choice of fitness function. Although, as will be seen later, the frequency of trading is a significant factor. Meanwhile, Lohpetch and Corne (2009, 2010) used standard mutation operators, as described by Angeline (1996), namely, *grow*, *switch*, *shrink*, and *cycle* mutation, and used standard subtree-swap crossover (Koza 1992). Finally, it is noted that, in the experiments whose results are summarized next, the population was initialized by growing trees to a maximum depth of 5; however, no constraint was placed on tree size beyond the initial generation, other than the pressure toward less complex trees which is a part of the fitness function.

Presented now are some results that indicate the performance achievable by such a GP system as described in the last section. In the experiments summarized here, from Lohpetch and Corne (2009, 2010), a population size of 500 was used, and other relatively standard GP settings, with a run continued for 50 generations. Here results for each of the daily, weekly, and monthly trading are shown, and it is found that outperformance of buy-and-hold can indeed be achieved even for daily trading, but moving from monthly to daily trading, the performance of evolved rules becomes increasingly dependent on prevailing market conditions. The data used is the S&P 500 index from 1960 onward. In Becker and Seshadri's demonstration of outperforming buy-and-hold, only monthly trading was used, and their results arise from training the rules over the period 1960–1991, and evaluating them on a test period spanning 1992–2003. This corresponds to "MonthlySplit1" in the following; however, it is clear from Lohpetch and Corne (2009) that more robust performance is obtained when a validation period is used. The following illustrative results therefore reflect a training/validation/test regime in which the GP training run evaluated fitness on the training period only, but the rule that achieved the best performance on a validation period was harvested, and this was the rule evaluated on the test period.

Results for four different monthly trading data splits are summarized below. The splits themselves are as follows, in which N gives the length of the validation period in years, immediately following the training period, and K gives the length of the test period in years, again immediately following the validation period.

- MonthlySplit1: 31 years training; $N = 12$, $K = 5$
- MonthlySplit2: 31 years training, $N = 8$, $K = 8$
- MonthlySplit3: 31 years training, $N = 9$, $K = 9$
- MonthlySplit4: 25 years training, $N = 12$, $K = 12$

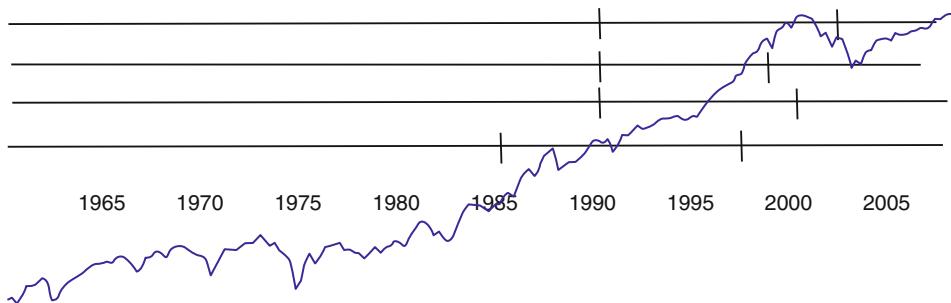

Corresponding splits for the weekly and daily trading experiments are also summarized here (for details see Lohpetch and Corne 2010). Four different weekly trading and daily trading data splits were also investigated, roughly corresponding to the monthly data splits in terms of the number of data points in each split. For example, WeeklySplit1 involved 366 weeks trading, 158 weeks validation, and 157 weeks testing. Similarly, the training periods for the daily splits were approximately 1 year in length. The four different weekly and daily splits started at different times, spread evenly between 1960 and 1996.

Figure 6 shows the four monthly data splits aligned against the S&P 500 index for the period 1960–2008. Note that the market movements were net positive in each part of each split, indicating that outperforming buy-and-hold was in all cases a challenge.

In Lohpetch and Corne's (2010) experiments, they also explored different lengths of window for the PC element of the fitness function. In Becker and Seshadri's work, the PC approach clearly results in improved performance, however, they only reported on the use of

Fig. 6

The S&P 500 index over the period 1960–2008, illustrating the four data splits for the case of monthly trading.

**Table 1**

Summary of results for monthly trading

Data split	PC period	Trials outperforming buy-and-hold	PC period	Trials outperforming buy-and-hold
Monthly Split1	6	10 out of 10	12	10 out of 10
Monthly Split2	6	9 out of 10	12	10 out of 10
Monthly Split3	6	10 out of 10	12	9 out of 10
Monthly Split4	6	10 out of 10	12	10 out of 10
Monthly Split1	18	10 out of 10	24	10 out of 10
Monthly Split2	18	8 out of 10	24	10 out of 10
Monthly Split3	18	8 out of 10	24	7 out of 10
Monthly Split4	18	10 out of 10	24	10 out of 10

12-month windows. Lohpetch and Corne experimented with different lengths for these windows for each trading situation, namely: 6-, 12-, 18-, and 24-month periods for monthly trading; 12 and 24 weeks for weekly trading, and 12 and 24 days for daily trading.

For each trading period (monthly, weekly, daily), Lohpetch and Corne did ten runs for each combination of data split and consistency of performance period. The outcome of the ten runs is summarized in [Tables 1–3](#), simply as the number of times that the result outperformed buy-and-hold.

As [Table 1](#) shows, monthly splits 1 and 4 were clearly well disposed to good performance, but performance was also rather robust on the other monthly splits. Note that outperforming buy-and-hold would seem to be more likely, according to a priori intuition, when the performance of buy-and-hold in the test period is relatively weak, but this is not the case for monthly splits 1 and 4 (see [Fig. 6](#)). The results are quite impressive from many points of view. In many cases, ten tests out of ten showed that a simple trading rule evolved by GP was able to outperform buy-and-hold in an upwardly moving market.

[Table 2](#) shows the results, summarized in the same way, for the case of weekly trading, and [Table 3](#) presents the corresponding results for the case of daily trading. These clearly

Table 2

Summary results for weekly trading

Data split	PC period	Trials outperforming buy-and-hold	PC period	Trials outperforming buy-and-hold
Weekly Split1	12	2 out of 10	24	7 out of 10
Weekly Split2	12	10 out of 10	24	5 out of 10
Weekly Split3	12	4 out of 10	24	4 out of 10
Weekly Split4	12	10 out of 10	24	10 out of 10

Table 3

Summary of results for daily trading

Data split	PC period	Trials outperforming buy-and-hold	PC period	Trials outperforming buy-and-hold
Daily Split1	12	0 out of 10	24	0 out of 10
Daily Split2	12	0 out of 10	24	0 out of 10
Daily Split3	12	10 out of 10	24	9 out of 10
Daily Split4	12	2 out of 10	24	4 out of 10

show increasingly less robust results. It certainly seems that this relatively straightforward GP method can find robust rules for weekly trading that outperform buy-and-hold in some circumstances (splits 2 and 4), with less reliable performance in other cases. However, Lohpetch and Corne (2009, 2010) were not able to discern any pattern that explains this from analyses of the data splits. Finally, for daily trading, [Table 3](#) shows that outperforming buy-and-hold is less likely, with strong performance in only one of the four data splits, and very poor performance in two of the data splits.

2.3.5 A Brief Discussion

The investigation of GP in financial applications and, in particular, the use of it to discover technical trading rules, remains an active thread of research in both industry and academia. In the published academic research, it was commonly found in earlier studies that rules found by GP were profitable, but usually not competitive with straightforward “buy-and-hold” strategies. However, as seen earlier, the situation is changing and it now seems that progress is being made in finding ways to use GP to produce effective and interesting rules that might be used by individual traders. There are several caveats, and of course this enterprise is only one thread of work in a wide area that also involves natural language understanding and many other areas of machine learning (e.g., to spot ideal trading opportunities based on the latest online news). However, this work represents another example of the way in which natural computation can help generate strategies for complex situations which are competitive with those that are self-designed.

It should also be noted that the approach described in this section is far from the last word in the application of GP to the specific area of technical trading. Pains have been taken to describe a

classic approach, and it has been shown that it can indeed find robustly profitable trading rules under a range of conditions – however, several more sophisticated ways to use GP in this area also exist. For example, rather than simply evolve a single rule that encapsulates both a buy and a sell signal, different rules can be evolved separately for buying and selling. Also, it is noted that interested researchers may pick up code for evolving technical trading rules (written by Dome Lohpetch) from the following site: <http://www.macs.hw.ac.uk/~dwcorne/gptrcode/>.

It is also worth mentioning alternative directions which attempt to gain on buy-and-hold by including risk metrics in the rules (or in their evaluation). Typically, a risk measure such as the Sharpe ratio (Sharpe 1966) is used to normalize the estimate of financial return, effectively downgrading the performance of rules that promote trading in volatile conditions, promoting rules more likely to be applied by investors. For example, in attempting to build on work by Fyfe et al. (1999), Marney et al. (2000, 2001) included the use of metrics for calculating risk, although still did not outperform buy-and-hold. More recently, Marney et al. (2005) used the Sharpe ratio and found that a technical trading rule easily outperformed simple buy-and-hold in terms of unadjusted returns, but not in terms of risk-adjusted returns. There is clearly much work still to do until techniques exist in the research literature that can robustly outperform buy-and-hold in a way that satisfies risk-conscious traders, although the progress and effort in this direction makes it clear that this will be achieved, as well as suggesting that private and unpublished research in commercial organizations has almost certainly achieved this already with appropriate use of GP and similar technologies.

3 Examples of Natural Computing’s “Outreach” Elsewhere in Science and Engineering

In this section, two areas of natural computation are selected that have wider implication for significant areas of science and technology. Mostly, an application of a natural computing technique may produce excellent results in its domain, and the impact of those results, though potentially significant, tend to remain solidly within that domain. Progress in general financial mathematics, for example, will not be revolutionized by the trading application discussed in [Sect. 2](#). However, sometimes an exemplar application will open up previously unconsidered possibilities in a whole subfield of science. In this section, two examples are discussed in which such broader consequences can be seen. The first is the use of (mostly) multi-objective evolutionary computation in the area of *closed-loop* optimization, in order to optimize a range of processes and products in the biosciences, process industries, and other areas. In this arena, evolutionary computing was never an “obvious” technique to try, given the potential cost in time; however, its use has time and again proven worthy, and this in turn leads directly to better and faster processes and products emerging from, for example, the use of the instruments that have been configured via evolutionary techniques. The second example area looked at in this section is the concept of *innovation*, which exploits multi-objective evolutionary computation in a way that leads to generic design insights for mechanical engineering (and other) problems. In multi-objective problems (see Deb 2001; Corne et al. 2003a), the result of solving the problem is (usually) a large collection of diverse solutions, each optimal in a sense, but traversing a Pareto surface of optimal from (for example) highly reliable and high-cost solutions to exceptionally cheap but less reliable ones. The notion of innovation is to exploit the prowess of evolutionary computing in obtaining such a diverse set, by further analyzing this collection of designs to

find, as it turns out, previously unknown generic design rules, which seem to be true of all “optimal” designs, wherever they sit on this Pareto surface. A well-designed natural computing approach to a specific problem in mechanical engineering, for example, thereby leads to new design principles that can have much wider impact than simply solving the given problem.

3.1 Applications in Analytical Science: Closed-Loop Evolutionary Multi-objective Optimization

Knowles (2009) provides a detailed and comprehensive summary of historical origins and current work in the broad area of closed-loop optimization using evolutionary multi-objective algorithms. A similar but briefer treatment is provided here, including a summary of two of the several interesting modern case studies covered in Knowles (2009).

As Knowles (2009) points out, the idea of using an evolution-inspired technique for producing solutions to optimization problems has been explored for around 60 years so far, starting in the 1950s. The celebrated British statistician George E.P. Box used the term “closed-loop” in describing the kind of evolution experiments that were first investigated, while Ingo Rechenberg (a pioneer in evolutionary computation) used the phrase “evolutionary experimentation.” In closed-loop evolution-inspired optimization, the evolution process is a combination of computation and physical experiment. The evaluation of candidate design solutions is done in the real world by conducting physical experiments. Much of the pioneering work in evolutionary computation (by Rechenberg and his team) was of this kind. In much more recent times, the closed-loop approach has been used, commonly with much success, in evolvable hardware research (see the chapter [• Evolvable Hardware](#) in this volume), in evolutionary robotics research, as well as in microbiology and biochemistry. In this section, some brief example case studies are described to illustrate the increasingly wide emerging impact of this technique at the evolution/engineering interface.

With a focus on closed-loop evolutionary multi-objective optimization (CL-EMO) in particular, two cases are looked at: (1) instrument optimization in analytical biochemistry and (2) on-chip synthetic biomolecule design; these are described in greater detail in Knowles (2009) as well as further references detailed later, along with other quite different examples. However, before these case notes, historical development and fundamental concepts in closed-loop optimization and CL-EMO will briefly be looked at.

3.1.1 Historic Highlights in Closed-Loop Optimization

In Berlin in the 1960s, Rechenberg, Schwefel, and Bienert conducted a series of studies in engineering and fluid dynamics, in which they tested the idea of using a process inspired by evolution to search for new and successful designs. Their work clearly demonstrated that complex design engineering problems (including: the optimal shape of a fluid-bearing pipe, and the design of a supersonic jet nozzle) could be addressed in this way with rampant success (see Chap. 8 of Fogel 1998, as well as Rechenberg 1965, 2000). The design process itself was found to be efficient and scalable, and the results were highly effective. Rechenberg and his team were using an early example of an evolutionary algorithm, but in which only the selection and variation steps were done by a microprocessor; the rest, the evaluation of candidate

designs, was done by constructing prototype designs and performing experiments to test their properties. Innovative solutions were found to all of the engineering design problems that they studied.

Predating Rechenberg's work, a similar principle was used by George Box, who introduced "evolutionary operation" (EVOP) in 1957. This was also an experimental method of optimization, which Box (1957) envisaged being used regularly in factories and similar processing facilities. Box's "closed-loop" scheme involved some human input, and was somewhat more deterministic than the approach taken in Berlin, but, just as Rechenberg's work, was inspired by principles from natural evolution. Box's methods were both successful and very influential (Hunter and Kittrell 1966), remaining in use today. Meanwhile, the work of Rechenberg's team was the beginning of the field of evolution strategies, one of the foundation stones of the current field of evolutionary computation.

Since these early studies, however, evolutionary computation as a whole has largely been concerned with entirely in silico optimization. The great majority of growth in this research area, as well as in industrial practice, concerns applications that involve convenient and entirely computational estimations of the fitness of computational abstractions of solutions. This is fine for a vast collection of scenarios, but there remains a need – in fact a quickly expanding one – for applications in which it makes sense for designs to be realized and evaluated physically throughout the simulated evolution process.

Research in evolvable hardware shows that, if the evolution process is given direct access to a complex physical structure, designs can be evolved that use entirely different principles than would be used by human designers, often exploiting aspects of the physics of the structures involved that are unfamiliar to human experts, or simply too difficult to use as part of the design process. Thompson and Layzell's work with field programmable gate arrays is exemplary of this. Meanwhile, evolutionary robotics projects have often relied upon the controllers being evolved in real time within physical robots, while they are performing real tasks in a real environment (Nolfi and Floreano 2004; Trianni et al. 2006). The benefits of such evolution experiments, exposed to and exploiting the true physics of the designs being evolved, are not just confined to evolutionary robotics (e.g., Davies et al. 2000; Evans et al. 2001).

Later, three further and recent uses of closed-loop evolutionary optimization are described, from recent work in which the third author (JDK) has been involved. Each of them is a scenario in which direct experimental evaluation of solutions is either the only option or is clearly preferable to simulation. Also each of them involves multi-objective evolution, a notable advance of the last 20 years (Fonseca and Fleming 1995; Coello 2000, 2006; Deb 2001; Corne et al. 2003a) which was not available to Box or Rechenberg. One of the several benefits of a multi-objective approach in these scenarios is that the different design objectives may simply be stated, without any need to define normalizations, weights, or priorities that mangle them into a single scalar (and usually misleading) measure of quality.

At this point, it is worth noting that there is widespread use of certain statistical methods in industry, for the types of problems that are considered in the "closed-loop" setting. The techniques employed are referred to as design of experiments (DoE) approaches, or sometimes experimental design (ED)-based approaches (Fisher 1971; Chernoff 1972; Myers and Montgomery 1995; Box et al. 2005). Such methods emphasize rational reasoning from all the information obtained so far, as opposed to more randomized exploration. Standard DoE is typically used for probing low-dimensional parameter spaces using few experiments, while evolutionary algorithms are typically used for optimization in high-dimensional spaces, using many evaluations, and optimizing many different types of structure, including permutations,

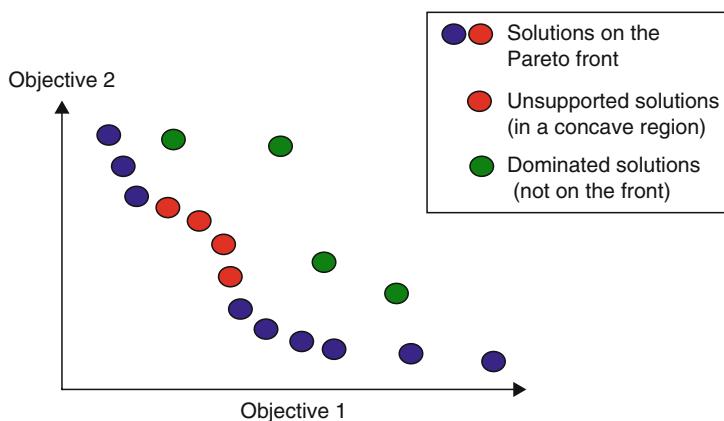

graphs, networks, and so on. However, there is an increasingly disappearing divide between the two types of approach, especially since the advent of sequential DoE, which incorporates aspects of evolutionary computing. The closed-loop optimization scenarios considered in this section lie between these niches, and benefit from aspects of both approaches.

3.1.2 Fundamentals of Closed-Loop Evolutionary Multi-objective Optimization

In closed-loop EMO, candidate solutions to a problem are generated by an algorithm in computer simulation, but their evaluation is achieved by physical experiment. Evaluations are fed back to the algorithm and its generation of subsequent solutions is a function of these. Thus, the process has the form of a closed loop, being at least partially sequential. Closed-loop problems can be defined generally as multi-objective optimization problems in which, essentially, one needs to find some ideal solution vector \mathbf{x} , which simultaneously minimizes each of a collection of k objective functions $f_1(\mathbf{x}), f_2(\mathbf{x}), \dots, f_k(\mathbf{x})$. Typically, a single physical experiment $g(\mathbf{x})$ yields the k measurements $f_1(\mathbf{x}), f_2(\mathbf{x}), \dots, f_k(\mathbf{x})$. That is, the k objectives are k different measurements that are made as the result of a single experiment, all of which need to be optimized in some way. Typically, at least some of the objectives will be in conflict (Brockhoff and Zitzler 2006), and no single solution is a minimizer of all functions. Rather, the improvement of one objective is only possible by sacrificing, or trading off, quality in some other objective. The solutions corresponding to optimal values of the k objectives are known as the Pareto set, and when plotted in objective space, form the Pareto front (see [Fig. 7](#)).

Fig. 7

An illustration of a Pareto front for a typical optimization problem with two objectives, both of which have to be minimized. Each of the solutions on the Pareto Front (PF) are optimal in the Pareto trade-off sense. For example, for any solution on the PF, no solution exists that is improved in one objective without being degraded on another objective. Often, some solutions on PFs are “unsupported” – these are valid optimal solutions in the Pareto trade-off sense, but for any linear combination of the objectives that might be used in a single-objective simplification of the problem, they would not be optimal.

Since solving such a vector optimization problem usually leads to a set of solutions, rather than a single one, there is, in most practical applications, a need for decision making to select one solution from this set. This aspect of multi-objective optimization is important and well studied (Fonseca and Fleming 1998; Miettinen 1999; Branke and Deb 2005), and the various alternative approaches will not be covered here. Suffice to say that in the experiences detailed later, the EMO algorithms were designed to find whole Pareto fronts, with the expectation that a human decision maker would make the final decision using the information incorporated in the output Pareto front.

3.1.3 Example 1: Instrument Optimization in Bioanalytical Chemistry

Modern biotechnology and bioanalytics often involve large-scale experiments which impose heavy demands on sophisticated laboratory instruments. To achieve timely throughput, these experiments often necessitate using configurations of instruments that go beyond the manufacturer's recommended settings. This situation happened in the "HUSERMET" project, which was a collaboration between several UK health authorities, two pharmaceutical companies, and the University of Manchester, undertaken between 2006 and 2009 (www.husermet.org). In this project, human blood samples were collected from around 2,000 people over a 3 year period, with the aim of understanding ovarian cancer and Alzheimer's disease in terms of the variations in metabolites (the chemical products of metabolism) present in patients suffering from, or free from, these diseases. The samples were analyzed with the help of various modern technologies for characterizing complex samples, including laboratory instruments that performed gas chromatography mass spectrometry. The configuration of such instruments is always subject to a degree of optimization in order to ensure that the analytes being detected can be seen, with maximal sharpness and minimal noise. This optimization is usually (though not always) *ad hoc*, subject to much domain knowledge.

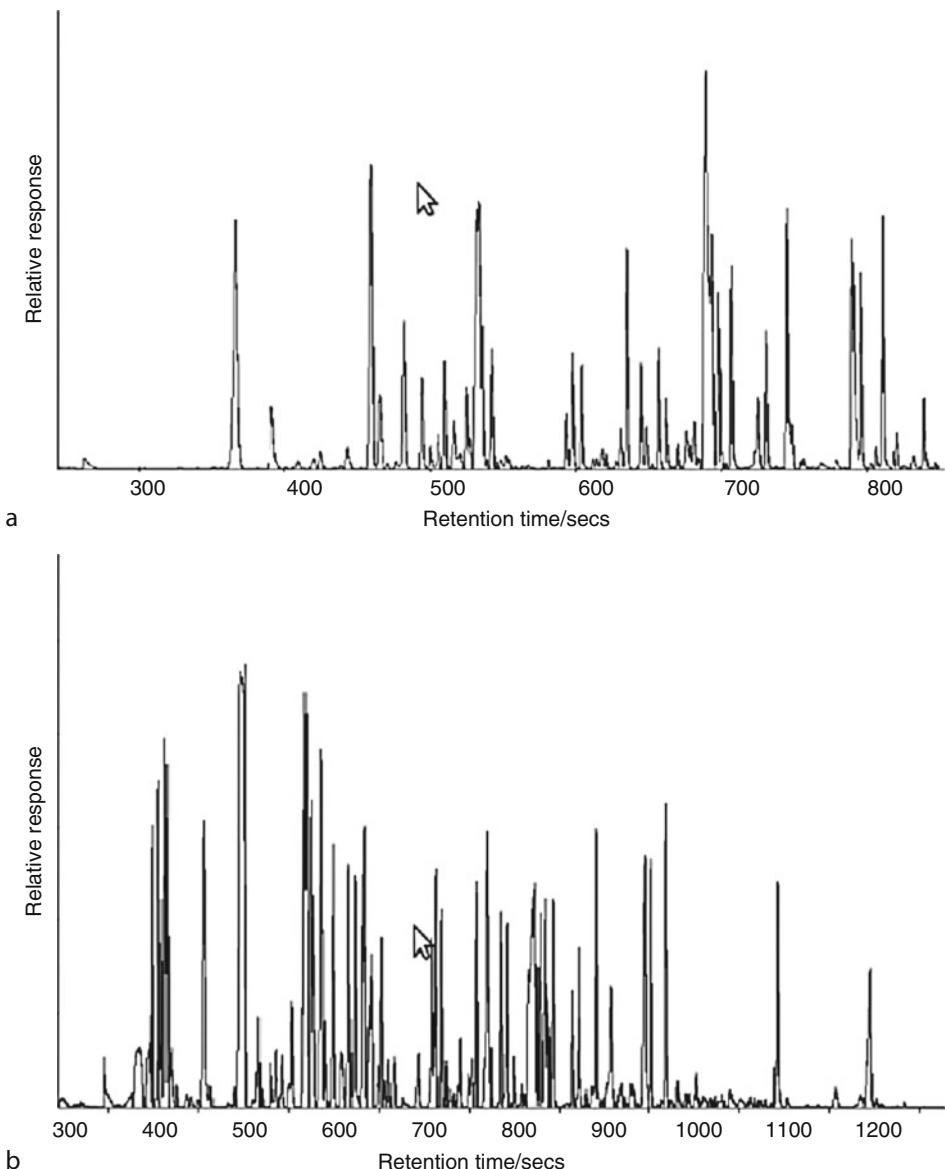

In the HUSERMET project, the need for a better instrument configuration optimization process arises from: the unusually large number and diversity of metabolites to be detected (around 2,000), the potential to vary around ten interacting instrument parameters, and the significantly conflicting nature of the optimization objectives. Instrument settings were needed that allowed fast processing of samples (preferably well under an hour), which conflicts with the desire to maximize the detection of the full complement of metabolites at low noise.

Optimizations of two instruments have been reported in detail in O'Hagan et al. (2005) and O'Hagan et al. (2007), respectively. The former study successfully used the evolutionary multi-objective algorithm PESA-II (Corne et al. 2001), but that study also directly inspired the development of the ParEGO algorithm (Knowles 2006), a multi-objective algorithm that is a hybrid of a surrogate modeling approach and an evolutionary algorithm. ParEGO was then used in the second study successfully, and settings derived from the evolutionary algorithms in both cases were subsequently used for the instruments to process the tasks of the HUSERMET project.

The major challenge in that project was the limited number of function evaluations that could be done. A function evaluation ties up an expensive instrument for an appreciable time, when it could otherwise be used more directly furthering the project's needs. This was even more bothersome, given the need to try to optimize three objectives simultaneously (chromatogram peaks, signal/noise ratio, and sample throughput). Only one instrument was available, and a single analysis of a serum sample takes between 15 min and over 1 h. The optimization process used 400 evaluations in total, with the EAs controlling the instrument

Fig. 8

Chromatograms indicating detection performance of the instrument optimized in the HUSERMET project: (a) from the initial generation of search; (b) toward the end of the search process. In (b), both the number of peaks and the range of retention times over which peaks are detected have improved, while maintaining noise at low levels.

settings and loading samples through a robotic interface that was designed especially for the optimization process. In **Fig. 8** some chromatograms can be seen, which indicate the instrument's performance characteristics before (*upper*) and after (*lower*) optimization. The optimized result achieved approximately threefold increases in the quantity of peaks

visible, while at the same time maintaining the signal/noise ratio at low levels, and achieving throughput of samples in around 20 min.

3.1.4 Example 2: Evolving Real DNA on Custom Microarrays

Another example covered in more detail in Knowles (2009) concerns the design of pharmaceutically active, highly targeted macromolecules. This is a significant goal in modern medicine, especially in the context of *ab initio* design, where one seeks a molecule with specific properties and activity, but has little or nothing to go on (in the sense of existing molecules with similar properties). In recent research, novel microarray-based technology has been used in the automation of such *ab initio* molecule design. Experimental biotechnology platforms are now available, which can synthesize, and then experimentally test in a variety of ways, any specified DNA sequence. Being able to synthesize any given sequence, and subject it various tests, means there is far less need for computational models which, in the current state of the art, are far from good enough (or fast enough) to support such a process.

The microarray used in the work described next (and more fully in Knowles (2009) and references therein) is the so-called CustomArray technology, available from Combinatrix Corp, which can be used to synthesize up to 90,000 specific bespoke DNA sequences of up to 40 bases long in a single experiment. Once the sequences have been synthesized, they can be tested for a variety of properties, but usually the main property of interest is the ability to bind them to a particular target molecule. In the testing (or assay) process for binding ability, the chip holding the sequences is “washed” with a solution containing the target molecule, and some form of fluorescent tagging is used so that binding can be observed; further automated processes can then estimate the strength of binding.

Short strands of DNA (or RNA) that bind strongly to specific targets are called *aptamers*, and hundreds of these have been developed for a wide variety of applications. Before the recent microarray-based work at Manchester (which is what is discussed here, with full details in Knight et al. 2008), new aptamers were almost always discovered by a method called SELEX (Tuerk and Gold 1990), or in vivo selection, in which the DNA strands are evolved in a test tube by repeated rounds of high-pressure selection and random mutation. As indicated, however, in the microarray approach one knows precisely the sequence information for every sequence tested, and can even exactly specify mutations or other variations to perform. This is not the case in SELEX, and one of the many benefits for the microarray approach is that it allows extremely richer possibilities for borrowing and exploiting algorithms from evolutionary computation, machine learning, and statistics.

Knight et al. (2008) reports the first use of an evolutionary algorithm to produce a DNA aptamer on the B3 Combinatrix platform. This happened after ten generations of evolution, eventually discovering several 30-base long strands that bound very strongly to the target molecule, allophycocyanin. The work in Knight et al. (2008) used a DNA chip that could hold 6,000 strands. With 90,000 strands on a chip now possible in more modern technology, one main challenge (from the optimization perspective) is to determine the best way to exploit such massive population sizes. Wedge et al. (2009) have recently explored such questions in silico simulations using contrived search landscapes, as well as real trials on the DNA landscape, revealing, among other findings, that higher-than-standard mutation rates consistently outperformed a range of other setups. This echoes findings in Corne et al. (2003b), which also explored large population sizes

and contrived in silico landscapes, partly to inform the (as then) emerging field of closed-loop protein evolution.

3.1.5 Some Concluding Notes on CL-EMO

For the examples described above, and several more in which CL-EMO has been used, building accurate computational models that could usefully replace real experiments is practically infeasible. The closed-loop alternative offers a more efficient and effective way toward the discovery of innovative solutions, easily making up for the time and expense of tying down the physical kit for the experimental period. One question often worth asking, however, is whether one needs to automate the optimization process at all in such scenarios. There is a processing step in which a computational process (here, e.g., an evolutionary multi-objective optimization algorithm) considers the latest experimental evaluation results, and outputs sample designs for the next sequence of physical evaluations – but this operation could easily be done instead by a domain expert. On the other hand, though, there are several objections to such human involvement: even experts can over-interpret results that are affected by noise or similar factors; similarly, humans are very prone to reason on the basis of simple models, ignoring interactions between parameters. Meanwhile, there is always a very real danger of experts preferring solutions that are (or are close to) known designs.

Problems where accurate computer modeling is infeasible, and for which closed-loop optimization is the efficient solution, are really quite common. For the moment, the main focus of the third author is on problems in modern biology, where there is a growing take-up of multi-objective optimization. Meanwhile, many other substantial areas are able to benefit greatly from CL-EMO; apart from drug discovery and development, large-scale problems such as flood defense design, forest fire control strategies, the location of renewable energy plants, and the task of genetically engineering more pest-resistant food crops and energy crops, can all be seen, to varying degrees, as closed-loop problems.

3.2 Innovation

This section describes a new idea, *innovation*, introduced in Deb and Srinivasan (2005, 2006), which (typically) exploits multi-objective evolutionary computation to find new and innovative design *principles*. Although optimization algorithms are routinely used to find an optimal solution corresponding to an optimization problem, the task of innovation stretches the scope beyond an optimization task and attempts to unveil new and innovative design principles relating to decision variables and objectives, so that a deeper understanding of the problem can be obtained.

Innovation is a common goal for engineers and designers, but there are actually very few (arguably no) systematic procedures for reliably achieving innovations. Goldberg (2002), however, suggests that a “competent” genetic algorithm can be an effective way to achieve an innovative design (and indeed there are numerous examples of innovative designs being discovered by evolutionary computation, including some discussed elsewhere in this chapter). However, the idea of innovation (Deb and Srinivasan 2005, 2006) extends this argument considerably, and gives a systematic procedure that can arrive at a deeper understanding of a given engineering design problem. This systematic procedure may lead to the discovery of new design principles – in particular, principles that are common to the diverse collection of optimal trade-off solutions.

Such common principles may, in many cases, provide a reliable recipe for solving given instances of the problem at hand. In this section, the innovation procedure will be explained and illustrated with two examples in engineering design. The material in this section borrows much from Deb and Srinivasan (2005), which introduces this idea, and contains several more examples. However, before looking at the procedure and examples, it will be helpful to recall some basics about the usually conflicting nature of objectives in the design process.

3.2.1 Multiple Conflicting Objectives in Design

The central idea in innovation involves the presence of at least two conflicting objectives for the design problem at hand. This is far from a limiting constraint – as argued in many places (see in particular Corne et al. 2003a for an introductory account of this argument), almost all realistic problems naturally involve several objectives.

Consider a typical design problem with two or more conflicting goals, such as an engine or generator whose mass needs to be minimized, but whose output needs to be maximized. Such a two-objective optimization task results in a set of Pareto-optimal solutions (see Fig. 7). One of the “extreme” solutions will be the best if the interest is only in mass, while the other extreme solution will be ideal for the output consideration, and there will usually be several solutions in between these extremes, also optimal in a sense, all of which share the property that if they are better than another Pareto-optimal solutions in one objective, they will be worse in the other. The intermediate solutions are invariably good compromises within the extremes, and the solution that may eventually be chosen by the designer will often be among these, and its choice will often be helpfully informed by the knowledge that the designer obtains by viewing the shape and the nature of the trade-offs displayed by the entire set of solutions that form the discovered Pareto front. However, what is of particular interest here is that this set of solutions will typically be very diverse, but all sharing the property of Pareto optimality. The idea of innovation arises from the attempt to see whether this property of Pareto optimality, for any given problem, is manifest in concrete features that the diverse solutions share. Another aspect of this is that the process of obtaining such a wide variety of solutions is itself a significant investment in computation time; *innovation* is a way to exploit this significant investment by performing a posterior analysis of the obtained set of trade-off solutions that may result in a set of “innovized” principles relating to the given design problem.

In designing an electrical motor, for example, this posterior analysis might reveal a feature of the diameter of a certain component and the power output that is shared by all of the Pareto-optimal solutions, but not other solutions. Any such relationships discovered would clearly be of great importance to a designer, and perhaps point toward a recipe for future design tasks in the same domain, as well as spark new theoretical insights into the problem. These are just two of a range of benefits that the so-called “innovized principles” could lead to, as discussed further in Deb and Srinivasan (2005), along with a convincing argument that one can often expect such principles to exist.

3.2.2 How to Innovize

The innovation procedure proposed by Deb and Srinivasan (2005) consists of two phases: in the first phase, the idea is to simply try to obtain the Pareto-optimal solutions of the design problem in question. In the second phase, they then analyze the solutions and extract innovized

principles. The first phase is not as straightforward as it sounds, since, of course, it can usually never be guaranteed that a true optima has been found for a realistic problem, unless an exhaustive search has been performed. However, the idea of the first phase is to do as well as one can in a reasonable time, since it is expected that the chance of obtaining valid principles of Pareto optimality is improved if one has true (or very close to true) Pareto-optimal solutions. In Deb and Srinivasan's procedure, this centrally involves making use of NSGA-II (Deb et al. 2002) (one of the most prominent and effective evolutionary multi-objective optimization algorithms) as the main engine in finding the Pareto front, but initially informed by a single objective method that has been used to find the extreme points on the Pareto front, and followed by various applications of a local search method and the normal constraint method (NCM) (Messac and Mattson 2004) to locally improve the output solutions from NSGA-II, as far as possible.

The second phase of innovization is then the analysis of the assumed Pareto-optimal solutions that emerge from the first phase. There is no fixed recipe for this process, other than to employ the usual common sense and expertise that underpins a data mining and knowledge discovery task in searching for commonality principles among these solutions that may become plausible innovized relationships. Deb and Srinivasan (2005) also pursue "higher level innovations" after this phase, which involve returning to the original problem, but investigating different areas of the design space by looking at neighboring problems (e.g., with different boundaries and constraints on the design task); this then enables new principles to be discovered that are likely to be at a higher level than previously, mapping design constraints to design recipes.

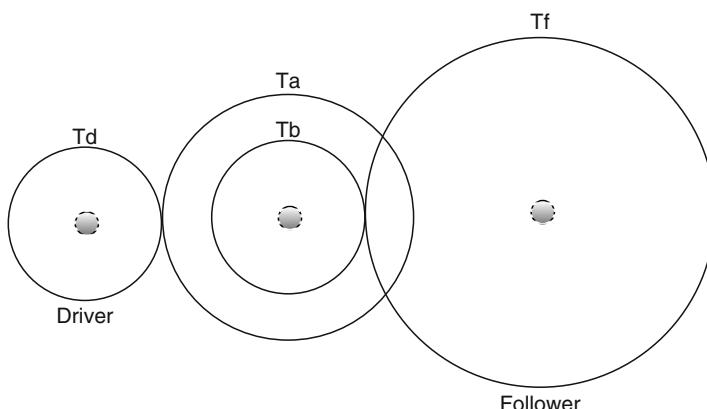

Just two from the increasing collection of results of this above innovization procedure in engineering design applications are now described. These were first described in Deb and Srinivasan (2005), among several other examples.

3.2.3 Example 1: Gear Train Design

Deb and Srinivasan (2005) give the example of the design of a compound gear train, in which a specific gear ratio between the driver and driven shafts is desired. The problem is illustrated in Fig. 9, and is a modification to a problem solved elsewhere (Kannan and Kramer 1994;

Fig. 9

A gear train with four gears (circles). The task is to achieve as close as possible a gear ratio of 6.931:1 between the driver and follower, while minimizing the sizes of each gear.

Deb 1997). The objective is to set the number of teeth in each of the four gears in a way that minimizes the error between the obtained gear ratio and a required gear ratio of 6.931:1, while also minimizing the maximum size of the four gears.

The diameter of a gear is proportional to the (integer) number of teeth, so these objectives can be formalized in terms of four integer decision variables: $\mathbf{x} = (x_1, x_2, x_3, x_4)$ referring, respectively, to the numbers of teeth in gears T_d (driver), T_b , T_a , and T_f (follower). The problem is then to minimize both f_1 and f_2 below:

$$f_1(\mathbf{x}) = \left| \frac{6.931 - \frac{x_3, x_4}{x_1, x_2}}{6.931} \right|$$

$$f_2(\mathbf{x}) = \max(x_1, x_2, x_3, x_4)$$

subject to the following constraints:

$$\frac{f_1(\mathbf{x})}{6.931} \leq 0.5,$$

$$12 \leq x_1, x_2, x_3, x_4 \leq 60$$

The constraints ensure that the difference between the designed gear ratio and the desired gear ratio is no more than 50%. After phase one of the innovation procedure, a collection of assumed Pareto-optimal solutions was obtained.  [Table 4](#) shows the two extreme solutions.

Phase two of the process then revealed several interesting principles relating to the problem, covering the whole set of Pareto-optimal solutions, which is summarized from Deb and Srinivasan's account as follows:

First, in order to minimize the maximal gear size, gears T_d and T_b need to have almost the smallest allowable number of teeth. To get as close as possible to the desired ratio (with error less than 0.1), the T_b and T_d values need to grow somewhat, but still remain close to their lower bounds. Another finding is that the maximum allowed gear size always occurs in a Pareto-optimal solution, either for T_a or for T_f . It is also noted that two distinct types of solutions emerged: (1) gear trains with very low error (very close to the desired gear ratio of 6.931:1), in which there is a great variety of ways in which the numbers on teeth in the four gears combine to almost achieve the 6.931 ratio in the first objective and (2) gear trains with a comparatively large error, with identical first- and second-stage ratios (except the one with the largest error). Although a large error can happen for many different combinations of errors in the two stages, the pressure of the second objective causes both stages of gear-ratios to be identical. Finally, regarding small-error gear trains, half of them have a larger first-stage ratio than second stage, and half have a larger second-stage ratio.

This is a fairly simple and straightforward example, although it brings out several interesting properties of optimal solutions of this type of gear train design problem that are difficult, if not impossible, to infer from the statement of the problem. One implication, for example, concerning recipes for gear train design, is that the process could be guided according to how important it is to closely meet the constraint. If a low error is desired, then it is clearly important

 [Table 4](#)

The extreme solutions obtained for the gear train design problem in Deb and Srinivasan (2005)

Solution	T_d	T_b	T_a	T_f	f_1	f_2
Minimum error	20	13	53	34	~0.00023	53
Minimum maximal gear size	12	12	22	23	3.4171	23

to examine many possible combinations of gear sizes. If a higher error can be allowed, then solutions with minimal size strongly tend to have equal first-stage and second-stage ratios.

3.2.4 Example 2: Welded Beam Design

This is a much-studied problem in the context of single-objective optimization (Reklaitis et al. 1983), in which a beam needs to be welded onto another beam and must carry a certain load F , as illustrated in  Fig. 10.

The problem is to establish the four design parameters (beam thickness and width, respectively, b and t ; length and thickness of weld, respectively, l and h) in a way that minimizes the cost of the beam, and also minimizes the vertical deflection at the end of the beam. The overhanging portion of the beam has a fixed length of 14 in., and is subject to a force F of 6,000 lb. Clearly, an ideal design in terms of cost will be less rigid and hence not ideal in terms of deflection, and vice versa. A formulation of this problem (Deb and Kumar 1995; Deb 2000) gives the objectives as follows, where x indicates the vector of design parameters:

$$f_1(x) = 1.10471 \cdot h^2 \cdot l + 0.04811 \cdot t \cdot b(14.0 + l)$$

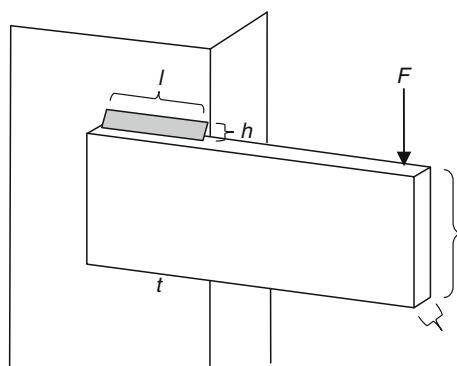

$$f_2(x) = \frac{2.1952}{t^3 \cdot b}$$

subject to these constraints:

$$\begin{aligned} \tau(x) &\leq 13,600 \\ \sigma(x) &\leq 30,000 \\ b &\geq h \\ P_c(x) &\geq 6,000 \\ 0.125 &\leq h, b \leq 5.0 \\ 0.1 &\leq l, t \leq 10.0 \end{aligned}$$

The first constraint specifies that the shear stress at the support location is below the allowable shear stress of the material (13,600 psi); the second ensures that the normal stress at the same location is below the material's allowable yield strength (30,000 psi); the third ensures the

 **Fig. 10**
The welded beam design problem.

obvious practical consideration that the weld is not thicker than the beam, and the fourth ensures that the applied load F is below the allowable buckling load of the beam. The highly nonlinear stress and buckling terms are as follows (Reklaitis et al. 1983):

$$\begin{aligned}\tau(x) &= \sqrt{(\tau')^2 + (\tau'')^2 + (l\tau'\tau'')/\sqrt{0.25(l^2 + (h+t)^2)}} \\ \tau' &= \frac{6,000}{\sqrt{2hl}} \\ \tau'' &= \frac{6,000(14 + 0.5l)\sqrt{0.25(l^2 + (h+t)^2)}}{2(0.707h \cdot l(l^2/12 + 0.25(h+2)^2))} \\ \sigma(x) &= 504,000/t^2 b \\ P_c(x) &= 64,746.022(l - 0.282346t)tb^3\end{aligned}$$

Following phase one of the innovation procedure, a set of Pareto-optimal solutions was obtained, and [Table 5](#) shows the extreme points of this Pareto set, along with an interesting intermediate point which Deb and Srinivasan refer to as T , which comes into the innovized principles discussed next.

Deb and Srinivasan's analysis of the many Pareto solutions obtained (spread liberally between those shown in [Table 5](#)) revealed the following innovized principles:

First, two distinct behaviors were found: from the intermediate transition solution T (shown in [Table 5](#)) toward higher-deflection solutions, the objectives behave differently than in the rest of the trade-off region. For small-deflection solutions, the relationship between the objectives was almost polynomial, with f_1 being roughly proportional to $1/f_2^{0.89}$. Next, it was found that, for all Pareto-optimal solutions, the shear stress constraint is active. In the small-deflection (large-cost) cases, the chosen bending strength (30,000 psi) and allowable buckling load (6,000 lb) are quite large compared to the developed stress and applied load. Any Pareto-optimal solution must achieve the maximum shear stress value (13,600 psi). So, to improve the designs in this region without sacrificing deflection, it would be necessary to use a material with a larger shear strength capacity. A third overall principle found was that the transition point (T) between two trade-off behaviors is related closely to the buckling constraint. Designs with larger deflection (or smaller cost) reduce the buckling load capacity. When buckling load capacity becomes equal to the allowable limit (6,000 lb), no further reduction is allowed. After this point (toward small-deflection solutions), the beam thickness must reduce in inverse proportion to the deflection objective in order to retain optimality.

Table 5

The two extreme solutions and an interesting intermediate solution T obtained by Deb and Srinivasan (2005) for the welded beam design problem. The units of the design parameters are inches

Solution	H	I	T	b	f_1	f_2
Minimum cost	0.2443	6.2151	8.2986	0.2443	2.3815	0.0157
Minimum deflection	1.5574	0.5434	10.000	5.000	36.4403	0.00044
Intermediate solution T	0.2326	5.3305	10.000	0.2356	2.5094	0.0093

Next, for small-deflection solutions, the beam width remains constant. This indicates that for most Pareto-optimal solutions, the width must be set to its upper limit. Although the beam width has opposite effects on cost and deflection, it is involved in the active shear stress constraint, and since shear stress reduces as beam width increases, it can be argued that fixing beam width to its upper limit would make a design optimal. Thus, if in practice the cost objective is not paramount, solutions which have a fixed width (the maximum 10 in. in this case) may be explored, thereby simplifying the inventory. However, along the Pareto trade-off surface, the weld length increases with increasing deflection, and the weld thickness decreases with increasing deflection. Deb and Srinivasan (2005) noted that these phenomena are counter-intuitive and difficult to explain from the problem formulation. However, the innovized principles for arriving at optimal solutions seem to be as follows: for a reduced cost solution, keep beam width t fixed to its upper limit, increase weld length l , and reduce beam and weld thickness (h and b). This “recipe” is valid while the applied load is strictly smaller than the allowable buckling load.

Beyond that point, any reduction in cost must come from reducing beam width below its upper limit, increasing beam thickness, and adjusting the weld parameters so as to make the buckling and shear stress constraints active. Finally, the minimum cost solution occurs when the bending stress equals the allowable strength (30,000 psi), at which point all four constraints become active.

Finally, to achieve very low-cost solutions, the innovized principles are different: for a reduced cost solution, one needs a smaller beam width, but larger beam thickness and weld parameters.

Deb and Srinivasan report a higher level run of the innovation procedure for this case, in which innovation was redone separately for different values of the three allowable limits in the first, second, and fourth constraints above. It was clear that all three cases produced similar dual behavior (different characteristics on either side of a single transition point) to that observed in the original case. All other innovized principles mentioned above (such as the constant nature of beam width, beam thickness being smaller with increasing deflection, and so on) remained valid. And significant further insights were obtained into the overall design problem, detailed in full in Deb and Srinivasan (2005).

3.2.5 Innovization: Concluding Notes

When facing an optimization problem with at least two conflicting objectives, the set of optimal solutions is very diverse. Having found such a set effectively and efficiently using evolutionary multi-objective optimization (judiciously combined with other methods that help locally optimize), the notion of *innovization* is to analyze this set of solutions to see if there are commonalities and patterns that might translate into general design principles for the problem at hand. It turns out that this is true, and interesting new principles (difficult or impossible to have been obtained otherwise) have emerged from several studies to date. The emerging truth seems to be that solutions along a Pareto front often seem to share similarities that seem to be principles of optimality for the problem at hand, irrespective of location on the Pareto front.

In this section, just two case-study results have been borrowed to illustrate the innovization principle. Deb and Srinivasan (2005) show several more examples, including spring design and multiple-disk clutch brake design, while one more recent study (Datta and Deb 2009)

displays an excellent example of the potential impact of innovation (and, hence, indirectly, of evolutionary multi-objective optimization) by finding new innovized principles for the setup parameters of a turning process using a lathe and a cutting tool that are overwhelmingly common in industry workshops. Finally, there is no particular reason to believe that innovation is constrained to engineering design. It will be interesting to see future applications of this idea in other design fields, such as electrical circuits, optical systems, communication networks, and the many other areas in which evolutionary multi-objective optimization is increasingly used.

4 Logistics and Combinatorics Made Easy: Robust Solutions and New Algorithms via Natural Computation

In this section, two areas will be considered that exemplify how natural computing (largely, learning classifier systems and evolutionary computation) has provided highly successful ways to address difficult logistics problems. Logistics usually relates to scheduling and timetabling problems of various kinds, but also included here is the closely related and general field of combinatorial problems in which a discrete collection of items of some kind must be arranged in an optimal way. There are innumerable examples of natural computing applications in this domain, and the first case here is simply a selection of one (of several possibilities) that combines the attributes of “interesting,” “real-world,” and “difficult” (looking here at the case of a real-world truck scheduling problem). Next, moving on to perhaps a more profound area that has emerged from the late 1990s, in which, rather than the use of evolutionary computing to solve “one problem at a time,” the use of natural computing to discover new *algorithms* is considered, which can then in turn be used on entire classes of problems, solving them efficiently and effectively. This is an area within the emerging field of “hyper-heuristics,” but with the particular focus on designing new algorithms which is referred to as “super-heuristics.”

4.1 Safe Streets via Robust Route Optimization

This section describes an application of natural computation in a critical seasonal logistical task, covered more fully in Handa et al. (2006). Local authorities in countries such as the UK, with marginal winter climates, are responsible for the precautionary gritting/salting of the road network in order to allow safer travel in icy conditions. This winter road maintenance task is extremely challenging as well as critically important to the locality, with a potentially major impact on both business and day-to-day life.

As Handa et al. (2006) note, in the case of the UK there are around 3,000 precautionary gritting routes that cover about 120,000 km (30% of the entire UK road network). On nights with forecasted snow or ice, these routes need to be treated so as to ensure the safety of road users. This typically costs between £200 and £800 per km of road (Cornford and Thornes 1996). Accurate road surface temperature prediction is required, in order to decide which roads need to be treated, however this decision can often be uncertain. Optimization of the route to be traveled by the gritting/salting trucks also plays a crucial role here. The consequences of a wrong decision – not treating a road that eventually becomes dangerous – are serious, but if grit or salt is spread when it is not actually required, there are obvious financial and environmental drawbacks. The goal of gritting route optimization is to minimize the

financial and environmental costs, while ensuring that roads that need treatment will be gritted in time. Further, it is essential that gritting routes are planned in advance, to enable effective use of limited resources (e.g., trucks and salt).

Mostly, the design of gritting routes relies heavily on local knowledge and experience. A “static,” often paper-based approach is typically used to optimize gritting routes, staying within constraints imposed by the road network itself, vehicle capacities, the number of vehicles, and the available personnel. This section describes the application of an evolutionary algorithm to this task. Covered in more detail in Handa et al. (2006), discussed here is a Salting Route Optimization (SRO) system that combines evolutionary algorithms with the latest version of the Road Weather Information System (XRWIS) commonly used by local authorities.

4.1.1 The Salting Route Optimization (SRO) System

A very important aspect of the SRO discussed here is its integration with XRWIS, which, recently trialed by the UK Highways Agency, is a high-resolution route-based forecast system that predicts road temperature for a 24-h period. XRWIS models surface temperature and condition at thousands of sites in the road network. Data are collected along each gritting/salting route by conducting a survey of the “sky-view factor” (a measure of the degree of sky obstruction by buildings and trees) (Chapman et al. 2002). This is then combined with other geographic, land use, and updated meteorological data to predict road conditions at typical spatial and temporal resolutions of 20 m and 20 min, respectively. The output is displayed as a color-coded map of forecast road temperatures and conditions that is then disseminated to highway engineers.

In the SRO, XRWIS provides forecast temperature distributions over time that are then input to an evolutionary algorithm module. Each temperature distribution (different distributions for different future timepoints), along with commercially available routing data, is transformed into an instance of a capacitated arc routing problem (CARP) (Lacomme et al. 2004). That is, each temperature distribution suggests a specific set of roads on the networks that need to be treated. The CARP is then defined as the need to find routes that serve this specific set of roads in a reasonable time frame, using no more than the available vehicle numbers and capacities, and ideally minimizing the number of vehicles used. An important point is that each timepoint leads to a different CARP instance, since the set of roads that require treatment may be different. The overall goal of the SRO system is not only to find a suitable series of salting routes, which ensure that the roads that require treatment are treated in time, but also to ensure that the routes do not vary too much, which in turn causes considerable confusion and distraction to the workforce. In this sense, the SRO system finds a *robust* solution, which ensures we can cover the most important sections of the road network.

Given the series of CARP instances, the evolutionary algorithm module finds solutions that are simultaneously good for all or many of these instances. In particular, a specially designed memetic algorithm is used (a combination of evolutionary and local search) as described next. In this approach, the fitness of a solution is calculated according to the entire ensemble of CARP instances. However, at each generation, the operators and local search processes concentrate on a specific instance. The different instances are weighted, and this weighting controls the selection of the instance in each generation, in a way described in the following.

4.1.2 Robust Solutions for Salting Route Optimization

Searching for robust solutions is currently a significant topic in the field of optimization in uncertain environments, since in many problems the decision variables or environmental parameters are subject to noise. In this case, Handa et al. (2006) required that solutions to the different CARP instances be as similar to each other as possible (so that daily changes in the temperature distribution do not lead to significant disturbance in the route to be followed), while at the same time requiring good performance in terms of the costs of the routes. Handa et al. modeled a robust SRO solution as one which optimized the following:

$$F(X) = \int E(X, a)p(a)da$$

in which X and a indicate route design variables (routes and possible temperatures), $E(X, a)$ indicates the distance cost of gritting routes X given temperature a , while $p(a)$ indicates the probability of temperature a . Hence, the idea is to find ideal gritting routes for each temperature distribution, but weighted by the prior probabilities of the forecast temperatures.

Although the distribution in temperature will vary daily across a road network, warmer (colder) sections are usually warmer (colder) than the rest of the network. So, even on cold nights, some warmer sections may not require salting, whereas colder sections may need treatment even in relatively warm conditions. The fitness function, as stated above, is impossible to compute exactly since its components are largely unknown; instead it is approximated by using a number of typical temperature distributions. Considering this and other issues, the fitness function used by Handa et al. (2006) was as follows, given a set of temperature distributions A_e :

$$F(X) = \sum_{a \in A_e} w_i \frac{E(X, a_i) - E^*(a_i)}{E^*(a_i)}$$

in which $E^*(a_i)$ represents the difficulty of finding a good route for temperature distribution a_i , and the w_i are weights, summing to 1, which balance the importance of different temperature distributions during the optimization process. The weights are adapted during evolution in a way that maintains a focus on the routes that are proving more costly, while the $E^*(a_i)$ values are lower bounds on the cost of the routes for each temperature distribution a_i , actually predetermined by prior runs of the memetic algorithm for this purpose described in Handa et al. (2005).

Handa et al. (2006) used a permutation-based encoding as follows. An individual solution comprised a permutation of arc IDs (road sections), interspersed with symbols representing individual trucks. For example, the individual:

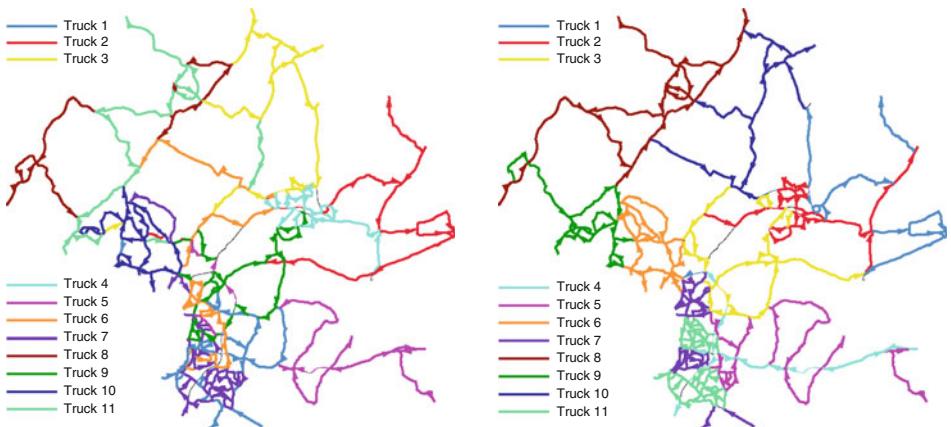

2 6 s1 5 4 7 1 s2 8 3

indicates a gritting route for two trucks; truck 1's route is road sections 5, 4, 7, and 1 (in that order), and truck 2's route is road sections 8, 3, 2, and 6 (note the wraparound involved in the interpretation).

At each generation of the memetic algorithm, crossover (the EAX operator proposed by Nagata and Kobayashi 1997) and local search methods are applied with regard to only one CARP instance (i.e., one temperature distribution) in every generation. That is, for example, the local search is guided by the fitness according to the selected instance only. The choice of instance is made stochastically according to the current weights of the temperature distributions. However, between generations, the fitness of each solution is calculated according to the

Fig. 11

Left: routes optimized by the SRO system for a cold day in South Gloucestershire; Right: existing routes obtained by human experts.

ensemble of instances using the fitness function described, and this then guides the selection of parents for the next generation.

4.1.3 Comparisons and Conclusions

In experiments by Handa et al. (2006) to test and validate this approach, robust solutions were evolved by using ten different temperature distributions, and these were then compared with the routes currently used by South Gloucestershire Council in the UK.

• *Figure 11* shows an example of routes found for a cold day, comparing the SRO system's routes (on the *left*) with the existing routes (on the *right*).

In comparison with the routes that were in use at the time, the robust solutions delivered by the SRO were able to provide more than 10% savings in terms of total distance traveled by the available trucks.

The SRO system was developed for finding optimized robust solutions for salting trucks, and as such it is an excellent example of an important real-world combinatorial problem that can be solved effectively via a system with natural computation at the core. In this case, especially given the integration with the XRWIS, the system can be regarded as proof of concept for similar tasks that need careful planning in relation to weather conditions, such as waste collection and parcel delivery.

4.2 Hyper and Super Heuristics

This section briefly considers a fairly new method in search and optimization, variously called hyper-heuristics or, as an emerging term in the community referring to a specific brand of approach, super-heuristics. In the context of selected applications of natural computation, the special aspect of super-heuristics is that they represent the use of a good global optimization or

learning method – hence, typically evolutionary computation or a learning classifier system – to discover new *algorithms* that solve problems of a given kind. This is as opposed to, and substantially more general than, using optimization or learning to solve a single problem instance.

In very broad terms, the general notion of hyper-heuristics refers to the idea of using an algorithm that manipulates a set of heuristics in order to solve a given problem. This is indeed a very common activity these days, and can be seen in many published applications of evolutionary algorithms, and of meta-heuristics in general (including, e.g., tabu search and simulated annealing). Typically, such an approach is sometimes called hyper-heuristic in the case that the encoding used involves lower-level heuristics in an integrated way. That is, rather than an encoding of a solution being a direct representation of a solution, the encoding is instead an indirect representation (examples will be looked at later). The interesting point is that, in some cases, an encoded solution for a given problem can actually be interpreted as an algorithm that can be applied to a large collection of instances of that problem, not just the instance currently being solved. In many so-called “hyper-heuristic” applications, this reusability of the encoding of a solution is only a side effect. When the term “super-heuristic” is used herein, this is meant to refer to the idea that evolving new general and reusable algorithms (for classes of instances, rather than a single instance of interest), is the specific goal of the process. However, it is noted that “super-heuristics” seems to have been first used in the literature by Lau and Ho (1999), to denote something more akin to standard hyper-heuristics, in which a set of heuristics are engineered by higher level algorithms in order to solve a specific problem instance. This section describes the ideas, amid some examples and historical notes. For alternative and more detailed accounts, a 2003 book chapter is recommended (Burke et al. 2003), or the current Wikipedia article on hyper-heuristics.

4.2.1 Potential Impact of Super-heuristics

The impact and importance of super-heuristics is partly evidenced by a negative point: despite a large collection of case studies, standard applications of meta-heuristics tend to be “one-off” and resource-intensive. For example, a particle-swarm optimization method developed to solve a small company’s daily process scheduling problems may seem successful in its own terms, but its existence does not necessarily accelerate the potential for other companies with similar (but not the same) problems to develop similar solutions. And, typically, the solution itself may be resource intensive, tying up considerable computing resources every morning. Also, the development of this solution will have typically been influenced by a perceived goal to produce solutions as optimal as possible, despite the fact that daily uncertainties and perturbations to the production process underline this optimality – that is, a large number of “reasonably good” solutions will have worked just as well.

In contrast, super-heuristics seem to open up the possibility for producing solutions that, though having an initial cost in development time, are much more flexible. The “solution” in this context would be a fast, constructive algorithm that tends to work well (as well as run much more quickly than a typical meta-heuristic implementation) on the problems typically faced by the company, and may well generalize to similar problems more successfully and easily than the meta-heuristic approach.

4.2.2 Hyper-Heuristics: Further Notions and Examples

Suppose there is an instance of a problem to solve. In particular, it is easier to think in terms of combinatorial and logistics problems, the kind in which a solution might be built step by step by making a series of decisions. For example, if a collection of student examinations have to be timetabled, first a room and a time for the largest exam might be found; then which exam to look at next might be decided, then where to place this next exam might be decided, and so on. For such problem domains, there is usually an available collection of “low-level” heuristics. For example, in timetabling, a common heuristic is to first sort the events that have to be timetabled according to some measure of difficulty. There are several such measures, based on the fact that some events are more difficult to place than others (e.g., can only fit in a small number of rooms, and potentially clash with many of the other events). One way to do timetabling constructively (such algorithms are often called “greedy”) is to repeatedly choose an event to timetable based on a difficulty measure, and then timetable it by finding a place and a time that suits. Each potential difficulty measure can be considered a different heuristic. Similarly, deciding where and when to place the event are also activities that can be based on a range of specialized heuristics. Very similar can be said of other, if not all, logistic or combinatorial problems.

With independent roots in the field of automated planning and scheduling systems (Minton 1988; Gratch et al. 1993; Cross and Walker 1994), an early and influential example of the hyper-heuristic approach being used for solving specific problem instances (i.e., one at a time) is concerned with open-shop scheduling problems in Fang et al. (1994). In Fang et al.’s work, several low-level heuristics were considered, all of which were relevant to the problem of “open-shop” scheduling, in which there are, say, j jobs that need to be scheduled, each consisting of a certain number of tasks. Each such task must use a specific resource (usually called a machine) for a specific amount of time, although the tasks that comprise a given job may be done in any order (when the order of tasks within a job is constrained, it is a job-shop problem). For example, PCs may arrive at a processing center with the operating system installed, and need to have a number of applications installed (for which order of installation is unimportant) by a number of experts, each expert in the installation of a particular application. Each “job” is a PC, which may have its own individual specification and subset of applications that need to be installed; this amounts to an open-shop scheduling problem.

Fang et al. (1994) used an evolutionary algorithm which constructed solutions as follows. A chromosome was a series of pairs of integers $[t_0, h_0, t_1, h_1, \dots]$ interpreted from left to right, meaning: for each i , “consider the t_i -th uncompleted job (always interpretable, when treating the list of uncompleted jobs as circular) and use heuristic h_i to select a task to insert into the growing schedule in the earliest place where it will fit.” Examples of the lower-level heuristics used are:

- Choose the task with the largest processing time
- Choose the task with the shortest processing time
- Find the tasks that can start earliest (there may be more than one) and choose the one with largest processing time
- Find the tasks that can be inserted into a gap in the schedule so far, and pick one that best fills this gap

This approach was called “evolving heuristic choice,” and led to excellent results on benchmark problems, including some new best results at the time of publication, and it marked the beginning of a wave of interest in what were later termed “hyper-heuristic” approaches.

An example following this work was that of Hart and Ross (1998), who looked at job-shop scheduling problems (where the ordering of tasks within a job is predetermined – for example, in the software installation example, it could well be the case that applications need to be installed in a certain order). Their approach relied on the fact that there is always an optimal schedule which is “active,” meaning that to get any task completed sooner, one would need to change the order in which tasks from different jobs get processed on one or more of the machines. Meanwhile, a well-known heuristic algorithm (due to Giffler and Thompson 1960) that generates active schedules was exploited. The explanation by Hart and Ross (1998) and in Burke et al. (2003) is now followed in explaining their approach. Giffler and Thomson’s active-schedule generation algorithm is as follows:

1. Let C = the set of all tasks that can be scheduled next
2. Let t = the minimum completion time of tasks in C , and let m = machine on which it would be achieved
3. Let G = the set of tasks in C that are to run on m whose start time is $< t$
4. Choose a member of G , insert it in the schedule
5. Go to step 1

In step 4, there is a choice to be made, which was exploited in Hart and Ross’ hyper-heuristic approach. Now consider a simplified version of this algorithm, which only generates so-called “non-delay” schedules.

1. Let C = the set of all tasks that can be scheduled next
2. Let G = the subset of C that can start at the earliest possible time
3. Choose a member of G , insert it in the schedule
4. Go to step 1

This time, there is a choice to be made in step 3. Hart and Ross’ approach was to use an encoding of the form $[a_1, h_1, a_2, h_2, \dots]$, again interpreted from left to right, where the a s are 0 or 1, indicating whether to use an iteration of the Giffler and Thompson algorithm or an iteration of the non-delay algorithm, in order to decide on the next task to schedule, and the h s indicate which of the 12 heuristics to use to make the choice involved in the selected algorithm. This method again produced excellent results on benchmark problems.

Finally, before moving on to two examples of what can be called “super-heuristics” (i.e., where general problem solvers are evolved, rather than algorithms for one instance at a time), an early real-world application of the hyper-heuristic approach is briefly mentioned. Described in Hart et al. (1998), the problem that needed to be solved was to schedule the collection of live chickens from farms in Scotland and Northern England, for delivery to one of two processing factories. A given instance of the problem arises from a set of orders from supermarkets and other retailers, which have to be fulfilled within given time windows. The specific resources that needed scheduling were of two types: the collection of live chickens from farms was done by a set of “catching squads” who moved around the country in minibuses; the delivery of chickens to processing factories was done by a set of lorries. In general, catching squads needed to move from farm to farm collecting chickens, and lorries needed to arrive at farms in time to be loaded with chickens caught by the squads, and then either move to another farm if able to hold more, or proceed to unload at a processing plant (and then perhaps back to a farm). The principal aim was to keep the factories supplied with work, while attempting to ensure that live chickens did not wait too long in the factory yard, for veterinary and legal reasons. There were several constraints. For example, different types of

catching squad were distinguished by differences in their contractual arrangements, relating to the amounts of work they would do per day or week (including, e.g., guaranteed minimum amounts of work). Meanwhile, the order in which a given squad could visit farms in 1 day was constrained according to the status of each farm in terms of certain chicken diseases, while lorry schedules also were subject to a range of associated constraints. Overall, the target was to create good schedules satisfying the many constraints, but that were also generally similar to the kinds of work pattern that the staff were already familiar with, and to do so quickly and reliably.

After several approaches which did not work very well, using what were the standard styles of evolutionary algorithm approach at the time (experts in classical scheduling methods had already been consulted by the company, and had tended to retreat in terror once the problem had been described to them), the eventual solution used two evolutionary algorithms in two stages. The first was a hyper-heuristic approach to assign tasks to individual catching squads in a way that was able to cover the current set of customer orders. In detail, a chromosome specified a permutation of customer orders followed by two sequences of heuristic choices. The first sequence of heuristics specified ways to split each order into convenient workloads, and the second sequence of heuristics specified how to assign those workloads to catching squads. The second stage was an evolutionary algorithm that took the set of tasks produced from the first stage, and delivered a schedule of lorry arrivals at each factory. For this real industry problem, a hyper-heuristics approach was central to a solution that worked successfully, whereas no previous approach had met the required standards.

Before moving on to “super-heuristics,” we note that the surface of applications that have found hyper-heuristics to be a highly flexible and successful approach has barely been scratched, albeit at the time of writing the application areas tend to be not very diverse, with most either involving timetabling (e.g., Terashima-Marin et al. 1999; Cowling et al. 2000; Burke et al. 2002; Bilgin et al. 2006) or scheduling (e.g., Hart and Ross 1998; Cowling et al. 2002; Ayob and Kendall 2003). For a much more comprehensive discussion of hyper-heuristics, readers may refer again to Burke et al. (2003), as well as Özcan et al. (2008).

4.2.3 Super-heuristics: Evolving and Learning New and Effective Algorithms

In an increasingly influential thread of research, Ross et al. (2002, 2003) extended the notion of hyper-heuristics to see whether new constructive algorithms, which could deal effectively with large sets of problem instances, rather than one instance at a time, could be evolved. In what is termed here as a “super-heuristic” approach, Ross et al. (2002, 2003) used a learning classifier system called XCS (Wilson 1998), and later an evolutionary algorithm, to try to learn an algorithm for solving hard bin-packing problems. The learning was done in Ross et al. (2003) with an evolutionary algorithm aiming to optimize the parameters for a fast constructive bin-packing algorithm, training on a set of test problems (i.e., a collection of different problem instances was involved in the fitness function). When the learned algorithm was then tested on a different set of test problems, its performance was found to be clearly competitive with state-of-the-art human-designed bin-packing constructive algorithms.

In bin-packing (as with many algorithms, and as discussed with scheduling), a typical constructive algorithm will build a solution one step at a time, each step involving the use of some heuristic to choose the next item to pack into a bin, and maybe another heuristic to

choose which bin to place it in (or a single heuristic covering the combined decision). The overall goal is to pack a given collection of items of different sizes into a set of fixed capacity bins, using as few bins as possible. In detail, the overall idea in Ross et al. (2002) and their later work (2003) is as follows. At each stage during such a constructive algorithm, there is a particular problem “state” that is characterized by the set of items left to pack, and the current partial packing of items into bins. In this state, it is reasonable to infer that some heuristics will be better than others for deciding on the next item/bin placement. So, Ross et al.’s approach was to define a constructive algorithm as a set of rules. Each rule in the set referred to a particular problem state, and specified what heuristic to use when in that state. Clearly, there are far more potential problem states than one can expect to be represented by the left-hand sides of such a rule; the method gets around this by having the rules essentially refer to points in the space of potential problem states, and the rule that “fires” at any particular time is the one that is closest to the current problem state.

The approach was first tested using 890 benchmark bin-packing problems in Ross et al. (2002), of which 667 were used to train the XCS learning classifier system, and 223 for testing. The single resulting learned constructive algorithm was able to achieve optimal results on 78.1% of the problems in the training set, and 74.6% of the problems in the unseen test set. This compared well with the best single heuristic tested, which achieved optimality 73% of the time. A notable finding in that work was that when the training set was confined to some of the harder problems, the learned algorithm was able to solve seven out of ten of those problems to optimality (compared with zero out of ten for the comparison human-designed heuristics). This approach was improved in Ross et al. (2003), with many interesting findings that showed highly competitive results for evolved algorithms on hard unseen problems.

Finally, we have a brief look at a different style of super-heuristic approach applied to a different domain, specifically the work of Fukunaga (2008), which concerns the satisfiability (SAT) problem. A SAT problem instance is a conjunctive normal form (CNF) expression, such as “(A or B or D) and (B or not(C)) and (D or E) . . .,” involving a number of logical variables (A, B, . . .), which may either be true or false, which in turn are the elements of a number of clauses, conjoined into the full statement. The problem is to discover whether or not an assignment of truth values to each of the variables exists, which results in each of the conjuncts, and therefore the entire statement, being true. Fukunaga’s work exploited a well-known general local search framework for SAT, as follows:

1. Generate an assignment A of truth values at random (e.g., $A = T, B = F, C = F, \dots$)
2. For a given maximum number of iterations:
 - 2.1. If A satisfies the formula, return YES
 - 2.2. Choose a variable V with a *Variable Selection Heuristic*
 - 2.3. Change A by flipping the value of variable V
3. Return UNKNOWN

The algorithm uses a “Variable Selection Heuristic” in Step 2.2, and this in turn was the focus of Fukunaga’s investigations. There are several well-known examples of variable selection heuristics, which are human-designed and typically used within the above algorithm framework. One example is GSAT (Selman et al. 1992), which involves choosing the variable that, if flipped, would cause the highest net gain in satisfied clauses, breaking ties randomly. Another, HSAT (Gent and Walsh 1993), works as GSAT, but breaks ties in favor of *age* – so, the variable that was last flipped longest ago in the overarching local search process is the one chosen to break the tie. Yet another, of several more, is the so-called GWSAT(p) (Selman et al. 1994), in

which, with probability p , a random variable from a random unsatisfied clause is selected, else GSAT is used.

Fukunaga (2008) noticed that variable selection heuristics in the SAT literature have certain common building blocks, including

- Scoring variables via a gain metric
- Selecting a variable from a subset of variables
- Ranking variables, and choosing the best (or second best)
- Consideration of a variable's "age"
- Branching (if x do A , else do B)

An insightful comment that Fukunaga makes is that in the history of SAT heuristics, developments typically come from finding new ways to combine these building blocks, rather than entirely novel heuristics. This begs a number of questions, one of which is whether or not automated methods may be able to find better combinations of these building blocks. The latter is in fact exactly what Fukunaga (2008) investigated, by using GP, with a function and terminal set designed in such a way that novel heuristics could be expressed in terms of the above ingredients. As with the previous super-heuristic approach discussed, the GP experiments involved using a large set of different SAT instances in the fitness function, and Fukunaga (2008) evaluates the results by testing the evolved variable selection heuristics on unseen test sets.

On a collection of 1,000 unseen test instances, Fukunaga's evolved variable selection heuristics are very competitive with the state-of-the-art variable selection heuristics, GWSAT, WalkSAT, and Novelty (McAllester et al. 1997). A handful of the new heuristics found in this way dominated the state-of-the-art heuristics in terms of success rate and speed. A further rather interesting finding was that one of the heuristics in a random search of expression trees was almost as good in terms of success rate, but usually faster, than the human-designed state-of-the-art heuristics.

4.2.4 Some Concluding Notes

The super-heuristics concept has the potential to play a major role in optimization over the next few years. One way to view this development is as a thrust toward more "general" optimization systems, which, for a wide variety of application areas, is a significant goal. In just one example of application area, *timetabling*, there has been very extensive research in recent years along the lines of hyper-heuristics and upper-heuristics; this has followed a statement in Ross et al. (1997), which was, "... all this naturally suggests a possibly worthwhile direction for timetabling research involving GAs. It is suggested that a GA might be better employed in searching for a good algorithm rather than searching for a specific solution to a specific problem." In agreement with Burke et al. (2003), we emphasize that this suggestion can be generalized to a much wider range of problem areas than has currently been addressed with hyper- and super-heuristic technologies.

5 Design: Art, Engineering, and Software

This penultimate section considers the theme of "Design," and discusses three quite contrasting examples. Design is an area of especial interest when we consider what natural inspiration

has to offer to practitioners of various sorts. Today, and for some considerable time still to come, the world is, to most intents and purposes, filled with two kinds of artifacts – those designed by nature, and those designed by human designers. The chief difference between these two kinds of artifacts is the specific design method that was employed. The naturally designed artifacts, as most scientists would agree, were designed by an evolutionary process – essentially an iterated process of randomized generation and test, in which new designs, often failures, sometimes improvements, emerge via slight random changes or randomized recombinations of old designs. With a “survival of the fittest” principle built in to this strategy, the successes are more often chosen than the failures when it comes to being the foundation for (or the parents of) new designs. Over time, this process continues to evolve new designs that are successful in their environment, and the examples seen today include everything from archaea to artichokes, baobabs to brains, *Escherichia coli* to elephants, and from wasps to the sophisticated set of processes that lead to the construction of wasp nests. It is overwhelmingly the case, however, that human-designed artifacts have not adopted this process. Humans prefer to design things in a rational way, which prefers the adoption of designs that have worked before for similar problems, and rejects the notion of any randomized exploration. Humans tend to stick to a battery of accepted design rules for the application in hand, and usually opt for a step-by-step constructive approach, rather than generating and later discarding many different designs at once.

Some criticisms of the human way of designing can be summed up in the following statement: the overreliance on established design rules imposes severe constraints on innovation, and probably limits the effectiveness of the resulting designs. Meanwhile, nature’s method for design may well not be perfect – it does indeed seem wasteful – however, it certainly beats the human method for innovation. One cannot yet design, with a rational approach, a biological flying machine as efficient as a mosquito, or an energy transduction system as efficient as photosynthesis. Meanwhile, it is notable that randomization is an integral part of nature’s method – undirected perturbations to designs tend to be anathema to the human approach, but are continually tried and tested in nature. Overall, it seems abundantly clear that nature has a lot to teach us about how to design things.

Perhaps unsurprisingly to most of readers, but nevertheless, it is hoped, inspiringly, the documented experiences so far in the arena of natural computation in design show that novel, effective, and unprecedented designs can be found by applying nature’s method to design the artifacts that need to be created. The next subsections discuss one of the more prominent and exciting examples in recent years, NASA’s use of evolutionary techniques to come up with entirely novel antenna designs that have been deployed on satellite missions. But before that we look at an example of the use of interactive evolutionary computation in artistic design, and this section ends with a brief look at how natural computation is making headway into the design of software.

5.1 Interactive Evolutionary Design of Batik Patterns

Evolutionary Art Systems (EASs) are increasingly popular (Romero and Machado 2008), commonly using evolutionary computation, usually interactively (e.g., Sims 1991; Lutton 2006), to generate aesthetic artworks. In some real-world applications, focusing on particular niches in art and design, EASs have been developed specifically to facilitate a designer’s activity. One recent such case, which is described here, is by Li et al. (2009), in which an EAS

tool is described for helping designers of Batik patterns, a traditional art in Indonesia and southeast Asia. Batik is a form of painting or writing on cotton cloth, applied with the aid of a tool called a cap (Kerlogue and Zanetini 2004). Nowadays, Batik is used in fashion, furnishing fabrics, and household accessories, as well as paintings and ornamentations in rooms and offices. However, fine-quality handmade Batik is very expensive, so it is potentially valuable to consider ways that would decrease Batik designers' effort and increase production of Batik.

Li et al. (2009) investigated the potential for an EAS-based Batik design system with such goals in mind. In doing so, however, they had to consider the difficulties commonly faced by EAS. First, the evolutionary process is often quite limited by the lack of an explicit correlation between genotypes and phenotypes. Essentially, the common ways in which aesthetic works tend to be encoded by manipulable genes (think of fractal patterns encoded in the typical way by mathematical formulae) are far removed from the works themselves, so that, for example, when human designers select what they think are good parents, they may find that none of the promising features they saw in the parents actually appears in the next generation. Another common difficulty is that the process can be tiresome for a human designer, spending hours sitting at a computer rating generated images. Li et al.'s work attempted to develop a Batik design system with innovations that addressed these issues. In particular, they devised a suitable encoding for various Batik styles, and they devised an "out-breeding" mechanism that provided an additional way to generate new patterns, which seemed to be on the aesthetic path being pursued by the designer. These issues are elaborated in the following subsections, but the reader is referred to Li et al. (2009) for a more complete account.

5.1.1 Encoding Batik Patterns

Li et al. (2009) explored the space of geometrical patterns used in Batik, and classified them into categories. They found that the most common features were repetition, and certain geometric transformations such as rotation, translation, and reflection. This led to a way to encode patterns in genotypes, which specify a number of nonredundant primitives along with transformations. The encoding is therefore based directly on features of Batik patterns, most basic elements of which include: triangle, polygon, circle, dot, star, and flower. Each feature is generated from one gene in the genotype.

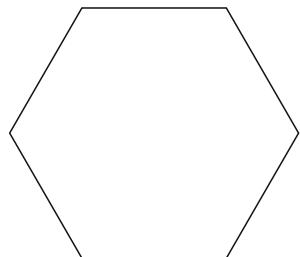

A genotype consists of a variable number of genes, each of which represents one feature in the phenotype. Every gene has two evolvable attributes. The first part is a specific basic pattern (e.g., a simple representation of a flower petal, or a circle, or a triangle); the second part, the transformation, is a vector of matrices, which each represent a transformation of the unit set. A matrix is encoded by six numbers, indicating a 2D linear transformation together with a translation. This representation is straightforward and easy to manipulate. The resulting pattern is made up of the union of the patterns induced by the different genes.  [Figure 12](#) shows some examples of single simple genes in this encoding, with their interpretations above, while  [Fig. 13](#) shows some patterns produced using the system, contrasted with some human-designed similar Batik patterns.

5.1.2 Boosting the Evolutionary Process

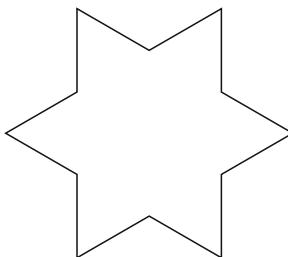

Li et al. (2009) use what they call an "out-breeding" mechanism to invigorate the pool of patterns produced during the interactive evolutionary process. In their EAS, two separate

Fig. 12

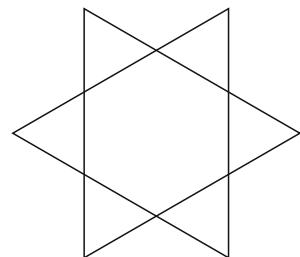

Simple examples of Batik pattern genes, and their interpretations.

(1,1, straight line, rotate, 6)

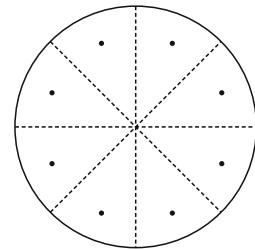

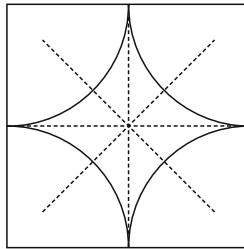

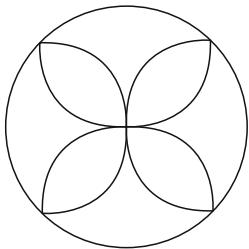

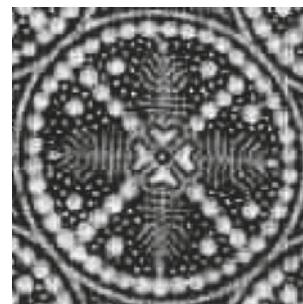

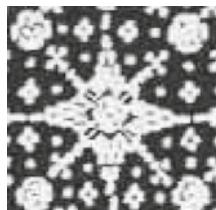

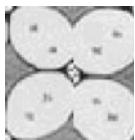

(2,1, straight line, rotate, 6)

(2,2, straight line, rotate, 6)

Fig. 13

Above: some real-world Batik patterns; below: similar individuals generated by the mathematical model, such as appear in the initial population of the Batik interactive evolutionary system.

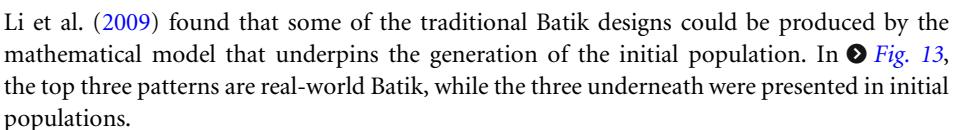

populations of patterns are maintained, displayed to the designer on separate panels. One population evolves in the normal way, based on treating the user's feedback as the fitness function. However, the second population evolves toward individuals that are maximally dissimilar to what seem to be the user's preferences, hence injecting considerable diversity into the displayed patterns. Whenever the first population seems to be stagnating, individuals in the second population will be introduced to the first, contributing diverse input to the gene pool.

The crux of this mechanism is the idea of “dissimilarity,” which requires a way to compare patterns. Li et al. (2009) preferred to investigate a measure that was related to the visual difference between patterns, expecting that a method based only on genotypic difference would not be satisfactory. They use a metric based on singular value decomposition (SVD) (Wang et al. 2000). In their approach, a pattern A is interpreted as a matrix, and they represent each pattern in terms of the singular values arising from the SVD of A , which in turn are likely to capture salient features of the visual perception of A . A similarity metric between two patterns is then defined on the basis of a normalized comparison of their vectors of singular values. The outbreeding process then operates as follows: In each generation, while one population continues to regenerate patterns according to the normal process, guided by the user’s evaluations, the outbreeding population regenerates in a way guided by using dissimilarity as the fitness measure, measured in terms of dissimilarity from the pattern that the user currently perceives as best. Li et al. (2009) report that the outbreeding mechanism is very effective in aiding the search for innovative patterns, and find that the “outbred” populations tend to be more elaborate and attractive than the “main” population!

Meanwhile, concerning the “standard” interactively evolved population, one notes that the generation of the initial population, and the subsequent evolution based on user-supplied fitnesses, relies on a collection of typical genetic operators as follows. The initial population is informed by using a mathematical model of Batik pattern space based on Li et al.’s preliminary characterization. The model is used to generate collections of genes, and then mutation operators are applied to these: either Gaussian mutation (in which each point in the basic pattern element of each gene is perturbed by the same random amount), or style mutation (in which the elements of a gene reflecting line styles are perturbed, for example from straight-line to curve). During the subsequent interactive evolution process, new patterns are produced by crossover and mutation of patterns deemed good by the user. Standard types of crossover and mutation are used for this in Li et al.’s work so far, for example, including linear combination and gene-swap-based crossover. Also, as explained fully in Li et al. (2009), their system has other features that are meant to aid the user’s design process, such as the ability to retrieve patterns that were produced earlier in the evolution.

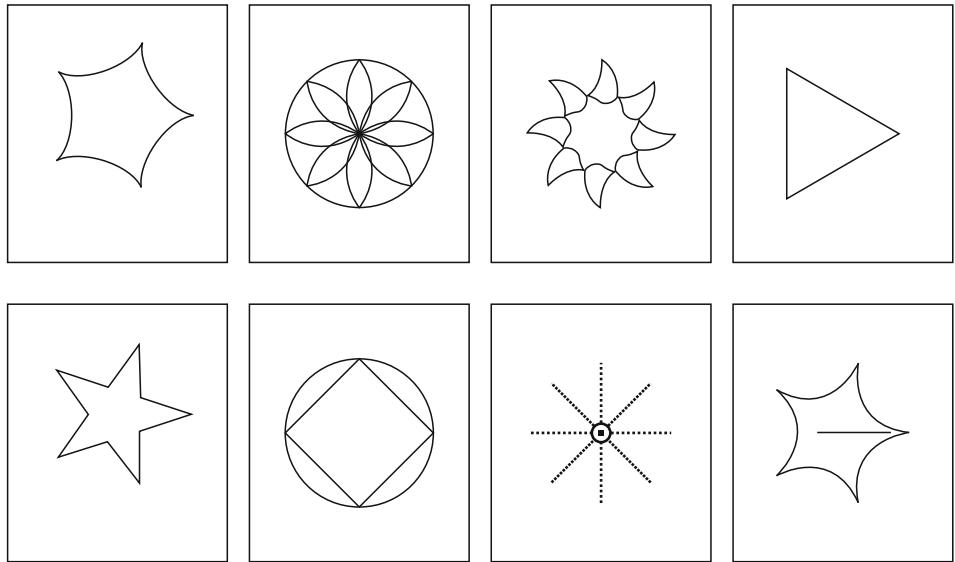

5.1.3 Empirical Notes

Li et al. (2009) found that some of the traditional Batik designs could be produced by the mathematical model that underpins the generation of the initial population. In  Fig. 13, the top three patterns are real-world Batik, while the three underneath were presented in initial populations.

Li et al. (2009) report on five experiments using their system, aimed partly at evaluating the outbreeding technique; each experiment ran the process twice, with and without outbreeding (but starting from the same initial populations). They measured, in particular, the time investment of the user before a satisfactory design was achieved. They found that, with the outbreeding mechanism in place, the design process took on average only 54% of the time taken using the interactive system without outbreeding. Further, the time with outbreeding was roughly 17% of the time it tends to take to design a new Batik pattern by hand. Further experiments confirmed in other ways that the outbreeding mechanism was effective in producing patterns, throughout the process, that tended to be well evaluated by users.  Figure 14 shows the initial population used for all of these experiments, and

Fig. 14

Initial populations used in Li et al.'s experiments.

**Fig. 15**

Tessellations of final-population designs using the Batik pattern interactive evolutionary system (with the outbreeding mechanism).

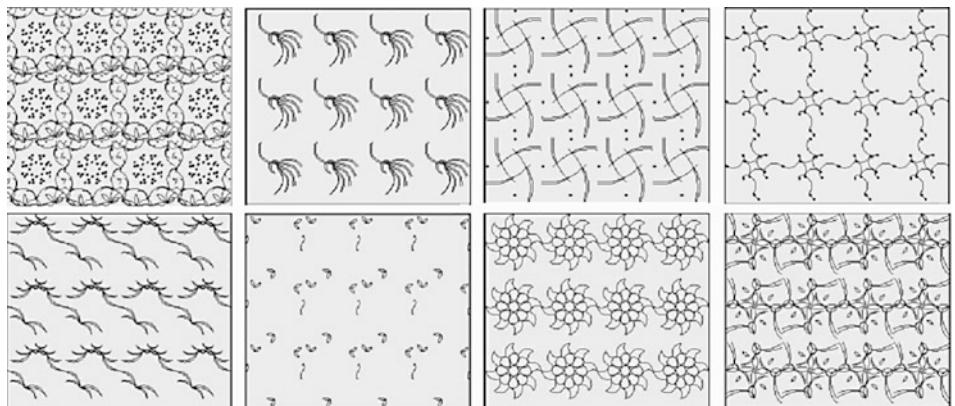

Fig. 15 shows some final-population designs that satisfied the users (produced with the outbreeding mechanism in operation), converted into tessellations.

5.1.4 Final Points and Notes

The interactive Batik design system described and discussed here is a nice example of how interactive evolutionary computation is beginning to be used in an increasing number of

applications that involve creativity. Experience with this system so far shows how it can both speed up and invigorate the process of generating interesting new patterns in the Batik “domain.” One of the keys to success in such enterprises is the wise design of the encoding, and we have seen a good example of that in this case. Li et al. (2009), as already seen, also showed an innovative approach to dealing with some of the ever-present problems (and, hence, research issues) in interactive evolution. The outbreeding mechanism was able to enhance diversity in the process, and at the same time reduce the time (and hence fatigue) of human users.

5.2 Novel Antennas for Satellites: Discarding the Rule Book

As elaborated further in Hornby et al. (2006), current practice in antenna design almost invariably involves designing and optimizing them by hand, and this approach is very limited as a way to develop new and better antenna designs. It requires significant time and expertise from human experts in the domain. An ongoing alternative in antenna design (in common with an increasing variety of such specialist areas) is to investigate evolutionary algorithms for this purpose. This has been happening since the early 1990s, with increasing success and take-up as developments in processing power have been seen, and also improvements in the quality of software simulations of antenna performance. To date, many types of antenna have been investigated using evolutionary design approaches. A particularly interesting and useful aspect of this approach is the opportunity to evolve antenna designs specifically for performance in a particular environment, so that the fitness function takes into account the effects of structures surrounding the antenna’s intended position. This consideration of the immediate environment is extremely difficult for human expert antenna designers to take into account.

This section summarizes the work reported in Hornby et al. (2006) and other publications from that group, which describe the experience and results of using evolutionary algorithms to evolve antennas for spacecraft associated with a number of NASA missions; in particular, two antennas designed for NASA’s Space Technology 5 (ST5) mission, and an antenna for a Tracking and Data Relay Satellite (TDRS) for a mission due to operate after 2010.

5.2.1 Antennas for NASA’s Space Technology 5 Mission

NASA’s Space Technology 5 (ST5) mission had the goal of launching multiple miniature spacecraft to test various innovative concepts for application in future space missions. Three miniaturized satellites were involved in ST5, called micro-sats, designed to measure the effects of solar activity on the Earth’s magnetosphere. These micro-sats were approximately half a meter across and half a meter high, weighing around 25 kg when fully fuelled, and each had two antennas, centered on the top and bottom. They were originally designed to operate in a geosynchronous orbit at approximately 35,000 km above Earth, and had a stringent set of requirements for the communication antennas. Details of the specific requirements are in Hornby et al. (2006), and one need not discuss them here, but (in common with similar antenna design tasks) these requirements were in terms of constraints on the gain patterns, voltage standing wave ratios, and input impedances, at both the transmit and receive frequencies; also the mass of each antenna had to be below 165 g, and the shape had to fit within a cylinder with height and diameter both below 16 cm.

To meet the initial design requirements in this instance, the team decided to constrain their search to a monopole wire antenna with four identical arms, equally spaced around the vertical axis. An evolutionary algorithm was therefore set to work to evolve the shape of a single arm, which in turn defined the entire antenna. Importantly, the encoding used by the team was one that allowed almost arbitrary designs for the arm, with no reference to the limited collection of known standard designs. Essentially it was a GP style approach, in which each node in a tree was an antenna-construction operator. Interpreting the tree top down from the root node, and given an initial “feed-wire” of a given small length and orientation, the operators and leaves of the tree effectively specified three-dimensional movements in the style of “turtle graphics,” adding sections of wire of specific lengths and orientations to the current partial design.

Having decoded a tree into an antenna design, the antenna was simulated by means of a sophisticated simulation platform, which yielded estimated performance characteristics which then had to be automatically evaluated against the design requirements. In common with the design requirements themselves, readers are referred to Hornby et al. (2006) for details of the fitness function, but suffice it to say that the requirements themselves and the simulation results are both curves involving performance characteristics at different spatial locations and frequencies, and the fitness function involved such things as estimates of distances between desired and actual curves, weighted in specific ways according to the importance of different requirements.

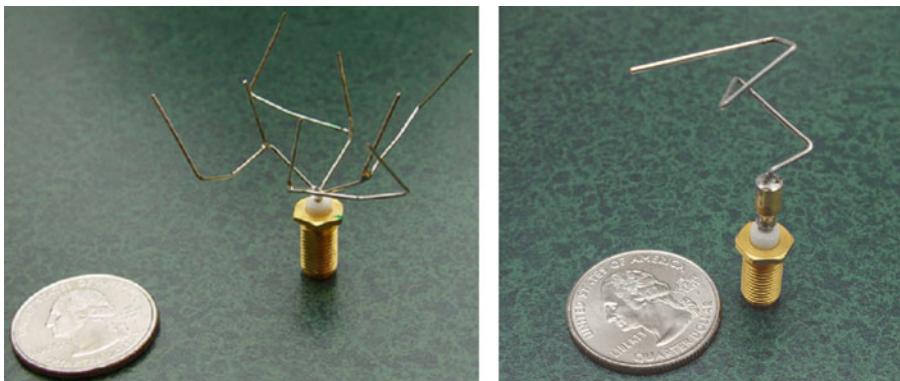

It so happened that the requirements for the ST5 mission changed while these initial antennas were being designed. New mission requirements effectively forced a single-arm antenna design, and this led to the need to redesign the fitness function for the antenna design process. In the operating environment context of Hornby et al.’s work, it is of particular interest and importance to note that an extremely effective antenna design was produced, for the initial set of requirements, in a short time when compared with the human expert design process. Moreover, with mission requirements altered partway through the process, the evolutionary algorithm approach needed only relatively minor modification and was still able to quickly produce an effective antenna for the new requirements.

To meet the initial mission requirements, the best evolved antenna design that emerged, “ST5-3-10,” is shown in  Fig. 16 on the left. This antenna met the initial mission requirements, and was indeed all set to be used on the mission itself, until the mission’s orbit (and hence many other aspects) was revised. The new evolved best antenna following the new requirements was the one shown on the right in  Fig. 16, the so-called “ST5-33-142-7.” The latter antenna design, which was delivered for prototype fabrication less than a month after the changes to the ST5 mission requirements, was found fully compliant with specifications when the prototype was tested, and on 22 March 2006 the ST5 mission was successfully launched into space using evolved antenna ST5-33-142-7. Hornby et al. (2006) report that this was the first computer-evolved antenna to be deployed for any application and the first evolved hardware in space. (One notes that this is clearly valid, if one confines oneself to hardware produced, by whatever means, in the local solar system; but one does not know about elsewhere.)

Hornby et al. (2006) note that the evolved antenna has a number of advantages over human-designed alternatives. These advantages include reduced power consumption, fabrication time and complexity, and improved performance. The ST5 mission managers had actually hired a contractor to produce antenna designs in addition to awaiting the findings of the evolutionary approach. The contractor used conventional design practices, and came up with a variant of one of the many standard designs. When this design was compared in simulation with the evolved design, it was found that if an ST5 craft used two evolved antennas (recall that

Fig. 16

Photographs, reproduced with permission, of prototype-fabricated evolved antennas. Left: the best obtained antenna for the initial ST5 mission requirements, ST5-3-10; right: the best obtained following the revised specifications, ST5-33-142-7.

each craft had two antennas), efficiency would be 93% improved over the situation where the craft instead used two of the contractor-designed antennas. Among other explication of the various benefits in Hornby et al. (2006), it is noted that the evolved antenna required approximately 3 person-months to design and fabricate, versus approximately 5 months for the human-designed one.

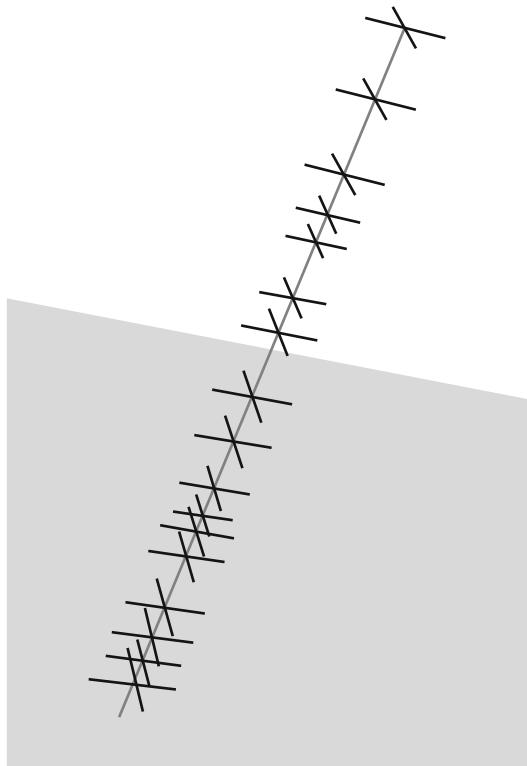

5.2.2 An Antenna for NASA's TDRS-C Communications Satellite

Later in 2006, the same team evolved an “S-band phased array” antenna element design for NASA’s TDRS-C communications satellite, part of a mission that was scheduled for launch sometime between 2010 and 2020. This time the evolutionary algorithm was combined with a hill-climbing algorithm, and the antenna design was somewhat more constrained toward a standard style; nevertheless the resulting design was simpler than the potential competing human designed antennas, consequently reducing testing and integration costs.

As Hornby et al. (2006) reports, the TDRS-C mission will carry several antennas, including among them a 46 element phased array antenna. Readers unfamiliar with the terminology may see [Fig. 17](#), from which it becomes clear what the individual elements are in the phased array. The design and performance specifications for this antenna involved electromagnetic performance issues, as was the case for the ST5 missions, but also certain constraints on the elements and their spacing.

A simpler encoding was used by the team for this case, in which an antenna was represented as a fixed length list of real numbers. Antenna parameters were determined from these simple “genes” in a fairly straightforward way, in which the majority of successive pairs of genes referred to the distance to the next element along the antenna’s axis, followed by the size of the next element.

In a similar process used for the ST5 mission antennas, the team set up around 150 separate experiments that each ran an evolutionary algorithm for a total of 50,000 evaluations (antenna simulations) each – the separate evolutionary algorithms each represented a random

Fig. 17**Best evolved TDRS-C antenna.**

point in parameter space, with different population sizes, mutation rates, and so forth. The best antennas from each of these 150 runs was then subject in a second stage to further improvement via a hill-climbing algorithm for 100,000 evaluations. Finally, the best of these were subject to further hill-climbing.

At the end of this process, most of the evolved antennas were very close to meeting the rather stringent mission specifications, and one of the evolved antennas exceeded the specifications. That one, shown in [Fig. 17](#), was further analyzed by an accurate electromagnetic software (WIPL-D version 5.2), and was subjected to some fine tuning via another evolutionary algorithm, and finally a resulting antenna design was fabricated and tested. The final design, shown in [Fig. 17](#), exceeds the design specifications, and it remains up to the mission leaders whether it is deployed in the TDRS-C mission.

5.2.3 Concluding Points

In this section, the work of Hornby et al. (2006) in evolving antennas for two NASA missions has been described. For both the ST5 mission and the TDRS-C missions it took approximately

3 months to set up the evolutionary algorithms and produce the initial evolved antenna designs. Following the revision in ST5 requirements, it took roughly 1 month for the team to evolve antenna ST5-33-142-7, and the team is indeed very confident (Hornby et al. 2006) that a change in requirements for the TDRS-C mission will result in a similarly fast redesign of an antenna meeting the new requirements.

As well as benefits in relative speed and ease of design, the evolutionary algorithm approach to designing antennas leads to many other advantages over manual design. One such advantage is the potential for performance characteristics that are simply unachievable with conventional design styles. Antenna design is one of several areas in which there is potential for unexplored areas of design space to be examined. These are areas of design space that human experts tend to steer away from, since the current state of theory and understanding is quite limited to the properties of a range of conventional designs. Evolutionary algorithms are far less wary of such ill-understood areas of design space, and, by finding exemplars in such areas that have outstanding performance (such as the ST5 designs discussed in this section), they may lead to more systematic study of such regions of the design space, leading to new design principles and new scientific insights.

5.3 Evolution in Software Design

As noted in Arcuri and Yao (2008), software testing is used to find bugs in computer programs (Myers 1979). Even though successful testing is no guarantee that the software is bug free, testing increases confidence in the software's reliability, and is an integral and extremely important part of modern software engineering. However, testing is very expensive, time consuming, and tedious, amounting to around half the total cost of software development (Beizer 1990). This investment in testing is not begrimed, since releasing bug-ridden software can be immensely more costly in the long run. In fact, it is often argued that far more testing should be done than is usually the case – in the USA, for example, it is estimated that around \$20 billion per year could be saved if better testing was done (Tassey 2002). The need for cheaper and faster testing is clear.

This section looks at recent work by Arcuri and Yao (2008), which is part of an area of research called search-based software engineering. In this particular thread, the idea is to investigate the use of evolutionary computation to improve aspects of the testing process. In particular, Arcuri and Yao (2008) are concerned with unit tests (Ellims et al. 2006). This relates to writing small pieces of software code that test as many parts of the project as possible. For example, the test code might call, with specific inputs, a Java method that adds two integers; the returned value is then checked against the expected value. If there is a difference, one can be sure that there is something wrong with the code. However, since testing all possible inputs of a method is usually infeasible, a suitable subset of tests needs to be chosen. Writing code for such “unit tests” requires some way to decide on a good collection of specific input cases, and is a very resource-hungry exercise.

Automated ways to generate unit tests are clearly of interest to the software design process, and this is the topic of Arcuri and Yao's (2008) work. Various approaches have been studied to automatically generate unit tests (McMinn 2004), but there is no known way to generate an optimal set of unit tests for any given program. Also, comparatively little has been done in this area for object-oriented (OO) software. This section describes Arcuri and Yao's (2008) recent

work that focuses on a particular type of OO software construct: *containers*. These are data structures (like arrays, lists, vectors, trees, etc.) designed to store arbitrary types of data. What usually distinguishes a container class is the computational cost of operations such as insertion, deletion, and retrieval of data objects. They are used in almost all OO software, so their reliability in commercial code is paramount.

Arcuri and Yao (2007) presented a framework for automatically generating unit tests for container classes, in the context of white box testing. They analyzed a number of different search algorithms, and compared them with more traditional techniques. They used a search space reduction that exploits the characteristics of the containers. Without this reduction, the use of search algorithms would have required too much computational time.

5.3.1 About Testing Java Containers

In each of the many kinds of Java containers (arrays, vectors, lists, trees, and so forth), one usually expects to find methods such as insert, remove, and find. The implementations (and hence computational expense) of these methods can vary much between containers; also, the behavior of such methods is often a function of the container's current contents. This situation considerably complicates the design of unit tests (McMinn and Holcombe 2003, 2005) – just because it is found that a method yields the correct result with certain inputs, it does not mean that it will always give the correct result with those inputs, perhaps depending on the current contents of the container.

The approach to testing containers therefore explicitly considers the sequence, S_p , of function calls. During a testing operation on such a container, the container is referred to here as a “Container under Test” (CuT), and a function call (FC) can be seen as a triple:

<object reference; function name; input list>

This simply refers to calling the given function (method) of the given object (container) with the given list of inputs. In Arcuri and Yao’s work, the CuT is subjected to a single sequence S_i of such FCs, rather than a different sequence for each of the functions’ branches. Naturally, in the unit test Java code, each FC is embedded in a different try/catch block, so that the paths that throw up exceptions do not forbid the execution of the subsequent FCs in the sequence.

The goal in testing is to achieve a maximal level of “coverage”; broadly speaking, this refers to the amount of code that is tested. All software is replete, for example, with case statements and “if X then Y else . . .”-style branches, and, without suitable design of test cases, many branches of the code may end up not being followed during the testing process. Given a suitable coverage-related criterion (there are several), it is then important to aim for the short sequence of function calls while achieving excellent coverage. Arcuri and Yao (2008) used *branch coverage* as their coverage criterion, although their approach is easily extensible to other coverage criteria.

In Arcuri and Yao’s formulation, they consider a coverage function $\text{cov}(S_i)$ which, in relation to a given CuT, returns the number of code branches covered when tested with the sequence of functional calls S_i . Where $\text{len}(S_i)$ is simply the number of function calls in the sequence, Arcuri and Yao attempt to optimize both $\text{cov}(S_i)$ and $\text{len}(S_i)$, preferring a shorter sequence in the case that the coverage of two sequences is the same. To some extent, it is clear that this is a multi-objective problem (see Deb 2001, and Sects. 3.1 and 3.2), however, Arcuri and Yao indicate a definite order of preference in this domain (coverage more important than

length), which influences their decision to treat it as a single-objective problem. They therefore attempted to find sequences that optimized $\text{cov}(S_i) + 1/(1 + \text{len}(S_i))$, although with various modifications and adaptations detailed in Arcuri and Yao (2008).

5.3.2 Smoothing the Test Landscape

Arcuri and Yao (2008) detail several complex factors involved in the enterprise of treating unit testing as an application for evolutionary computation, along with their solutions to these issues. Here, only one such issue will be discussed, of particular pertinence to the “engineering” of problems when considering artificial evolution of solutions. This relates to helping the evolutionary process by making the fitness assessments more informative. The problem in this case is that the number of branches covered (i.e., the number returned by $\text{cov}(S_i)$) does not give any indication of how close the sequence S_i is to being able to cover additional branches. Put another way, two sequences S_i and S_j may have the same coverage value, but one may be much “nearer” than the other (i.e., requiring a mutation to just one of its FCs) to a sequence that has higher coverage.

In many branch statements, in which the predicates accessing the branch are quite simple, random sequences of FCs will have little difficulty finding inputs that force coverage of all its branches (this is why a random search, as will be seen later, tends to achieve good coverage). But when the predicate is more complex, it is typically the case that only a very small portion of the space of potential inputs will lead to certain branches being covered. The search is likely to fail.

One approach to this issue is to consider the *Branch Distance* (BD) (Korel 1990). Any particular branch will be entered if a given statement is true (such as $0.2 < x < 0.3$); the BD is a real number that tells how far the relevant predicate is from being true (in the latter case, BD will be low if $x = 0.4$ and high if $x = 10$). Making use of such information in the coverage metric would help the evolutionary search process, by helping to distinguish between pairs of sequences that would otherwise have the same simple coverage value. BD is the topic of much research effort in software testing (e.g., Baresel et al. 2002; Harman et al. 2002; McMinn and Holcombe 2004). This research tends to consider approaches in which different test sequences focus on different branches, without considering the issues involved with the precise sequencing of function calls affecting the results. A difference in Arcuri and Yao’s approach is the attempt to evolve a single test sequence that covers all branches.

The technique they adopt is to modify the $\text{cov}(S_i)$ defined earlier, incorporating within it a simple measure of branch distance for any uncovered branch, which takes into account how many times the predicate associated with a branch is evaluated. For example, if only one FC in the sequence invokes a predicate with two branches, then only one branch will be covered. However, if in another sequence there are two FCs that test this predicate, both invoking the same branch, then it can be said that this second sequence is closer to covering the second branch, since (if coverage of this other branch is possible at all) this requires only mutation of the input list of one of the FCs in the sequence. There are various ways in which the coverage metric could be modified to take branch distance into account, and it turned out important to use different variations in different circumstances, as is mentioned later, and of course discussed more fully in Arcuri and Yao.

5.3.3 Evaluating Natural Computation for This Task

Arcuri and Yao (2008) tested five approaches: random search (RS), hill-climbing (HC), simulated annealing (SA), a genetic algorithm (GA), and a memetic algorithm (MA). RS is a natural baseline used to understand the effectiveness of other presumably more sophisticated algorithms, and often it brings surprisingly good results. In the current context, one can expect RS to give good results in terms of coverage. The RS worked simply by repeatedly generating random sequences, evaluating them, and returning the best at the end of the process; for pragmatic reasons, it was necessary to specify a maximum length for each sequence.

For the other methods, it was necessary to design neighborhood (and genetic) operators that would operate on sequences to produce variants. In all cases, the encoding of a sequence of FCs was entirely straightforward. The “chromosome” is simply an explicit (variable length) sequence of FCs, each a triple as described above. For neighborhood (mutation) operators, the natural choice was made to use operators of the following type:

- removing an FC from a sequence;
- inserting a new FC into the sequence, in a random position;
- modifying the parameters of a randomly chosen FC in a sequence.

In the GA, single point crossover was also used, in which a child sequence was generated by using the first K (randomly chosen) FCs in one parent, and completing the child with the FCs from position $K + 1$ onward in the second parent. The MA was a simple hybrid of the GA and HC, which repeatedly ran HC on each new individual produced by the GA, until a local optimum was reached. Although the RS, HC, GA, and MC were fairly standard in their SA implementation, various modifications and sophistications were included to control the acceptance of new mutants during the search, in an attempt to balance the coverage and length considerations. These details, and of course other parametric details of all of the algorithms, are explained in Arcuri and Yao (2008).

Arcuri and Yao (2008) performed tests on separate Java containers that implemented Vector, Stack, LinkedList, Hashtable, and TreeMap, respectively, from the Java API 1.4, package java.util, and BinTree and BinomialHeap from the examples in Visser et al. (2006). Described here is only a selection of their results, focusing on the four cases which involved the largest number of public functions under test (PuT). These were: Vector (34 PuT), LinkedList (20 PuT), Hashtable (18 PuT) and TreeMap (17 PuT), respectively, with 1,019, 708, 1,060, and 1,636 lines of code, and achievable coverage of 100, 84, 106, and 191 branches. The latter figures for achievable coverage are based on Arcuri and Yao’s experience of around a year’s worth of experimentation, with inspection of the container code confirming that non-covered branches seem unreachable.

Each of the five algorithms was tested, to a limit of 100,000 sequence evaluations per trial, using 100 trials per algorithm and container pair; a selection of Arcuri and Yao’s results are summarized in  Table 6. When one considers the coverage results in the context of the highest achievable coverage mentioned above, it turns out that only TreeMap presents a particularly difficult coverage task. The MA achieves the best mean coverage result on TreeMap, and indeed the MA is reported by Arcuri and Yao (2008) as statistically superior to the other algorithms in all cases except Vector (based on a Mann–Whitney U test). In all container cases except Vector (including the others reported in Arcuri and Yao 2008), the MA shows either the best mean coverage, or it shares first position for coverage while having a better mean length. Not surprisingly, random search tends to have worse performance than the other algorithms,

Table 6

Some results from Arcuri and Yao (2008), showing coverage and lengths obtained when evolving sequences of function calls for five separate containers, using five algorithms: random search (RS), hill-climbing (HC), simulated annealing (SA), genetic algorithm (GA), and memetic algorithm (MA)

Container	Algorithm	Mean coverage	Variance in coverage	Mean length	Variance in length
Vector	RS	85.21	1.52	56.99	7.73
	HC	100.00	0.00	47.67	1.05
	SA	99.99	0.01	45.76	1.11
	GA	99.99	0.01	46.87	1.63
	MA	100.00	0.00	47.89	2.64
LinkedList	RS	69.96	1.82	55.27	14.00
	HC	84.00	0.00	38.48	10.27
	SA	82.47	2.25	33.60	5.29
	GA	83.83	0.26	36.66	3.64
	MA	84.00	0.00	36.43	3.58
Hashtable	RS	92.92	1.17	54.45	25.97
	HC	106.00	0.00	35.25	0.19
	SA	105.84	0.74	34.98	0.77
	GA	101.14	6.50	31.10	6.31
	MA	106.00	0.00	35.01	0.01
TreeMap	RS	151.94	5.85	54.11	26.87
	HC	188.76	0.71	51.23	10.08
	SA	184.19	5.75	40.68	5.88
	GA	185.03	3.46	42.14	8.44
	MA	188.86	0.65	50.55	10.31

although it can often achieve reasonable coverage. When coverage from RS is good, however, the length of the sequence of FCs tends to be poor; this is readily understood given the nature of the “difficult” branches in testing, as also indicated above. Finally, it should be pointed out that Arcuri and Yao’s system was not able to generate inputs that could cover all branches in the CuT; for example, for pragmatic reasons, branches in private methods were not considered, while around 10% of the public methods were not directly callable.

5.3.4 On Related and Similar Work

Arcuri and Yao (2008) point out the difficulties in comparing their approach with traditional systems in software testing, including the fact that there is no common benchmark scenario, and no reasonable way to replicate the ways that other authors instrumented the software to be tested. However, they point out that traditional techniques (e.g., King 1976; Doong and Frankl 1994; Buy et al. 2000; Marinov and Khurshid 2001; Boyapati et al. 2002; Visser et al. 2004;

Xie et al. (2004, 2005) tend to have considerable challenges with scalability, and invariably rely on considerable prior effort, such as the need to generate algebraic specifications or other formal representations of the functions to be tested; this is particularly tricky when predicates are highly nonlinear, involve loops, nonlinear data types, and so forth. Arcuri and Yao's evolutionary computation-based approach, however, needs no such prior specification effort, and is applicable to any container. Meanwhile, although there are many difficulties with direct comparison with results from traditional techniques reported in the literature, the evolutionary computing approach, especially the MA, seems to have significant benefits in terms of speed. However, much further work is warranted in this field, including hybrids of natural computation and traditional approaches.

As noted by Arcuri and Yao, the use of natural computation in software testing has been gaining a research following in recent years. Other examples include Tonella (2004) who used evolutionary algorithms for generating unit tests of Java programs, while Wappler and Wegener (2006) used strongly typed genetic programming (STGP) also for testing Java programs. Seesing (2006) also investigated STGP for a similar purpose, while Liu et al. (2005) used a hybrid approach, involving ant colony optimization (see the chapter [Swarm Intelligence](#) in this volume) to optimize the sequence of function calls, and a multi-agent evolutionary algorithm to optimize the input parameters of those function calls. Meanwhile, Arcuri and Yao's research described in this section began with presenting new encoding and search operators and a dynamic search space reduction method for testing OO containers (Arcuri and Yao 2007), also testing the Estimation of Distribution Algorithms on this problem (Sagarna et al. 2007).

5.3.5 Summary Thoughts

In this section, we have seen an example of how evolutionary computation is beginning to be used in software engineering. The work focused on showed a comparison with a selection of other methods, and also discussed comparisons with standard techniques in the software engineering industry, and found advantages for the evolutionary computation approach in both scenarios. The empirical tests by Arcuri and Yao (2008) showed that their MA usually performs better than the other algorithms tried. However, there remain clear challenges for improvement (e.g., the performance on the TreeMap container was not completely satisfactory).

Arcuri and Yao conclude, based on their results as well as the related literature, that in testing the OO software, nature-inspired algorithms seem to be better than the standard techniques based on symbolic execution and state matching, since they seem able to solve more complex test problems in less time. Arcuri and Yao's work also included the unusual approach of trying to cover every branch at the same time with a single sequence. This has yet to be compared to the traditional approach of testing each branch separately.

6 Concluding Notes

A *selection* of application areas in which natural computation shows its value in real-world enterprises of various sorts has been discussed. This selection has been quite eclectic. Other authors would have chosen a different set; at another time, the same authors would have chosen a different collection. The main message we mean to convey by such statements is that, for the purposes of demonstrating the significant impact and potential of natural computation

in practice, there is certainly no shortage of documented examples that could be selected. We presented here just ten applications, ranging from specific problems to specific domains, and ranging from cases familiar to the authors to highlights known well in the general natural computation community. However, all of them share, one hopes, the property of displaying (each in their own way) a clear indication of the proven promise or great potential for the impact of nature-inspired computation in high-profile and important real-world applications. Similarly, it is hoped that these applications share the property of being inspiring to both students and practitioners; many were selected on the basis of proving particularly popular with students, in the context of getting them interested in the study of natural computation.

When designing a chapter such as this, the first problem one faces is that natural computation is almost too successful in practice. One may ask, for example, why does one not mention more from the thousands of successful real-world applications of neural computation, or fuzzy systems? Well, first of all, they have indeed just been mentioned. But second of all, the positioning of this article in the Broader Perspective part of the Handbook suggests a focus on the novel and unusual; on the less generally known, and on areas whose potential is clear, yet only beginning to be realized in practice.

Naturally, therefore, the center of gravity in this article has turned out to be evolutionary computation. Sandwiched between the more familiar, tried and tested topics of neural and fuzzy systems, and the several emerging areas of natural computation that are currently less “on the map” with application studies, evolutionary computation is a highly flexible child of natural computation that excels in displaying the promise for this field. But, in passing, we saw, in Blondie24, how different areas of nature-inspired computation collaborate to remarkable effect. We have also seen, in the aircraft maneuver study, and in the discussions of super-heuristics, how learning classifier systems – themselves inspired by the adaptive behavior of intelligent organisms – contribute toward natural computing’s expanding gallery of successes. Meanwhile, other chapters in this volume cover some of the successes of swarm intelligence, SA, artificial immune systems, and more.

The real-world value of some of the more established natural computing techniques has been proven to be unquestionably immense. It is worth pointing out that this was never anticipated in the “early days” for each individual technique. In the case of neural computation, for example, Minsky and Papert’s analysis of the capabilities of two-layer networks led (if not deliberately) to much skepticism and delay in the exploration and take-up of neural networks for pattern recognition. In evolutionary computation’s earliest days, the algorithms were usually considered as intellectual curiosities, with the occasional promising application studies considered as one-offs. There seems to be a lesson here for the promise and potential of the several less mature and emerging natural computing ideas – those discussed in this volume, as well as others. In anticipation, one waits and sees.

Abstract

Artificial life has now become a mature inter-discipline. In this contribution, its roots are traced, its key questions are raised, its main methodological tools are discussed, and finally its applications are reviewed. As part of the growing body of knowledge at the intersection between the life sciences and computing, artificial life will continue to thrive and benefit from further scientific and technical progress on both sides, the biological and the computational. It is expected to take center stage in natural computing.

1 Introduction and Historical Overview

The phrase *artificial life*, referring to a specific coherent research programme, is normally attributed to Chris Langton. He specifically applied the term as a title for the “interdisciplinary workshop on the synthesis and simulation of living systems” that he organized in September 1987, in Los Alamos, New Mexico (Langton 1989). It was then adopted for a biannual international conference series (now up to *Artificial Life XI*, held in Winchester UK, in August 2008), and alternating with the biannual *European Conference on Artificial Life* (ECAL), first held in Paris in 1991. The *Artificial Life journal* (with Langton as first Editor-in-Chief) was founded in 1993. The journal and the two conference series are now formally coordinated through the International Society for Artificial Life (ISAL) (<http://www.alife.org>), which was established in 2001.

Langton’s original announcement of the 1987 workshop defined the new field as follows:

- ▶ Artificial life is the study of artificial systems that exhibit behavior characteristic of natural living systems. This includes computer simulations, biological and chemical experiments, and purely theoretical endeavors. Processes occurring on molecular, cellular, neural, social, and evolutionary scales are subject to investigation. The ultimate goal is to extract the logical form of living systems. (Langton 1987)

It is clear that, from the outset, Langton’s vision was for a very broad, thoroughly interdisciplinary, endeavor, and indeed that is how the field has largely developed. There has been a consistent focus on using tools of computer science to model and simulate biological systems; but also a specific goal of using *synthesis* to start an exploration of the space of *possible* life. Indeed, Langton’s own first use of the phrase “artificial life” was in his paper “*Studying artificial life with cellular automata*” (Langton 1986). This was presented two years before the first artificial life workshop, at the conference *Evolution, Games, & Learning* organized by the Los Alamos Center for Non-Linear Studies (CNLS) in May 1985. In this paper, Langton was already introducing “artificial life” as a direct lineal descendant and inheritor of von Neumann’s seminal research programme, begun in the late 1940s, combining “automata theory” with problems of biological organization, self-reproduction, and the evolution of complexity (von Neumann 1949, 1951, 1966).

But while von Neumann’s influence was certainly strong, there were many other contributions and precursors to the field. The phrase “artificial life” is, in part, a deliberate play on “Artificial Intelligence” or AI. The original premise of AI, dating from Turing’s 1950 paper on “*Computing machinery and intelligence*” (Turing 1950), was that “intelligence” was an intrinsically computational or software phenomenon. It could therefore be divorced from

any particular underlying hardware implementation, including all the particular biological details of terrestrial life. By the 1980s however, after 30 years of intensive and well-resourced efforts, AI was still showing little clear progress toward its central goal of realizing human-level intelligence by means of computer programs. Indeed, as early as 1977, Popper was already declaring:

- ▶ “... computers are totally different from brains, whose function is not primarily to compute but to guide and balance an organism and help it to stay alive. It is for this reason that the first step of nature toward an intelligent mind was the creation of life, and I think that should we artificially create an intelligent mind, we would have to follow the same path. (Popper and Eccles 1977)

In 1988, the mounting challenges and criticisms of GOFAI (“good old fashioned AI” (Haugeland 1989)), were summarized in a special edition of *Daedalus*, the Journal of the American Academy of Arts and Sciences (Graubard 1988). This documented a renaissance of interest in the biological underpinnings of intelligence. Artificial life can therefore be seen as just one of the particular results of this splintering of AI, along with subsumption-architecture robotics (Brooks 1985), parallel distributed processing (Rumelhart et al. 1986) (the “new” connectionism), Neural Darwinism (Reeke and Edelman 1988; Edelman 1987), embodied intelligence (Varela et al. 1992), etc. And indeed, in some ways, artificial life continues to function as an integrative term, bridging between these more specialized and disparate research programmes.

A specific debate that artificial life has inherited from its roots in AI, is that between “weak” and “strong” forms. In the AI case, a distinction is made between the claim that an AI system provides a more or less effective *simulation* of intelligence, and the claim that it is “really” intelligent. The distinction is particularly associated with the philosopher John Searle, whose famous “Chinese Room Argument” claimed to prove that however well digital computers might simulate intelligence, computation could never be sufficient to genuinely *realize* intelligence (Searle 1980). Clearly an analogous distinction can be drawn within artificial life, between merely simulating and actually realizing “real” life (Levy 1993). In that case, it is generally focused on whether “life-like” organization, which exists only in a purely computational/virtual world, could ever properly be described as genuinely living. However, Searle’s abstract philosophical argument cannot be transferred directly into the artificial life domain as it relies on conscious introspection. Perhaps because of this, the issue has received comparatively less intense attention in this field. In any case, while much artificial life research is carried out in computational/virtual worlds, and thus might be subject to this kind of debate, it is generally considered that work in so-called wet artificial life, working *in vitro* with real chemical systems (e.g., Luisi and Varela 1989; Rasmussen et al. 2008), is certainly immune to this kind of critique.

Other significant influences and inspirations for artificial life include morphogenesis (Turing 1952), cybernetics (Wiener 1965), general systems theory (Bertalanffy 1976), mathematical/relational biology (Rashevsky 1940), theoretical biology (Waddington 1969), self-organization (Yovits and Cameron 1960), hierarchy theory (Pattee 1973), autopoiesis (Maturana and Varela 1973), and genetic and evolutionary algorithms (Fogel et al. 1966; Holland 1975; Rechenberg 1975).

A specific precursor to the modern artificial life conference series was the conference on *Automata, Languages, Development* (Lindenmayer and Rozenberg 1976) organized by Rozenberg and Lindenmayer, March–April 1975 in Noordwijkerhout, Holland. One of the

participants, Alvy Ray Smith, has subsequently commented that (<http://alvyray.com/Papers/PapersCA.htm>):

- ▶ I like to call this conference ALife0 — for Artificial Life 0 conference — since it was the first attempt I know to attempt cross-fertilization between biologists and computer scientists. Many of the players at this conference were present for ALife1, ALife2, etc [...] Other participants at ALife0 were Karel Culik, Pauline Hogeweg, John Holland, Aristid Lindenmayer, and Stanislaw Ulam.

In summary, artificial life is now a mature and well-established discipline (or “inter-discipline”) in its own right. The following sections will present the fundamental questions it is concerned with, a selection of specific theories and formalisms it relies on, and we review some applications and conclude with a discussion of the key open problems for future research.

2 Fundamental Questions

2.1 What Is (Artificial) Life?

- ▶ By extending the horizons of empirical research in biology beyond the territory currently circumscribed by life-as-we-know-it, the study of Artificial Life gives us access to the domain of life-as-it-could-be, and it is within this vastly larger domain that we must ground general theories of biology and in which we will discover practical and useful applications of biology in our engineering endeavors. (Langton 1995)

The question of “what is life?” is clearly fundamental to a discussion of the field of artificial life, as the answer (or answers) would be expected to underpin the scope, problems, methods, and results of its investigations.

The starting point is, of course, natural life, the domain of conventional biology. Historically, it was conjectured that the very distinctive properties and characteristics of natural living systems reflected a fundamental *constitutional* distinction: that living systems incorporated (or were literally “animated by”) a distinct and unique “substance” – the so-called *elan vital* that identified this class of theories as forms of *vitalism*. However, from the pioneering inorganic synthesis of urea by Wöhler in 1828 onward, vitalism progressively lost credibility. With the explosive growth of molecular understanding of basic biological mechanisms in the second half of the twentieth century (traditionally dated from the elucidation of the chemical structure of DNA in 1953), vitalism in this sense has now all but disappeared from scientific consideration. There is now a clear scientific consensus that there is no *material* distinction between the domains of living and nonliving systems; rather the differences (which are, of course, still objectively real and substantial) arise from differences in material organization.

However, it is still very much an open question as to what exactly these differences in organization *are*. Conventional molecular biology continues to make rapid progress in teasing out the detailed molecular basis for particular low-level mechanisms of operation in natural organisms; but by focusing on dismantling organisms into molecular components, these investigations, though still valuable in themselves, risk eliminating precisely the higher order organization that is distinctive of natural life. More recently, and partly in reaction to this, there has been growing interest in what is termed *systems biology*: The explicit study of how low-level molecular mechanisms are successfully integrated into higher level “systems” (Wolkenhauer 2007); and also, in *synthetic biology* that investigates the synthesis of entirely novel classes of living systems, either by manipulation of natural organisms and their components

(Smith et al. 2003; Regis 2008) or even by attempting de novo creation of life from entirely nonbiological substrates (Rasmussen 2008).

All these strands of investigation are still essentially premised on the study of existing natural life on Earth; or, as Langton puts it, “life-as-it-is” rather than “life-as-it-could-be” (Langton 1992b) (even synthetic biology, in its current state, largely relies on preexisting biological components, or close analogues of them).

By contrast, the field of artificial life, from its inception, has had a specific goal of investigating the most general possible formulations and instantiations of “living phenomenology.” In particular, it has explicitly brought to bear the possibility of creating computer-synthesized universes, or *virtual worlds*, in which even the most basic laws of “physics” or “chemistry” can be arbitrarily manipulated, in whatever ways may prove most conducive to any particular study.

Of course, this lack of hard boundaries makes “artificial life,” as a field of study, significantly ill-defined. Unlike the case for natural life, there are, as yet, no clear criteria for what virtual world phenomena should qualify as “living” or sufficiently “life-like” to legitimately count as lying within this field. In large measure, this simply reflects the continuing debate and investigation within conventional biology, of what specific organizational (as opposed to material) system characteristics are critical to properly living systems. The key advantage and innovation in artificial life is precisely that it has this freedom to vary and explore possibilities that are difficult or impossible to investigate in natural living systems. In this context, a precise definition of “life” (natural or artificial) is not a necessary, or even especially desirable condition for progress.

2.2 Hierarchy and Emergence

A specific and pervasive feature of natural life is hierarchical organization – from molecules to cells to tissues to organs to multicellular organisms to societies of organisms. Hierarchical design is also common in artificial engineered systems – for example, from semiconductor materials to logic gates to processors to computers to the Internet. At first sight, the hierarchical structure of natural living systems might be viewed as simply the natural outcome of evolutionary optimization for certain engineering benefits: modularity, standardization, ease of repair, robustness, etc. However, there are significant difficulties in such a simplistic account. In particular, evolution by natural selection must operate without foresight: So the opening up of evolutionary “potential” per se, via a new hierarchical level of organization, cannot be a direct locus for immediate selection to operate. The fundamental question here relates to the emergence and establishment of new levels of Darwinian “actors.” This is a process that has evidently occurred repeatedly in natural evolution (the origin of the first protokaryotes; the origin of the eukarotes; multicellularity, sociality, etc.); however, without circular reasoning, this cannot itself simply be assigned to a process of Darwinian selection (not, at least, at the same hierarchical level). In natural biology, this is the focus of investigation into so-called *major transitions in evolution* (Maynard Smith and Szathmáry 1997).

In the case of artificial life, while there have been some examples of model systems demonstrating some degree of emergence of hierarchical organization (e.g., Rasmussen et al. 2001b), the achievement to date has been limited, both in terms of evolutionary potential and in number of hierarchical levels, and is the subject of significant ongoing debate within the

community (Gross and McMullin 2001; Rasmussen et al. 2001a). This can be expected to be a particularly active area of continuing research (Baas 1994).

2.3 Constructive and Autopoietic Systems

A problem closely associated with emergence and hierarchy, yet somewhat distinct, is that of “self-construction” systems. Natural life, at all hierarchical levels, exhibits a characteristic ability to maintain its system organization while simultaneously turning over components at the lower hierarchical levels. Thus, a cell can stably maintain itself (and even grow and divide) while continuously regenerating all its significant molecular components (metabolizing environmental substrates as necessary); similarly, a multicellular organism maintains its organization while constantly replacing its component cells; and a social insect colony may long outlive most, if not all, of its constituent individual organisms. While this is a typical phenomenon of natural life, it is very different from the behavior of conventional engineered systems. The latter may well have complex hierarchical organization, but this organization is typically static: The system is assembled once, and then retains its fixed compositional structure for its functional lifetime. Indeed, it is typical of engineered systems that failure of any component, at any hierarchical level, will at least significantly impair system level function, and will commonly result in full system failure. Although so-called “fault-tolerant” systems may be engineered to incorporate significant redundancy, this often involves static assembly of additional components at manufacture time. Functional lifetime is extended as failing components are automatically removed from service; but once this pre-built redundancy is exhausted, system failure follows from any further component failure. Further, even such redundant systems are generally vulnerable to failures in the “failure-detecting” components that cannot also simply be duplicated without potentially entering into infinite regress.

This is a complex problem to address, but natural life provides a “proof of principle” that such self-constructing organizations are possible. Artificial life certainly offers a potentially very fruitful avenue for further investigation. In particular, artificial life allows “virtual worlds” to be formulated in which problems of self-construction can be simplified, and the core organizational mechanisms can be exposed and subjected both to mathematical analysis and experimental exploration. While a variety of work in artificial life bears on this, some of the most direct contributions might be summarized as follows:

- The Chilean biologists Maturana and Varela pioneered the abstract concept of *autopoiesis* (literally “self-production”) as a description of the core mechanism of organizational self-maintenance in biological cells (Varela et al. 1974). Almost 15 years before the modern computational study of artificial life was even named (Langton 1989), they were already using a molecular level, agent-based, abstract chemistry to give a concrete demonstration of this abstract theory of cellular organization. In essence, the proposal is that biological cells are dynamic, self-sustaining, chemical networks (an abstraction of cell metabolism), which also create and maintain a spatial boundary (an abstraction of a cell membrane), where the contained network and the boundary reciprocally rely on each other for stability. While some technical deficiencies were identified in the original presentation of this work (McMullin and Varela 1997), it has given rise to a sustained and continuing programme of active research (McMullin 2004).

- Also in the 1970s, Holland proposed the so-called α -universes (Holland 1976) and, independently, Hofstadter described the *typogenetics* system (Hofstadter 1979). Both involved one-dimensional fragments of computer code, which could interact with each other. In both cases, they were explicitly inspired by aspects of the molecular replication and translation machinery of biology, and were concerned with understanding the reflexive interactions that arise when the “same” class of entities (molecules) can sometimes function as executable “code” (enzyme/protein) and sometimes as literal “data” (nucleic acid), and the possibility of collective self-reproduction and maintenance. These were, however, restricted to theoretical/analytic treatments, and were not subject to empirical investigation until much later (McMullin 1992; Snare 1999; Kvasnicka et al. 2001).
- This same tension between syntax and semantics in materially instantiated dynamic systems is also at the core of Pattee’s analysis of what he terms “semantic closure” (Rocha 2000; Cariani 1992).
- A related, but independent line of investigation was pioneered by Kauffman and others, in the form of “collectively autocatalytic sets” (Farmer et al. 1986; Kauffman 1993). Such a set is formally similar (though more strictly defined) to the contained chemical network of an autopoietic system, but without the requirement for a self-generated spatial boundary. The key result here was the demonstration, in completely abstract virtual “chemistries” that such collectively autocatalytic sets can spontaneously arise, quickly and under relatively weak constraints on the underlying chemistry.
- Fontana and Buss self-consciously launched a mathematical and computational investigation of “constructive dynamical systems,” based around the so-called *alchemy* system (Fontana and Buss 1994). These systems deliberately diverge from the classical concept of “dynamical systems” by relaxing the normally strict demarcation between “state variable” and “dynamic law.” The authors demonstrated and analyzed a number of organizational phenomena, including forms of “self-sustaining closure” where more-or-less complex dynamic aggregates of components successfully sustain themselves, even as all the individual components are continuously diluted or degraded.
- As a comprehensive overview treatment, Dittrich et al. (2001) provide a summary of the general approach of building computational models of arbitrary “artificial chemistries,” as a platform for investigating these and other problems. More recently, Dittrich and Speroni have developed a primarily algebraic mathematical analysis in a comprehensive way, in the form of “*Chemical organisation theory*” (Dittrich and di Fenizio 2007). However, while an important advance, the difficulties of incorporating dynamics (chemical kinetics) and the interaction of chemical self-production and spatial demarcation (the self-constructed “boundary” of autopoietic theory) remain substantial.
- A quite different and more radical approach to the problem of biological self-maintenance was proposed by the theoretical biologist Robert Rosen over an extended series of works (Rosen 1959, 1972, 1985, 1991). In brief, Rosen argues that the self-constructing organization characteristic of natural living systems, which he termed “closure under efficient causation” transcends the possibilities of conventional dynamical systems in a fundamental way; with the consequence that it cannot be realized in any “computational” universe. This is a complex and contentious theoretical claim which, not surprisingly, continues to be the focus of considerable critique and criticism (e.g., Chu and Ho 2006). Rosen’s work was also a strong influence in Kampis’ development of a comprehensive mathematical treatment of what he terms “self-modifying” systems (Kampis 1991).

2.4 Complexity (and Its Growth)

- ▶ There is a concept which will be quite useful here, of which we have a certain intuitive idea, but which is vague, unscientific, and imperfect . . . I know no adequate name for it, but it is best described by calling it “complication.” It is effectivity in complication, or the potentiality to do things. I am not thinking about how involved the object is, but how involved its *purposive operations* are. In this sense, an object is of the highest degree of complexity if it can do very difficult and involved things. (von Neumann 1949, p. 78, emphasis added)

Arguably the most fundamental problem in the theory of biology is that of the growth of “complexity”; with “complexity” understood in the sense explained by von Neumann above, of the ability to do complicated things. While this is certainly an informal definition, it suffices to clearly demarcate this notion from purely syntactic, combinatorial, or computational concepts of complexity.

Von Neumann is a key figure in the early development of abstract computational modeling approaches to understanding biological phenomena; indeed, in this respect he can be considered as having instigated the earliest investigations in artificial life, as the term is now understood (McMullin 2000a). In particular, in the late 1940s, (von Neumann 1949) he started to draw attention to an apparent paradox arising from the contrast between any mechanistic (i.e., not vitalistic) understanding of living organisms and common experience of engineering artificial mechanisms or automata. While it is quite generally possible to design machines that construct other machines, this process is normally *degenerative in complexity*: a machine of a given complexity (such as an automated factory) can only construct machines of comparatively lower complexity (such as cars or phones or televisions etc.). Whereas, if the theory of Darwinian evolution is accepted, then biological “machines” (organisms) must be capable of constructing descendant machines of greater complexity. Granted, these increases in complexity may occur only in very small increments, and even then only in some lineages and accumulating over geological periods of time; but nonetheless it must be possible, in principle, for biological organisms to give rise to offspring more complex than themselves.

Von Neumann quickly developed an outline resolution of this paradox, in the abstract form of what he termed a “general constructive automaton.” This was inspired by Turing’s earlier formulation of a universal computing automaton (Turing 1936), and also by von Neumann’s own contemporaneous involvement in designing and building the earliest electronic stored program digital computers (von Neumann 1945). In essence, a general constructive automaton is a *programmable* constructor or assembler, capable of constructing an indefinitely large set of target automata – loosely, a “universal” set comprised of all automata that could be assembled from a given, finite, set of primitive components. Significantly, von Neumann hypothesized that a general constructive automaton, relative to a specific set of components, might itself be realizable as an assembly of these same components. With this conceptual architecture and some relatively minor technical elaboration, von Neumann showed that this would then give rise to an indefinitely large set of automata, spanning an indefinite large range of complexity, all of which would be fully connected by a network of heritable “mutations” (essentially, chance variations in the construction programs). That is, there would exist mutational pathways leading from the simplest to arbitrarily complex members of this set; with all these machines also, incidentally, being capable of self-reproduction. (While terminology in the field is not completely consistent, in this

chapter “(self-)reproduction” is reserved to mean this von Neumann style process, involving separate actions of copying and decoding; whereas “(self-)replication” is used to denote a process of copying only.)

In retrospect, this was already an astonishing achievement. Von Neumann effectively described the abstract architecture of biological self-reproduction, based on separate processes of syntactic copying (replication) and semantic “decoding” (translation) of a passive information carrier; he showed how this architecture supported self-reproduction, heritable mutation, and thus evolutionary growth of complexity; and he presented all these, at least in outline form, in 1948, five years before the chemical structure of DNA was even identified (von Neumann 1949).

However, as yet this was still only a sketch of a solution. To make it properly convincing, he needed to present a concrete set of “primitive parts” and show that with these, it would actually be possible to realize an example of a general constructive automaton. This proved to be a complicated and potentially intractable problem: any plausible “real world” set of components would introduce many ancillary complications – mechanics, thermodynamics, etc. Following a suggestion from Stanislaw Ulam, von Neumann instead formulated an artificial, virtual, world that would simplify away these ancillary complications. He proposed a two-dimensional “tessellation automaton,” or, as it is now called, a *cellular automaton* (see [Sect. 3.1.1](#) for a general introduction to CA). Within this simplified virtual world, von Neumann then successfully developed a fully detailed design for an example of a general constructive automaton. He had planned this as a first step in a much more general and comprehensive “theory of automata.” However, he put his unfinished manuscript aside in 1953; and due to his untimely death in 1957, was never to return to this project. The manuscript was subsequently edited by Burks and formally published in 1966 (Burks 1966).

Von Neumann’s achievement, both in theoretical insight and technical implementation, was considerable, and it gave rise to an extended program of further research. Many different cellular automata worlds have been formulated and investigated, and many variants on von Neumann’s architecture for evolvable self-reproducing automata have been demonstrated (Thatcher 1970; Codd 1968; Langton 1984b). Conway’s *Game of Life* has particularly popularized the study of life-like phenomena in cellular automata worlds (Berlekamp et al. 1982). More recently, it has become feasible to actually implement von Neumann’s original designs on real computers (Pesavento 1995).

Nonetheless, seminal as this work was, it also explicitly left certain questions still very much unresolved. In particular, as von Neumann himself was clearly aware, the mere existence of mutational pathways from simple to complex automata does not mean that evolution will actually follow such pathways. Indeed, in von Neumann’s original cellular automaton world, the embedded self-reproducing machine was extremely fragile. It could only operate successfully at all on the condition that the rest of the world was completely quiescent; and, of course, once it completes one round of reproduction, that could no longer be the case. Parent and offspring would then interfere with each other’s structure and operation, and both would rapidly disintegrate. While this problem could be superficially avoided by constraining each complete, successively constructed automaton to restrict its further operation to separate regions of the space, it rules out any possibility of natural selection; and, in any case, cannot be sustained in the long term if there is any possibility of stochastic, component level, malfunction, or failure (which itself is actually *desirable*, as a source of the random variation that is the grist to the mill of Darwinian evolution).

2.5 Coreworlds: Spontaneous Evolution of Computer Programs

- ▶ Nothing in Biology makes sense except in the light of evolution. (Dobzhansky 1973)
- ▶ Discovering how to make such self-reproducing patterns more robust so that they can evolve to increasingly more complex states is probably the central problem in the study of artificial life. (Farmer and d'A. Belin 1992)

Although the cellular automata models of von Neumann and his successors have not, to date, demonstrated extended evolutionary dynamics, various other artificial life models have addressed evolution more directly, through attempts to demonstrate evolution among populations of virtual (software) agents in virtual worlds. The most systematically investigated framework is to envisage these as small machine code programs, each executed by a separate, parallel processor, but all sharing a single main memory (“core”). Generically, these approaches can be referred to as *coreworlds*. In principle, the parallelism could be implemented directly with a sufficiently large pool of hardware processing elements, dynamically allocated as agents are created or destroyed; but it is typically just realized with conventional timeslice-based multithreading of a much smaller pool of hardware CPUs (often just one).

The earliest work adopting this methodological approach can be traced to the seminal investigations of Nils Barricelli, carried out between 1953 and 1963 (Barricelli 1957, 1963). In fact, this work was carried out on the original computer designed and built at the Princeton Institute for Advanced Studies (IAS) between 1946 and 1952 under the direction of von Neumann. Barricelli was a visitor to the institute at von Neumann’s invitation; and took the opportunity to conduct an investigation of the role of “symbiogenesis” in the origin of life. He programmed the IAS computer to directly model patterns of numbers that could interact with each other within a circular array (effectively the main memory system of the machine), according to some fixed local rules. This is conceptually similar to a one-dimensional cellular automaton. Although these patterns of numbers did not have the general computing ability of Turing machines, Barricelli demonstrated the existence of patterns that could self-replicate, as well as various forms of competitive and cooperative (symbiotic) interaction between patterns. Somewhat strangely, in his published description of this work, Barricelli only obliquely related it to von Neumann’s own contemporary work on self-reproducing and evolving automata. In any case, the insight and innovation of this work was not widely recognized at the time, and has only recently been properly reinstated through George Dyson’s investigations of the early history of digital computing at the IAS (Dyson 1997, 1998).

The first attempt to study the dynamics of competition among co-resident *general purpose programs* in a shared memory was pioneered by Vysotsky et al. at Bell Labs in the early 1960s (though not published until 1972), and appears to have been independent of Barricelli’s study (Vysotsky 1972). This was effectively created as a form of computer programming game in which different programmers provided hand-coded programs, which were then instantiated in a common core, and executed to see which would survive longest. Again, self-replication was a key feature. An interesting aspect was that, unlike almost all later work, these programs were implemented in the native (IBM 7090) machine code, rather than in a virtual machine code to be executed by an interpreter. This allowed comparatively much higher execution speed, but with some associated limitations. For example, as programs could not be written to be position independent, successful self-replication required active relocation processing, as opposed to simple self-copying. In this early implementation, a “lethal” program was relatively quickly developed by R.H. Morris, and the original game was put aside.

The α -universes described by Holland in the mid-1970s (Holland 1976) may again be mentioned here. Although formulated independently, and with quite different motivations, this proposal was somewhat similar to the Vyssotsky system. In particular, it again envisaged an essentially linear core memory inhabited by concurrently executing fragments of computer code. However, in other ways this was actually much closer to Barricelli's work in that the specific intention was to investigate the spontaneous emergence of crude collective self-reproduction activity, rather than simple competition between programs pre-coded by human programmers; but, in any case, as already mentioned in [Sect. 2.3](#), this system was not experimentally investigated until much later (McMullin 1992).

The more direct descendent of the Vyssotsky system was the *Core War* game, developed by Dewdney and others in the early 1980s. This now relied on an interpreter and offered much more varied gameplay opportunities (Dewdney 1984). Following the establishment of an international tournament (Dewdney 1987), *Core War* has had a sustained following, and remains active to this day (<http://corewars.org/>).

Although the *Core War* framework is predicated on the idea of human programmers coding the competing programs, it does also naturally lead to the question of whether, under conditions of potential mutation during self-replication, there could be an autonomous and sustained evolutionary process, not relying on programmer intervention. This was explicitly studied by Rasmussen et al. in a system they called the *coreworld* (Rasmussen et al. 1990). In this instantiation, however, the system suffered from a similar limitation to that of the von Neumann style cellular automata systems. While the world could be seeded with an initial self-replicating program, as its offspring filled up the core they quickly began overwriting each other and the self-replicating functionality and thus the potential for sustained Darwinian evolution was lost. This issue was addressed by Ray, in the *Tierra* system, developed and investigated in the early 1990s (Ray 1992). *Tierra* was based on the idea of competing and interacting self-replicating programs in a shared core memory. Programs were now given an ability to employ "memory protection" to limit overwriting by other programs. On its own, this would simply lead to the core filling with programs once, and then no further self-replication (much less evolution) would be possible. To overcome this, Ray added a mechanism for random removal of programs (the so-called "reaper"). This addition allowed for continuing self-replication and the possibility for longer term evolution. He also adopted a significantly different instruction set, incorporating a biologically inspired "template" addressing mode. With these innovations, Ray was able to demonstrate an extended process of evolution, with multiple episodes of Darwinian natural selection. The system produced a surprising array of evolutionary phenomena, including optimization of program length, obligate parasitism, and facultative "hyper-parasitism" (as a defense against obligate parasites).

Tierra has led to a wide variety of related work, such as:

- The *Avida* system of Adami and Brown that introduced a more conventional 2-D spatial world in which programs would colonize nodes, and also be evaluated for their ability to complete extrinsically defined computing tasks (Adami and Brown 1994).
- A proposed extension to *Tierra* into a multiprocessor networked environment ultimately to be distributed across the wider Internet, under suitable "sandbox" execution controls (Ray 1995).
- *Nanopond* (<http://adam.ierymenko.name/nanopond.shtml>), a highly simplified implementation of a 2-D spatial "program evolution" system, drawing on elements of both *Tierra* and *Avida*, but implemented in less than 1,000 lines of C source code.

- The *Amoeba* system, developed by Pargellis, which specifically demonstrated the possibility of spontaneous emergence of a self-replicating program in coreworld-like systems (Pargellis 2001).

Evolution in coreworlds can also usefully be compared and contrasted with several other related but divergent research fields and investigations:

- There has been a separate line of research into the logic of so-called *Quine* programs. These are defined as computer programs that produce their own source code as output. The original discussion is generally credited to Bratley and Millo (1972), though the term “Quine program” is usually attributed to Hofstadter (1979). The existence of Quine programs in general-purpose programming languages essentially follows from Kleene’s recursion theorem. But while the formulation of specific Quine programs in different languages has been a hobby among programmers, these programs have not generally been embedded within an execution environment in which exponential growth, Darwinian selection, and evolution could actually take place. It has not therefore, particularly influenced research approaches in artificial life. That said, through its definitional restriction to programs that must self-reproduce without having direct access to self-inspection, the study of Quine programs draws attention to the logical distinction between proper von Neumann style genetic “self-reproduction” and the “self-replication” by copying normally adopted in coreworlds. It is, in fact, a very open question as to what the effect of this architectural choice is on evolutionary potential (McMullin et al. 2001).
- The replication and propagation of programs in controlled coreworld environments obviously also lead to the idea of self-replicating programs propagating in open, networked, computer environments. This is the realm of computer malware – computer viruses, worms, etc. And indeed, this connection was explicitly made by Dewdney already in the immediate aftermath of the Morris Internet worm incident in 1988 (Dewdney 1989). However, while malware development certainly involves an arms race between the human developers on both sides, there is to date no evidence of effective *autonomous* evolution of “free-living” malware.
- There is significant overlap in inspiration between evolution in coreworld-like systems, and work in evolutionary algorithms, and, especially, *genetic programming* (GP) (Koza 1992; Willis et al. 1997; Banzhaf et al. 1998). This, in turn, has a long history extending back at least to Samuel’s late 1950s investigations in machine learning (Samuel 1959). However, the major distinction is that GP is generally driven, directly or indirectly, by an externally provided evaluation function (used as an extrinsic “fitness” to drive an imposed evolutionary algorithm) rather than the coreworld approach, which is to investigate spontaneous autonomous evolutionary dynamics, in which the software agents are responsible for their own replication and relative fitness emerges from their bottom-up ecological interactions.
- Investigations into the evolution of cooperation by Axelrod and others should also be mentioned here (Axelrod 1984, 1987). Although not generally using a coreworld-like framework, and focused on a relatively narrowly defined pattern of interaction (the iterated prisoner’s dilemma), using an extrinsically applied genetic algorithm, this examination of the problem of cooperation, and coevolution between “cooperating” and “defecting” strategies has been very influential in the wider fields of political science, ecology, and complexity theory.

To summarize, the general experience of the investigation to date of evolution in core-world-like systems is that the evolutionary potential of these systems is interesting but still strictly limited. Indeed, they can be viewed as formally similar to pure artificial “replicator chemistries,” comparable to the systems already mentioned in [Sect. 2.3](#) above, and exhibiting similar phenomena of collective autocatalytic closure and self-maintenance (McMullin [2000b](#)). Thus, both von Neumann-style genetic self-reproduction in cellular automaton worlds, and replication by simple copying or self-inspection in coreworlds, naturally lead directly into the problems of biological robustness, self-maintenance, and hierarchical organization already discussed above. The integration of self-reproducing or self-replicating programs with self-maintenance and individuation (autopoiesis), and the demonstration of sustained evolutionary growth of complexity in a purely virtual world remains perhaps the key “grand challenge” problem in the field of artificial life.

3 Theory of and Formalisms in Artificial Life

A number of formalisms have been effective and widely used in artificial life systems. Among them are cellular automata, rewriting systems, and complex dynamical systems. Other formalisms have been used to analyze artificial life systems, like network analysis. In this section, the most important synthetic and analytic tools will be described.

3.1 Automata

The theory of abstract automata defines finite state automata as behavioral models of machines that possess a finite number of states, a set of transitions between those states, and machine actions (such as “read input” or “write output”). Based on this notion, an entire field in computer science (automata theory) has been formulated, which addresses their mathematical features and the use of these entities. One variant of automata of particular relevance to artificial life are cellular automata.

3.1.1 Cellular Automata

A cellular automaton (CA) is composed of a large interconnected collection of component finite state automata. These possess, besides states and transitions, an additional feature, a location within a neighborhood, often constituted as a grid. The neighboring “cells” (although the word “cell” here gives rise to the term “cellular automaton,” note that it is *not* being used with its specifically biological sense; it rather just means a discrete, spatially demarcated, component of a larger, static, locally interconnected, array) or “nodes”, which are themselves finite state automata with a different location, receive the state of the particular automaton as input, and also, reciprocally, provide their own states as inputs that inform a particular automaton which state transition to realize. CA are typically defined to be structurally homogenous, that is all cells contain the same finite state automaton and all share the same local neighborhood pattern. Of course, cell *states* vary dynamically in time and across the cells of the automaton; and it is such spatiotemporal patterns of states that are used to represent so-called *embedded* machines or automata. Such a model can thus be used to model spatially extended systems and study their dynamical behavior. CA have also been used as a modeling

tool to capture behavior otherwise modeled by partial differential equations (PDEs); and indeed can be regarded as a discrete time, discrete space, analogue of PDEs.

Cellular automata play a particularly useful role, in that they possess the twin features of being applicable for synthesis of system behavior, and for analysis of system behavior. They have been thoroughly examined in one-dimensional and two-dimensional contexts (Wolfram 1986, 1994), and have been considered in the fundamental contexts of computability (Wolfram 1984) and parallel computing (Toffoli and Margolus 1987; Hillis 1989).

As mentioned previously (❸ Sect. 2.4), von Neumann, following a suggestion of Ulam, originally introduced CAs as a basis to formulate his system of self-reproducing and evolvable machines. The von Neumann CA was two dimensional with 29 states per cell. According to Kemeny, von Neumann's core design for a genetically self-reproducing automaton would have occupied a configuration of about 200,000 cells (a size dominated by the "genome" component, which would stretch for a linear distance of about 150,000 cells) (Kemeny 1955, p. 66).

In fact, von Neumann's contributions stand at the cradle of the field of artificial life by showing, for the first time, a mathematical proof that an abstract "machine-like" entity can be conceptualized, which can construct itself, with that copy being able to achieve the same feat in turn, while also having the possibility of undergoing heritable mutations that can support incremental growth in complexity. This was a breakthrough showing that above a certain threshold complexity of an entity, this entity is constructionally powerful enough not only to reproduce itself (and thus maintain that level of complexity) but to seed a process of indefinite complexity growth.

While von Neumann achieved this result in principle, a large number of scientists have since succeeded in pushing down the complexity threshold. In the meantime, much simpler CAs (with smaller number of states per cell) have been shown to support self-reproducing configurations, many of those as 2D loops (Langton 1984; Sipper 1998). In fact, the smallest currently known example in this form is a cellular automaton with eight states per cell where the self-reproducing configuration is of size five cells (Reggia et al. 1993). However, in many of these cases, the core von Neumann requirement to embody a "general constructive automaton" in the self-reproducing configuration has been relaxed: So the potential for evolutionary growth of complexity is correspondingly impoverished.

Cellular automata also have been used in the design of the Game of Life (Gardner 1970, 1971), which draws inspiration from real life in that replication and transformation of moving entities, again in a 2D CA, were observed (for a comprehensive introduction, see Berlekamp et al. (1982) and Conway's Game of Life, <http://en.wikipedia.org/wiki/conway> and online resources therein).

The discrete nature of states, space, and time available in cellular automata has led to a number of applications of these tools, many of which could be considered artificial life applications in the widest sense. For example, the patterning of seashells has been modeled using discrete embodiments of nonlinear reaction-diffusion systems (Meinhardt 2003). Scientists in Urban Planning have started to use the tool of cellular automata to model urban spread (White and Engelen 1993).

3.2 Rewriting Systems

Rewriting systems are a very general class of formal systems in mathematics, computer science, and logic, in which rules for replacing formal (sub)structures with others are

repeatedly applied. Rewriting systems come in many forms, such as term rewriting, string rewriting, equation rewriting, graph rewriting, among others, and have been at the foundation of programming languages in computer science and automated deduction in mathematics. String rewriting systems, first considered by Axel Thue in the early part of the twentieth century (Dershowitz and Jouannaud 1990; Book and Otto 1993), have a close relationship with Chomsky's formal grammars (Salomaa 1973). Many rewriting systems have the goal of transforming particular expressions into a normalized form, deemed to be stable in some sense. Prior to reaching this stable form from a starting expression, the rewriting process goes through a series of transient expressions. For example, mathematical equations can be formally rewritten until they reach a form in which it is possible to read off solutions.

It can be seen, therefore, that rewriting allows a sort of dynamics of symbolic systems. It is worth noting that rewriting systems provide the basis for the λ -calculus (Barendegt 1984), which has been used to implement artificial chemistries.

In a more general artificial life context, transformations based on rewriting systems can be used to describe growth and developmental processes. For example, besides transforming complex expressions into normal form, another approach uses rewriting to generate complex objects from simple start objects. This has provided the formal basis to studies of biological development through what were later called L-systems (Lindenmayer 1968). The difference between L-systems simulating growth and development and formal grammars lies in the order of rewriting. While formal grammars consider rewriting in a sequential fashion, L-systems consider parallel (simultaneous) rewriting, much closer to the asynchrony of the growth of real cells. But central to all these models is the recursive nature of rewriting systems (Herman et al. 1975). Lindenmayer and, later, Prusinkiewicz and Lindenmayer (1990) have pioneered the use of turtle commands of computer languages like LOGO to visualize plant patterning and growth.

P-systems (Paun 1998; Paun and Rozenberg 2002) are a more complex class of rewriting systems used in artificial life. They are similar to artificial chemistries in that production of symbolic chemicals is prescribed by reaction rules that could also be considered as rewriting rules. In addition to reactions, however, P-systems contain membranes, which limit the availability and direct the flow of material. This provides a higher-level means of structuring environments, something artificial chemistries with well-stirred reactions are unable to do (Dittrich et al. 2001).

In the meantime, a large number of applications of rewriting systems have appeared. For example, such classical artificial life systems as *Tierra* have been reformulated as rewriting systems (Sugiura et al. 2003); Giavitto et al. (2004) describe applications of rewriting systems in modeling biological systems, and virtual cities have been modeled with the help of L-systems (Kato et al. 1998), just to name three examples.

3.3 Dynamical Systems Modeling with ODE

Artificial life systems are often couched in terms of the mathematical language of dynamical systems, captured by ordinary differential equations. This formalism is used for describing the continuous change of state of a system via the change in time of n quantified state variables $\mathbf{q}(t)=\{q_1(t), q_2(t), \dots, q_n(t)\}$. A very simple and linear example of a dynamical system is a system

consisting of two-state variables q_1, q_2 , which develop according to the following differential equation

$$\frac{dq_1}{dt} = a_{11}q_1 + a_{12}q_2 \quad (1)$$

$$\frac{dq_2}{dt} = a_{21}q_1 + a_{22}q_2 \quad (2)$$

Coefficients a_{11}, \dots can be lumped together into a matrix A , and the stability of the dynamical system can be examined based on a solution to the equation $d\mathbf{q}/dt = A \times \mathbf{q}(t) = \mathbf{0}$.

3.3.1 Nonlinear Dynamical Systems

More interesting than this basic dynamical system are those which provide for nonlinear interactions between components and the environment. This can be achieved by higher order terms in the coupling of state variables. For instance

$$\frac{dq_1}{dt} = a_{11}q_1 + a_{12}q_2^2 \quad (3)$$

$$\frac{dq_2}{dt} = a_{21}q_1^2 + a_{22}q_2 \quad (4)$$

would already provide such an example.

Chaotic Systems

Nonlinear couplings are the hallmark of chaotic systems, as nonlinearities in the coupling of state variables tend to amplify small fluctuations (e.g., noise in state variables) into large global state changes. Of course, all these depend on the size of the fluctuations. It is well known that as long as fluctuations are small relative to the strength of nonlinear interactions, systems act in quasi-linear mode and can be formally linearized. However, once either the fluctuation signal is big enough, or the nonlinear interactions become stronger, systems tend to behave in less predictable ways, for example, start oscillating, and might even transit into a chaotic regime characterized by short-term predictability and long-term unpredictability (Argyris et al. 1994). In the artificial life community, the notion of chaos has played an important role as the extreme case of unpredictability beyond life, much as the predictability of dead matter lies at the other end of the spectrum. This notion was first developed in the context of cellular automata (Langton 1992a), but later extended to other systems.

Constructive Systems

Dynamical systems can be extended by considering a notion of change in the number of state variables. For instance, if each of the variables characterizes the concentration of a chemical substance, and some of the substances are consumed or produced for the first time, this can be captured by changing the number and/or assignment of state variables. Simulation might proceed by alternating between a low-level simulation of, for example, individuals of species, and high-level events that signal the birth or extinction of a particular species (Ratze et al. 2007). While couched here in ecological terms, the same approaches apply to the substances of artificial chemistries. Constructive dynamical systems are an active area of research whose exploration has barely begun.

3.4 Complex Systems

The relation between complex systems and artificial life is complicated. Some might argue that artificial life is a subfield of complex systems. This opinion draws from the argument, valid in both complex systems research and artificial life, that these kinds of systems work by producing emergent effects through the interaction of many entities. As such, living systems (and their artificial counterparts) are complex systems, but not the only ones, since, for instance, societies, economies, or legal and norm systems might legitimately be called complex systems too. On the other hand, one might argue that if systems like societies or economies are behaving as complex systems, making use of emergent phenomena and top-down causation, they really can be considered to be alive. If that argument is followed it could be stated that complex systems are part of the research in artificial life.

In this section, it is preferred not to resolve this tension, but rather to focus on one area of research that one legitimately can consider as at the intersection of the two: networks. Networks and their associated formalisms are peculiar since they provide evidence for a phenomenon frequently seen in artificial life systems, as well as in complex systems: There is no easy way to dissect these systems into cause and effect relationships. Indeed, networks allow us to formalize the concept that causes and associated effects have a many-to-many relationship.

If a simple cause–effect relationship is visualized as an edge between two nodes or vertices in a graph, while the nodes themselves symbolize the entities that might or might not be in these relationships, one can easily see that networks, with nodes of in-degree and out-degree larger than one will be able to capture multiple cause–multiple effect relationships. This is a key characteristic of complex systems, as opposed to simple systems, where simple pathways exist between causes and their associated effects.

3.5 Networks

The recent surge in network research (Albert and Barabasi 2002) can be attributed to the realization that networks are the quintessential structure to capture emergent phenomena. Without network infrastructure, emergent behavior of a system would be transient and very quickly disappear, like fluctuations. It is when a network infrastructure is in place that originally weak and transient signals of emergence can be captured and stabilized into identifiable phenomena.

Network studies have revealed widespread characteristics in complex systems, such as small-world features or scale-free connectivity (Watts 1999; Strogatz 2001) that have been ascribed to the generation or evolution of these networks. The dynamics of network evolution is an active area of research (Dorogovtsev and Mendes 2003).

But even the much simpler formalisms of static networks provide useful insights into complex systems and artificial life systems, because there is a deep relationship between autocatalytic sets (Farmer et al. 1986) and closed paths on networks, which in mathematical terms is the result of a connection between graph theory and algebra. Networks can be formally represented by directed graphs $G = G(N, E)$, defined by the set of N nodes and the set of E edges or connections between those nodes. Edges or links between nodes are often represented by an ordered pair of nodes, called the connectivity matrix. If connections are only present or absent, symbolized by a “0” or “1” entry in the matrix, this is called the adjacency matrix A of a graph G . The adjacency matrix has a set of eigenvalues and eigenvectors, which can be easily computed by solving the characteristic equation of A : $|A - \lambda I| = 0$, where λ are

eigenvalues of A and I is the unit matrix. Given that A is a nonnegative matrix, the Perron–Frobenius theorem states that the largest eigenvalue λ_1 of A is real. If this eigenvalue is $\lambda_1 \geq 1$, then there exists a closed path through the graph (Rothblum 1975). Closed paths are deeply related to autocatalytic sets, which were first introduced in chemical systems where each sort of molecules present is catalyzed by at least one other sort of molecules (Eigen 1971). This relation would be considered equivalent to an edge in the graph of all molecular sorts (nodes). Autocatalytic sets correspond therefore to closed paths in that graph.

In the wider context of a theory of organizations (Fontana and Buss 1994; Speroni di Fenizio et al. 2000), autocatalytic sets or closed and self-maintaining sets (organizations) are the key to life-like processes, in that they maintain whatever structure or organization has come into existence. This is the core of the previous statement that emergent phenomena need the stabilizing infrastructure of a network (and its closed paths) to move from the status of a fluctuation in a system to that of an identifiable phenomenon.

The deep connections between algebra and graph theory indicated here would merit a much more detailed discussion, yet space is a constraint here. Suffice it to say that networks are the stage for a dynamics of the chemical (or otherwise) sorts of agents symbolized by the nodes. Thus, it can be said that a dynamical system can be imposed on these networks, and once this dynamics starts to interact with the structure of the network, the most interesting phenomena will be observed (Jain and Krishna 2001).

3.6 Other Formalism

The list of formalisms discussed here is not exhaustive. For instance, the area of statistical mechanics has also contributed valuable insights into artificial life (see, e.g., Adami 1998). Category theory, chemical organisation theory, and other approaches can also be legitimately mentioned as contributing to our understanding of artificial life phenomena.

4 Applications

A huge number of applications can be considered to make use of artificial life techniques in the wider sense (Kim and Cho 2006). It is difficult to even list these applications comprehensively. Instead, a few applications have been selected here to demonstrate the width of the applicability of its concepts.

4.1 Biology

The most obvious application of artificial life is in biology. It was already noted that there is a close relation between artificial life models and synthetic biology (Ray 1994) and that artificial life models in fact are a useful tool for the exploration of questions in biology (Taylor and Jefferson 1994). For a more recent example, see Strand et al. (2002).

4.1.1 Synthetic Biology

The current state of synthetic biology does not acknowledge this connection extensively, despite, historically speaking, emerging from artificial life research. Key questions in this

area today are, how to generate biological entities (cells, proteins, genes, organisms) that have some purposefully designed function (Ferber 2004). The question how systems function that can be ascribed to be “living” has been separated off into the field of “systems biology,” another newcomer to biology with inheritance from artificial life (Kitano 2002). Artificial life was always concerned with “Life as it could be,” that is, alternative designs that can be termed living, designed for a purpose (as engineers would do), or for scientific inquiry, and it was following systems thinking long before systems biology was established (Langton 1997).

4.1.2 Health/Medicine

The modern health-care system is so complex now, that complex systems thinking and ideas from artificial life are ripe for application (Plsek and Greenhalgh 2001). This will entail the understanding of system behavior and response to attempted changes, financial issues such as exploding health-care costs and redesign of the system to become more adaptive.

Medicine has long benefited from its relation to biology, which will result in new applications for artificial life methods as well (Coffey 1998; Hamarneh et al. 2009). Notably, regenerative medicine will be the beneficiary of model systems provided by artificial life (Semple et al. 2005).

4.1.3 Environmental Science and Ecology

In environmental science, the *Gaia* theory (Lovelock 1989) has benefited from simulations provided by artificial life models (Gracias et al. 1997; Downing 2000; Lenton 2002). Artificial life approaches have been used to design sustainable architecture, at least on a local level (Magnoli et al. 2002). In the design of other systems, for example, for recycling, artificial life models have been successfully applied (Okuhara et al. 2003).

Ecosystem research in general has made use of artificial life models, from the setting up of “artificial ecosystems” whose behavior can then be explored in the computer (Lindgren and Nordahl 1994) to the examination of characteristics necessary to provide opportunity for ecosystem formation (Wilkinson 2003). Further, artificial life models have been applied to questions of astrobiology (Centler et al. 2003), another offshoot with some roots in artificial life research.

4.2 Engineering

A number of applications in the engineering subdisciplines have been examined, with autonomous robotics being a very prominent one.

4.2.1 Autonomous Robotics

While it is natural to expect artificial life to contribute to biology, its contribution to the field of engineering is less to be expected. But given the tight connection between behavior and autonomous robotics, it is perhaps less a surprise. In fact, an entire conference series has been

termed “from animals to animats” (Meyer and Wilson 1991; Asada et al. 1998), carrying with it the notion of machines that behave adaptively. Recent reviews and summaries of autonomous robotics as the field pertains to artificial life can be found in Eaton and Collins (2009), Harvey et al. (2005), and Pfeifer et al. (2005).

Often, emergence of behavior or functionality is studied in behaving artifacts like robots, using the bottom-up principles of artificial life. Notably, the interaction of software or hardware parts of robots can be assumed to be closely influenced by artificial life thinking. For instance, the subsumption architecture of Brooks (1990, 1991) has been a closely studied subject in the interaction of behavioral modules. Different sorts of swarm-like behavior (Reynolds 1987; Bonabeau et al. 1999) and, more recently, specifically constructed swarms-bots on the hardware side (Mondada et al. 2004; Groß et al. 2006) have been studied extensively.

Finally, groups of robots cooperating as social robots, and interacting and cooperating with each other, have been studied (Fong et al. 2003). All these applications emphasize the real-world character of robotics problems, and the embodiment of agents (Steels and Brooks 1995).

4.2.2 Transport

Traffic and our societies’ transportation systems are collective systems of an enormous complexity. Their modeling, simulation, and design stand to win substantially from new biological principles (Lucic and Teodorovic 2002; Wang and Tang 2004). Notably, principles gleaned from the organization of insect societies (Deneubourg et al. 1994), and from insect behavior (Theraulaz and Bonabeau 1999), that even give rise to new optimization algorithms (Dorigo and Stützle 2004), are relevant here.

Artificial life applications are not restricted to the movement of physical objects on roads, but are also widespread in other infrastructure networks, such as communication networks (Tanner et al. 2005), notably the Internet (Prokopenko et al. 2005). Early on, it was already proposed to consider computer viruses as a form of artificial life (Dewdney 1989; Spafford 1994) spreading in these communication networks (Bedau 2003).

Already there is a large number of engineering applications for artificial life, but this number is only bound to grow over the coming years (Ronald and Sipper 2000). The reader is referred to (Kim and Cho 2006) for a recent overview of artificial life in engineering.

4.3 Computer Graphics, Virtual Worlds, and Games

Terzopoulos (1999) has summarized a number of applications of artificial life in computer graphics.

4.3.1 Computer Graphics

In particular, Sims’ work is worth mentioning (Sims 1991, 1994). He used virtual organisms that coevolved in competition with each other to demonstrate the power of artificial evolutionary systems for developing naturally looking moving behavior. Terzopoulos built animated systems resembling simulated (“artificial”) fishes, again studying locomotion (Terzopoulos et al. 1994).

The breve visualization environment (Klein 2002) offers a very natural way to interact with artificial life simulations (Spector et al. 2005).

In general, the aim of these tools is animation of agents equipped with virtual sensors and actors, in a life-like fashion (Miranda et al. 2001; Conde and Thalmann 2004). This development was able to close the gap to games (Maes 1995; Reynolds 1999; Rabin 2002).

4.3.2 Virtual Worlds

Magnenat-Thalmann and Thalmann (1994) provide an early overview of how artificial life ideas could be put to use in creating virtual worlds. One key idea, also found in other application areas, is to make use of unpredictability in the form of random events, as they are also present in the real world of life through mutation and chance encounters. This line of inquiry is continued with further work on multi-sensor integration in virtual environments, see, for example, Conde and Thalmann (2004). The more complex the inner workings of agents are, and the more complex the environment is providing stimuli, the more intelligence is required to allow for realistic simulations. Aylett et al. discuss the connection between an adaptive environment and the intelligence of the agents/avatars populating it (Aylett and Luck 2000).

More recently, artificial life virtual worlds have been put to use in social scenarios, such as urban environments. For instance, Shao and Terzopoulos (2007) integrate motor, perceptual, behavioral, and cognitive components in a model of pedestrian behavior. Building on Reynolds (1987, 1999), this allows much more realistic simulation of multi-individual interactions in complex urban settings than was possible previously. An entire area, crowd simulation has now emerged using these techniques (Lee et al. 2007).

Virtual worlds are bound to expand enormously in the future, and artificial life applications will continue to proliferate.

4.3.3 Games

Artificial life helped to grow the area of (evolutionary) game theory (Alexander 2003; Gintis 2009) and provided valuable insights into more traditional board games (Pollack et al. 1997). But its most notable and unique success is in areas where traditional games have not been able to contribute much: multiuser games, distributed over the Internet.

One now classical example, and one of the earliest games that made headlines and really was a commercial success for some time, was Steve Grand's game "Creatures" (Grand et al. 1996). The idea behind this game was very simple: Evolution through breeding of creatures using genomes of characteristics that could be combined in multiple ways. By exchanging creatures over the Internet, a multiuser sphere was created setting in motion something akin to real evolution, with implicit fitness, not controlled by any central agency (Grand 2001). Prior to this commercial application, Ray's Tierra was distributed over the net in a large experiment (Ray 1998).

4.4 Art

The connection between artificial life and art can be easily seen when considering applications in computer graphics. However, there is a much deeper connection, having to do with

creativity and surprise, which is one of the hallmarks of evolutionary systems that, like artificial life, concern themselves with emergent phenomena. A discussion of these connections is provided in Whitelaw (2004). In a 1998 special section of the journal *Leonardo* (Rinaldo 1998), the connection was examined from various viewpoints. Bentley and Corne (2002) and references therein look at creative processes from an evolutionary perspective, which might be argued to be a superset of artificial life approaches. Arts applications range from painting (Todd and Latham 1992, 1994) (even painting by robots (Moura 2004)) via video installations to sculpture (Baljko and Tenhaaf 2006). Creativity is also considered in the area of sound generation and music (Bilotta and Pantano 2002; Berry and Dahlstedt 2003). Again, artificial life work is often put together with evolutionary work in composition (Romero and Machado 2007).

4.5 Artificial Societies and Artificial Economies

Agent-based modeling using artificial life ideas has also been applied to formulate systems best described as artificial societies and artificial economies.

The area of artificial societies was spawned by the seminal work of Axtell and Epstein (Epstein and Axtell 1996), which used the idea of bottom-up effects in social systems to generate models of social systems that could be simulated in a computer. These ideas have been further developed by Epstein (2007). Social simulation in general (Gilbert and Troitzsch 2005) has now moved to center stage in the social sciences, and a new journal has been established to examine artificial societies (<http://jasss.soc.surrey.ac.uk/JASSS.html>). In the context of social science, emergence (Goldspink and Kay 2007) and learning (Gilbert et al. 2006) have become important topics of discussion.

These very same techniques can also be applied to markets, at which point an artificial society mutates into an artificial economy (Zenobia et al. 2008). The formulation of economies as complex adaptive systems is already somewhat older, and Kaufmann (1993) points out models of economies based on ideas of evolution of complex systems. The power of these ideas lies in their natural ability to treat nonequilibrium phenomena, a topic for the most part carefully avoided by many traditional economists, since it would have to be based on nonlinear systems (Arthur 2006). Recently, another subfield of artificial life, artificial chemistries, have been applied to model economies (Straatman et al. 2008).

5 Conclusion

As we have seen in this chapter, artificial life is a vivid research area, spawning interesting research directions, and providing inspiration for a large number of applications. While the boundaries of the area are fuzzy, there is no doubt that over its 20 years of existence as a named field, artificial life has exerted substantial influence on a whole number of other research areas.

To judge the perspectives of a field, it is perhaps best to focus on its main objectives. The proposal of Bedau (Bedau et al. 2001; Bedau 2003) is followed and slightly changed in dividing the central goals of artificial life into three broad thrusts, all posited here as questions:

- (A) What is the origin of life, or how does life arise from the nonliving?
- (B) What are the potentials and limits of living systems?
- (C) How does life relate to intelligence, culture, society, and human artifacts?

These questions belong to the most challenging and most fascinating in all of science today. From each of these questions derives an entire research programme within artificial life that can be formulated with a non-comprehensive number of tasks:

- (A1) Generate a molecular proto-organism *in vitro*.
- (A2) Achieve the transition to life in an artificial chemistry *in silico*.
- (A3) Determine the threshold of “minimal” life in the organic world *in vivo*.
- (A4) Determine whether fundamentally novel living organizations can arise from inanimate matter.
- (A5) Simulate a unicellular organism over its entire life-cycle.
- (B1) Determine what is inevitable in the open-ended evolution of life.
- (B2) Establish a set of mechanisms for the generation of novelty and innovation.
- (B3) Determine minimal conditions for evolutionary transitions from specific to generic response systems.
- (B4) Create a formal framework for synthesizing dynamical hierarchies at all scales.
- (B5) Determine the predictability of evolutionary manipulations of organisms, ecosystems, and other living systems.
- (B6) Develop a theory of information processing, information flow, and information generation for evolving systems.
- (C1) Explain how rules and symbols are generated from physical dynamics in living systems.
- (C2) Demonstrate the emergence of intelligence and mind in an artificial living system.
- (C3) Evaluate the influence of machines on the next major evolutionary transition of life.
- (C4) Provide predictive models of artificial economies and artificial societies.
- (C5) Provide a quantitative model of the interplay between cultural and biological evolution.
- (C6) Establish ethical principles for artificial life.

Inasmuch as life constitutes a large part of the natural world, artificial life will constitute a large part and exert heavy influence on the area of natural computing discussed in this handbook.

Acknowledgments

WB would like to thank the Canadian Natural Science and Engineering Research Council (NSERC) for providing continuous operating funding since 2003 under current contract RGPIN 283304-07. Abstract

The convergence between computer science and biology occurred in successive waves involving deeper and deeper concepts of computing. The current situation makes computer science a suitable candidate to become a philosophical foundation for systems biology with the same importance as mathematics, chemistry, and physics. Systems biology is a complex and expanding applicative domain that can open completely new avenues of research in computing and eventually help it become a natural, quantitative science. This chapter highlights the benefits of relying on an algorithmic approach to model, simulate, and analyze biological systems. The key techniques surveyed are related to programming languages and concurrency theory as they are the main tools to express in an executable form the key feature of computing: algorithms and the coupling executor/execution of descriptions. The concentration here is on conceptual tools that are also supported by computational platforms, thus making them suitable candidates to tackle real problems.

1 Introduction

Computing and biology have been converging for the past two decades, but with a vision of computing as a service to biology that has propelled bioinformatics. This field addresses structural and static aspects of biology and produced databases, patterns of manipulation and comparison, searching tools and data mining techniques (Spengler 2000; Roos 2001). The most relevant success has been the Human Genome Project that was made possible by the selection of the right language abstraction for representing DNA (a language over a 4-character alphabet) (Searls 2002).

In biology, there is now a heightened interest in system dynamics for interpreting living organisms as information manipulators (Hood and Galas 2003) and moving toward systems biology (Kitano 2002). There is no general agreement on a definition of systems biology, but whatever definition one selects, it must embrace at least four characterizing concepts, as systems biology transitions in the following ways:

1. From qualitative biology toward a quantitative science. Often, biological phenomena are explained through textual descriptions and sometimes cartoons that highlight the interaction of components without any quantitative information. Furthermore, the cartoons are superpositions of different snapshots of the interconnection network of biological elements that vary over time. As a consequence, temporal ordering of events is also not easily retrievable.
2. From reductionism to system-level understanding of biological phenomena. Biology has mainly studied single components of systems following the idea that by putting together the knowledge on the single components the system behavior would also have been elucidated. The emergent behavior due to interaction of subsystems makes the unravelling of the system dynamics impossible.
3. From structural, static descriptions to functional, dynamic properties. The list of components and their three-dimensional structure coupled with the description of their chemical and physical properties does not allow one to infer the way in which those components operate in context. A focus on the interactions (dynamics) is needed from the very beginning of the studies.

4. From descriptive biology to mechanistic/causal biology. Although some attempts to model the dynamics of systems exist (and hence partially move in the right direction with respect to item 3 above), most of the approaches hide within mathematical variables the elementary, mechanistic steps that a system performs to accomplish a goal. As a consequence, it is very difficult to disentangle the causality of events that govern the evolution of a system.

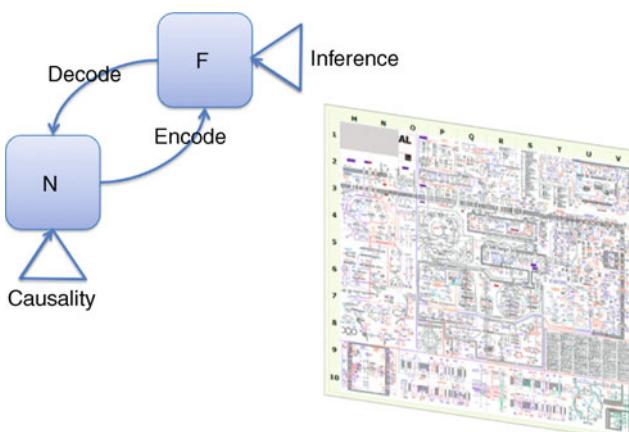

The above features highlight that causality between events, temporal ordering of interactions, and spatial distribution of components, within the reference volume of the system at hand, are becoming essential. This poses new challenges to describe the step-by-step mechanistic behavior that enables phenotypical phenomena, a behavior that both bioinformatics and classical mathematical modeling do not address (Cassman et al. 2005).

The complexity of studying the behavior of whole systems, rather than small isolated parts, calls for a stronger formalization of biological concepts that allows one to automatically manipulate biological knowledge. Therefore, the role of modeling becomes an essential and integral part of the new discipline of systems biology. The metabolic network represented in the right part of Fig. 1 is an illuminating example that informal reasoning cannot provide reasonable outcomes. Models can no longer be simple cartoons like the ones found in biology textbooks and cannot be equations, because they hide both the mechanistic behavior of systems and the inherent concurrency of biology in representations that are too abstract.

Rosen's description of modeling (left part of Fig. 1) perfectly fits the situation (Rosen 1998) as well as his statement "I have been, and remain, entirely committed to the idea that modeling is the essence of science..." Nature is governed by causal laws that make systems vary over time and space. The complexity of real systems makes it impossible to study and analyze them directly. Abstractions are mandatory to encode into a formal system, the relevant characteristics needed to study the properties of the real system in which one is interested. One then uses the formal system corresponding to the abstract representation to perform inferences and proofs of properties. In this way one derives some knowledge that is only true in

Fig. 1

Left Rosen's representation of the relationships between nature and formal models. Right: a graphical representation of a metabolic network.

the abstract world; one then needs to *decode* the findings and reinterpret them in the natural world by establishing a precise coupling between inference and causality. However, this is exactly what computer science has been doing since its early days, by using algorithms and semantics of programming languages, to ensure strong and coherent coupling of phenomena at different levels of abstraction. Therefore, algorithms and formal specification languages are suitable candidates to address the modeling challenges of systems biology.

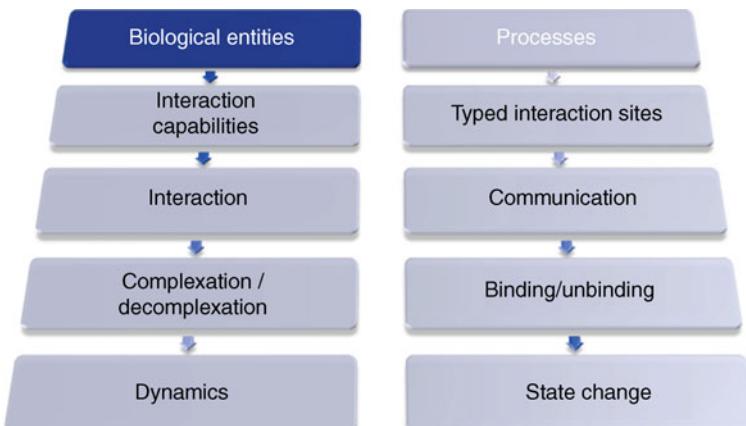

Algorithms expressed by computing languages are a conceptual tool (Wing 2006) that helps elucidate fundamental biological principles by forcing modelers/biologists to think about the mechanisms governing the behavior of the system under question at the right level of abstraction. Since the dynamics of biological systems are mainly driven by quantities such as concentrations, temperatures, gradients, etc., one must clearly focus on quantitative algorithms and languages, that is, the selection mechanism of the next step is determined according to probabilistic/temporal distributions. These distributions allow one to model the kinetics (speed) of interactions that is determined by the chemical and physical quantities listed above. Furthermore, algorithms can help in coherently extracting and organizing general biological principles that underlie the huge amount of data produced by high-throughput technologies, thus producing knowledge from information (data).

Algorithms need a syntax to be described and a semantics to be associated with the descriptions of their intended meaning so that an executor can precisely perform the steps needed to implement the algorithms with no ambiguity. In this way, one is entering the realm of programming languages from both a theoretical and practical perspective.

The use of programming languages to model biological systems is an emerging field that enhances current modeling capabilities (richness of aspects that can be described as well as user-friendliness, compositability and reusability of models) (Priami and Quaglia 2004). The metaphor that inspires this (see ▶ Fig. 2) is one where biological entities are represented as programs being executed simultaneously and the interaction of two entities is represented by the exchange of a message between the programs representing those entities in the

Fig. 2

The metaphor underlying algorithmic systems biology. The left column represents biological objects and their properties and capabilities, while the right column represents the corresponding computer science concepts.

model (Regev and Shapiro 2003). Note that interaction capabilities could also be represented with untyped interfaces or simply through channel names as in most approaches. However, the typing information separates the names used to communicate/interact between entities and the information on the shapes/types of the active domains/receptors that de facto determine the sensitivity or affinity between entities. Therefore, the modeling process is much closer to the natural behavior of systems and helps the modeler think in terms of the fundamental blocks of biological systems. The biological entities involved in the biological process and the corresponding programs in the abstract model are in a 1:1 correspondence, thus coping by construction with the combinatorial explosion of variables needed in the mathematical approach to describe the entire set of states through which a single component can pass.

The simultaneity of the execution of programs requires one to take concurrency into account. Concurrency must not be considered a tool to improve the performance of sequential programming languages and architectures, which is the standard practice in most actual cases. Concurrency is the key concept that permits the execution of algorithms to exhibit the emergent behavior produced at system level by the set of local interactions between components without the need to specify it from the beginning. This aspect is crucial for the predictive power of this approach.

Some programming languages that address concurrency as a core primitive issue and aim at modeling biological systems are emerging, for example, Welch and Barnes (2005) and Dematté et al. (2008b), from the field of process calculi (Bergstra et al. 2001). These concurrent programming languages are suitable candidates to easily and efficiently express the mechanistic rules that propel algorithmic systems biology (Priami 2009). Therefore, it seems natural to check whether the programming and analysis techniques, developed for computer networks and their formal theories, could bring new light to biology when suitably adapted. Note that process calculi are not the only theoretical ground for algorithmic systems biology. Petri nets, logic, rewriting systems, and membrane computing are other relevant examples of formal methods applied to systems biology (for a collection of tutorials see Bernardo et al. (2008) as well as the other chapters of this book). Other approaches that are more closely related to software design principles are the adaptation of UML to biological issues (see www.biouml.org) and statecharts (Harel 2007). Finally, cellular automata (Gutowitz 1990) need to be considered as well with their game of life.

Scalability is an issue for systems biology. Design principles of large software systems can help in developing an algorithmic discipline for systems biology in order to move from toy examples to real case studies. A library of biological components can be easily built and used to derive models of large systems that are ready to be simulated and analyzed just by composing the available modules (Dematté et al. 2008a). Note that here we refer to shallow compositionality (de Alfaro et al. 2001) (i.e., syntactic composition of modules) and hence the well-known problem of composing stochastic semantics does not affect the definition of libraries.

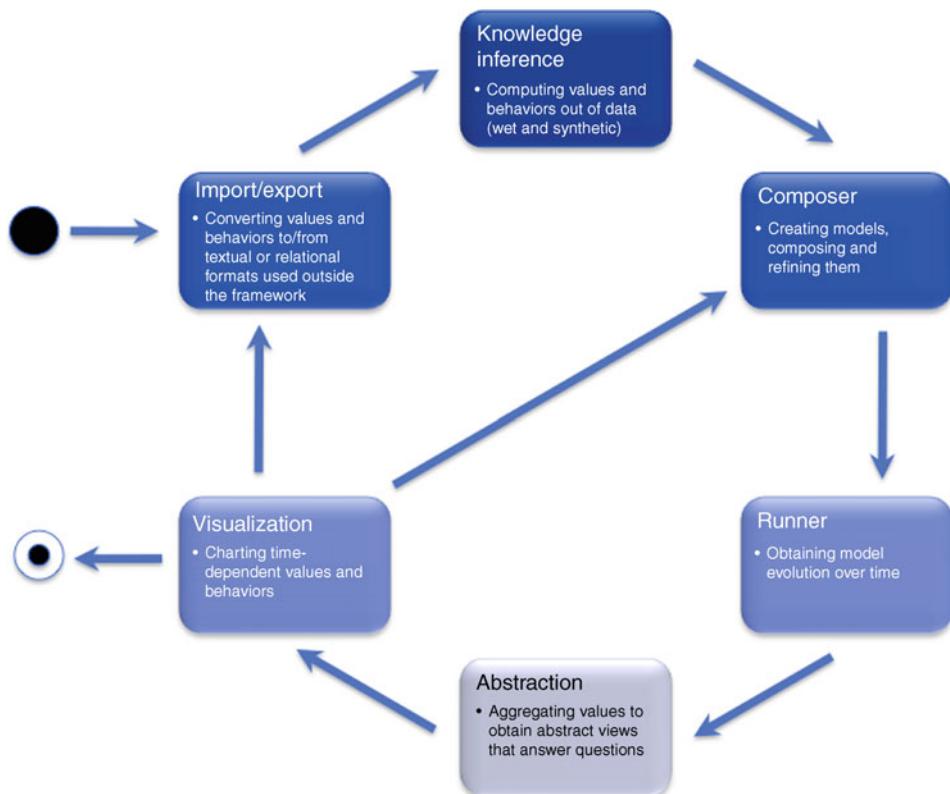

Algorithmic systems biology raises novel issues in computing by stepping away from qualitative descriptions, typical of programming languages, toward a new quantitative computing so that it can fully become an experimental science, as advocated in Denning (2007), that is suitable to support systems biology. This would also foster the move toward a simulation-based science that is needed to address the larger and larger dimensions and complexity of scientific questions and available data. Algorithmic systems biology fully adopts the main assets of computer science: hierarchical, systematic, and algorithmic (computational) thinking and creativity in modeling, programming, and innovating.

1.1 Organization of the Chapter

The organization of the chapter follows a high-level schematic workflow of how models and experiments can be tightly integrated in the algorithmic systems biology vision (see [Fig. 3](#)). The next section deals with modeling languages derived from process calculi, which are described in the chapter [Process Calculi, Systems Biology and Artificial Chemistry](#) of this handbook. The modeling language is the core component of the composer in [Fig. 3](#). In order to feed models with quantitative information needed to drive simulations, [Sect. 3](#) discusses knowledge inference. Then, in [Sect. 4](#) the simulation of models is addressed and the features of a computational platform are described. These aspects are part of the runner box in the figure that mainly relates to the quantitative implementation of the modeling language. The same section also discusses the post-processing of data obtained from the execution of biological models and shows how to infer new hypotheses to restart the workflow. The key activities of post-processing are collected in the boxes *Abstraction* and *Visualization* in the figure.

Fig. 3

A typical workflow for algorithmic systems biology. All boxes contain examples of the activities that can be performed. (Figure prepared by Ivan Mura.)

2 Model Specification

The main challenges for building algorithmic models for the system-level understanding of biological processes include the relationship between low-level local interactions and emergent high-level global behavior; the partial knowledge of the systems under investigation; the multilevel and multi-scale representations in time, space, and size; the causal relations between interactions and the context-awareness of the inner components. Therefore, the modeling formalisms that are candidates to propel algorithmic systems biology should be complementary to and interoperable with mathematical modeling; be algorithmic and quantitative; be interaction-driven, compositional, scalable, and modular; address parallelism and complexity; and express causality.

Most of the issues above are naturally addressed by process calculi (see the chapter ➤ [Process Calculi, Systems Biology and Artificial Chemistry](#)), and therefore the concentration here is on the conceptual and computational platforms developed from that theoretical foundation. The brief history of this field is recalled by grouping the modeling languages into three different generations. The first two are described in the chapter ➤ [Process Calculi, Systems Biology and Artificial Chemistry](#) and the details are not entered into, but their limitations highlighted to model real biological systems in a composable and scalable manner. Guerriero et al. (2008) is referred to for a survey of process calculi applied to biology and here stochastic π -calculus (Priami 1995; Priami et al. 2001) and beta-binders (Priami and Quaglia 2004) are considered as representatives of the two generations of calculi. Then BlenX is examined as an example of the last generation of modeling languages.

2.1 First Generation of Calculi for Biology

For a long time, the only calculus equipped with a quantitative implementation to model and simulate biological systems has been the stochastic π -calculus. This calculus attracted the interest of many researchers and has been used in a variety of case studies that show the feasibility of the programming language approach to model biological systems. Although successful in proving the potential of process calculi, the stochastic π -calculus suffers from some limitations in modeling biology. In fact, it was designed to model and analyze the performance of computer networks and hence it is strictly tuned to computer science. As a matter of fact, many tricks are needed to encode biology, and some natural primitives to describe common biological phenomena are missing.

According to the metaphor, biological entities are represented by π -calculus processes (hereafter for simplicity modeling proteins and their interactions are assumed). Proteins are characterized by functional units called domains. For instance, a protein P with three domains (D_1 , D_2 , and D_3) can be represented by three processes with the same names as the corresponding domains that are glued together to form a process P representing the protein. The π -calculus has no primitive to model physical attachment of sub-processes into larger processes, and therefore it uses the scope of names to identify boundaries. Intuitively it is assumed that the three domains share a secret (a private name) that states that they are bound together to form a protein. Thus, the protein can be modeled as $P = (\text{vx})(D_1|D_2|D_3)$, where (vx) is the declaration of the new name x with scope of the process P . The behavior of P is determined by the parallel composition of its domains and the shape or physical boundaries of P are determined by the backbone channel x that is shared only by the domains.

The scope of the channel determines the physical boundaries of the biological entities. Real biological systems contain multiple copies of the same protein; since concentrations of species affect the selection mechanism of the next action to be performed in a stochastic simulation, multiplicity is modeled through parallel composition yielding $MultiP = P|..|P$. Finally, a system contains multiple species so that it ends up in $Sys = MultiP|MultiP_1|..|MultiP_n$.

The processes encoding the domains implicitly describe the interaction capabilities of the protein through the names used in their syntactic definition. Recall that the π -calculus communications are determined by complementary actions (send “!” and receive “?”) performed on the very same channel name that must be shared between the partners of the interaction. For instance, if $D_3 = a!y.D'_3$, the protein P can interact with all the other entities that are willing to perform an input on the shared channel a , for example, the protein Q made up of the single domain $D_4 = a?w.Q'_4$.

If the interaction of two proteins has to form a complex, the attachment must be programmed through communication of private names so that the scope of the communicated name is changed to include the two proteins. According to the interpretation of the scope of private names as boundaries of physical objects, one has to dynamically manipulate the scope to create and destroy different complexes during the execution. For instance, if one considers the system $((vx)(vy)P)|Q$ after the interaction of D_3 and D_4 , the new system will be $(vy)((vx)(D_1|D_2|D'_3)|D'_4)$. The residual of protein P and the residual of protein Q after the interaction share the private name y that P sent and made available to Q ; therefore, they are interpreted as being physically attached. The detachment of the proteins must be programmed as well by opening the scope of the name y . For instance, if $D'_4 = z!y.D'_4$ and it performs the output of the private name with no other process willing to perform the input on the channel z , the resulting system no longer has a restriction on the name y , which becomes available to the whole system and hence the two proteins detach.

Note that both interaction and complexation are based on a key-lock mechanism of affinity. In fact, the partners of a reaction must share the same channel and must perform synchronous complementary operations on it. Real biology does not work in the same manner. Interaction can happen even if the shape of the active domains that are going to react are not exactly complementary to one another. Hence, a given domain can interact with different strengths and probabilities with whole families of partially complementary domains. In order to model this in π -calculus-like formalisms, one must explicitly write the whole set of alternatives relying on the choice operator in the processes. For instance, if the domain D_3 can interact with n different domains, one should specify it within the protein as $P = (vx)(D_1|D_2|a_1!y.D'_3 + \dots + a_n!y.D'_3)$. Furthermore, any complementary domain must contain a receive operation on the very same channel a_i representing the compatibility between the two entities.

The main limitations (listed below) of the π -calculus family formalisms stem from the fact that these calculi have been designed for artificial, known computer systems that can interact only when the port and addresses of the partners are perfectly and exactly known. Furthermore, the identity of the programs is not an issue in computer science, in which it is enough to ensure a global behavior as described by the algorithms to be implemented.

Processes. The same syntactical concept is used to model many different biological entities at different levels of abstraction, such as domains, proteins, and whole systems.

Restriction. A primitive intended to declare names and identify their scope is used to represent compartments, membranes, and complexes.

Complex/Decomplex. Creation and destruction of complexes of biological entities is not a primitive operation, but shows up from the interplay of private names and the variation of their scopes through open and close operations. It must be programmed through particular classes of communications. A further confusion that arises in this class of calculi is that channel names are used both to define the boundaries of complexes as well as to manipulate the structure of programs. A characterization of the minimal set of primitives needed to model this phenomena is discussed in Cardelli and Zavattaro (2008).

Low-level programming. The reversibility of reactions as well as the complementarity of complexation and decomplexation must be programmed through communication and name passing. The very same structure of communications determines the network of interaction of the biological entities. In other words, one needs to specify all the arcs of the network through a complementary pair of send and receive on the same channel rather than inferring it from the sensitivity or affinity of interaction of entities as it happens in biology.

Interaction. The interaction of biological entities can occur only if the entities share the very same channel name. This implies a perfect key-lock mechanism of interaction that is not realistic in the biological domain. In fact, the interaction can happen with different strengths or probabilities depending on the complementarity of the active domains and on the concentration of the entities in the reaction volume. The non-key-lock mechanism must be coded; in case of complexation/decomplexation, one also needs to program all the reversible interactions for all the different channels representing the different shapes that can create interactions.

Incremental model building. Most of the information related to the interconnection structure of the entities and on the sensitivity/affinity of interaction is hard-coded into the syntax of the processes through the send/receive pairs. This means that whenever new knowledge, for example, on the capability of interaction of entities, is discovered, a new piece of code must be produced and distributed in various parts of the specification that are not well identified. As a consequence, incremental model building is strongly affected with a negative impact on the scalability of the approach. In fact, the compositional modeling style of all the calculi used so far in the biological context is simply a way of structuring a description of a system by identifying sub-systems that run in parallel rather than a true scalable and compositional methodology.

Identity of entities. Biological entities—for example, proteins—can take on different states during their lifetime depending on the interactions in which they participate. One of the main criticisms of the mathematical modeling of these phenomena is that a new variable is needed for any different state of the same biological entity, thus causing to the well-known combinatorial explosion of the variables and consequently equations. The very reason here is that no identity of the considered entities is maintained in the model. In the π -calculus-like approach, the identity of entities in the initial description can coincide with the processes to which names can be assigned. However, during the execution of the programs, prefixes are consumed and the identity is lost as well.

Implementation. Stochastic simulation selects the action to be performed considering the number of equal entities in the system at a given time (e.g., the number of proteins P). If one assumes that entities are represented by processes, one has to count all the pieces of programs that represent the same object. Due to name passing and the naming of channels in general, it could be that two syntactically different programs represent the very same semantic object, and, hence, the same entity. The technical tool used to address this

equivalence is commonly known in the process algebra field as structural congruence. Efficiency in computing is therefore mandatory because it must be done at any step of computation and it is not so immediate for π -calculus. Indeed the entities change their structure after any execution step and their number is then continuously changing. This is due to the fact that processes can be created and updated dynamically. Efficiency in the execution of models is also fundamental due to the large size of the real biological systems. Parallel implementation of algorithms for running models written with process calculi are not available at this stage.

Qualitative versus quantitative descriptions. Biology is mainly driven by quantities, whereas process calculi are usually qualitative descriptions of behavior. Stochastic process calculi handle the kinetics of systems by associating channel names with rates identifying exponential distributions. Most of the time, the kinetic parameters for real biological interactions are not known and must be estimated to fit some phenotypical behavior that is measurable experimentally. Therefore, mixing quantitative and qualitative information imposes the modeler to rewrite the model or to heavily work on it in order to carry out parameter estimation and sensitivity analysis. Furthermore, limiting the description of kinetics to exponential distribution may cause all the high-level abstractions like (such as Hill-functions or even more complex dynamics that are used in mathematical modeling) to explode into elementary steps in order to hide unknown details within models. Unfortunately, most of the time the details to explode these macro-processes are not available and makes it difficult to apply the approach.

Space. Many biological phenomena are highly sensitive to the localization within the reference system volume of the reactants. There is an extremely limited and difficult to manage notion of space, and it must be hard-coded in the language.

Connection with standards. A very limited and preliminary activity is emerging to connect process calculi with SBML (see e.g., Eccher and Priami (2006)). No interoperability between computational tools is available.

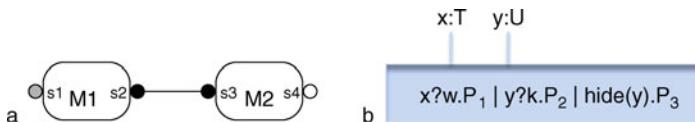

Predictive models. Most of the previous items and the introductory description show how any possible dynamic of the modeled system must be coded in the specification. This means that execution can provide the user with different paths due to different selection of alternatives or different temporal ordering of concurrent events, but all the observed action has been created by the modeler and explicitly programmed. Consequently, the predictive power of the models is limited, although it can still provide much more information on the dynamics of systems and their mechanistic behavior than classical ODE-based mathematical modeling.

2.2 Second Generation of Calculi for Biology

The second generation of process calculi directly defined to model biological systems improved the easiness of expressing basic biological principles considerably. The most representative languages are the κ -calculus (Danos and Laneve 2004) and beta-binders (Priami and Quaglia 2004, 2005) because they are equipped with computational platforms to execute specifications and are innovative with respect to many other extensions of process calculi. The main step ahead is the clear 1:1 correspondence between biological entities and objects of these calculi (see  Fig. 4). Although an entity can occur in several different states, this

Fig. 4

κ -calculus (a) and beta-binders (b) maintain the identity of biological entities by relying on boxes with interfaces that describe the interaction capabilities of the modeled entities. Besides the 1:1 correspondence between biological components and boxes specified in the model, there is also a 1:1 correspondence between functional activities of domains and interfaces (binders). The interfaces of the boxes in the κ -calculus are identified by unique names written within the boxes. Interfaces can be either bound (s_2, s_3), visible (s_4) or hidden (s_1). Protein complexes are formed by joining interfaces through arcs. The rule-based manipulation of systems simply creates, deletes, and changes links, thus manipulating complexes. The interfaces of beta-binders boxes have unique names that act as binders for their occurrences within the box (x, y). The names of the interfaces are equipped with types (T, U) over which a compatibility of interaction is defined, thus relaxing the exact complementarity of actions over the same channel name to allow interactions. The boxes of beta-binders contain a π -calculus like description of their internal behavior. Primitives to manipulate the state of the interfaces that can be active/visible or hidden are provided (see the *hide* primitive in the figure that makes a visible interface hidden).

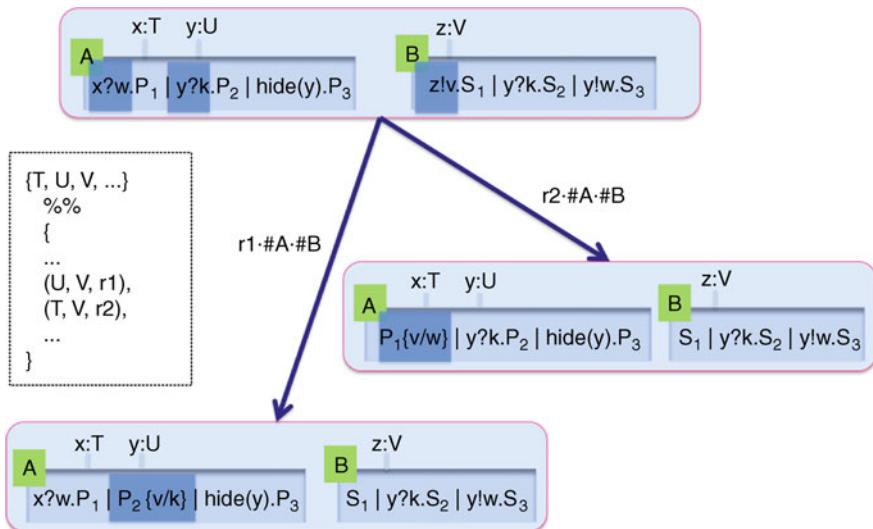

generation of calculi introduces well-defined syntactic boundaries that allow one to group all the states of an entity into single objects. This makes it easier to count and trace the behavior of the modeled entities. Furthermore, the whole set of states through which an entity can pass are implicitly encoded in the program describing the internal behavior of objects, rather than being all listed explicitly and represented with different placeholders, for example, variables in ODEs. Finally, note that other calculi have been defined as well (Cardelli 2005; Regev et al. 2004).

κ -calculus is a formal, rule-based calculus of protein interactions. It was conceived to represent complexation and decomplexation of proteins, using the concept of shared names to represent bonds. The units of κ -calculus are proteins, and operators are meant to represent creation and division of protein complexes. Once the initial system has been specified and the basic reductions have been fixed, the behavior of the system is obtained by rewriting it. This kind of reduction resembles pathway activation. Although this calculus has the merit of being directly inspired by biology, it does not offer a natural support for managing the evolution of compartments. Furthermore, the whole set of possible reactions must be specified since the beginning, so that the predictive power of the models is limited as in the previous generation of calculi.

Beta-binders are strongly inspired by both π -calculus and biological examples. They associate biological entities with boxes. Interaction is still communication-based and can occur either within a box if the same channel name is used or between different boxes if they have compatible interfaces (even if they have different names and hence the interaction is over different channel names). In fact, typed interfaces of boxes enable promiscuity of interaction (sensitivity/affinity versus complementarity). For an example, please see Fig. 5. Note that types here do not play the same role played by names in π -calculus. In fact, the same type can be compatible with many different types, thus allowing interaction over different channels and between different boxes.

Fig. 5

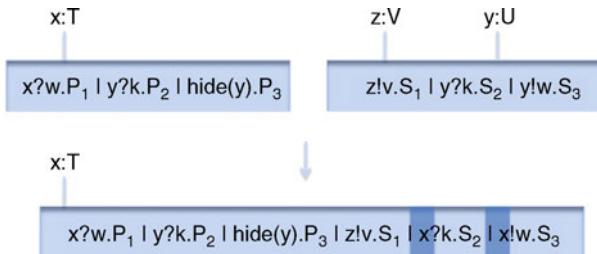

The communication between boxes in beta-binders occurs when there are interfaces with compatible types over which one box is willing to output a value and another box is willing to receive a value. For instance, the box A is willing to receive both on its interfaces $x : T$ and $y : U$, while the box B is willing to send a value v over its interface $z : V$. In a separate file, the compatibility between types is specified by inserting a tuple for any pair of types one wants to be compatible. For instance, the tuple $(U, V, r1)$ means that interfaces with types U and V can interact, and the kinetic of the interaction is specified by a rate $r1$. According to the specified compatibilities and the actions enabled over the corresponding interfaces, the two transitions depicted in the figure can occur independently of the channel names used to specify the send and receive operations. Since the compatibility also specifies the rate of the interaction, the actual rate of the transitions is computed taking into account the number of molecules available in the system ($\#A$ and $\#B$).

The enclosing surfaces (boxes) of entities cannot be nested and maintain a strict correspondence between processes and biological entities. Primitives to manipulate interfaces can be included in the description of the internal behavior of boxes. Finally, the physical rearrangement of boxes is implemented by defining completely general special split and join functions that operate on the structure of boxes and that are not inserted in the flow of control. This choice enables a higher level of nondeterminism with respect to any calculus defined so far, and better accommodates the specification of systems for which there is a considerable lack of knowledge. In fact, one does not need to completely specify, in the flow of control, the merging or division of boxes as it happens in other approaches, but one only needs to specify general conditions on the structure and on the status of the binders of boxes that enables the corresponding joining and splitting. Furthermore, the higher level of nondeterminism enhances the predictive power of models because the modeler does not have to specify the whole set of reactions from the beginning; they are instead computed by the run-time of the language. For an example, please see [Fig. 6](#).

Fig. 6

The figure shows an example of join of two boxes. The join function returns the list of binders of the new box as well as two renaming functions to change the names of the parallel composition of the original boxes to adapt them to the new binders. The function *comp* defines the affinity between the types *T* and *U* and the notation $\beta(x : T)$ denotes an interface (binder) named *x* with type *T*.

$$f_{\text{join}} = \lambda B_1 B_2 Q_1 Q_2. \text{if} [B_1 = \beta(x:T)B_1^* \text{ and } B_2 = \beta(y:U)B_2^* \text{ and } \text{comp}(T,U)] \\ \text{then } (B_1, \sigma_{\text{id}}, \{x/y\}) \text{ else nothing}$$

Although κ -calculus and beta-binders solve many of the problems identified at the end of the previous section for the first generation of calculi, they still suffer from some drawbacks listed below. (Here one uses the same categories used in the previous section, and those not listed are no longer considered an issue; the ones introduced here refer to issues raised by the second generation of calculi that were not present in the previous generation.)

Complex/Decomplex. κ -calculus provides the best support for manipulating complexes. The main limitation is that the rules for creating complexes and manipulating them must all be specified by the modeler on the basis of the structure of the boxes. No support is provided by the implementation of the language to automatically compute the steps to be performed for this fundamental mechanism of biological interaction.

Low-level programming. Almost nothing is changed on this item with respect to the previous generation of calculi. The only improvement is that the interaction network can be implicitly modeled in beta-binders by adequately defining the compatibility function between types.

Interaction. The key-lock mechanism of interaction is relaxed in beta-binders, while it is hidden in the complexation and decomplexation rules of κ -calculus.

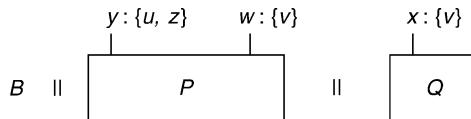

Incremental model building. The identification of entities with boxes in both calculi makes the extension of models easier because the parts of the specifications to be changed are clearly identified.

Implementation. The association between boxes and biological entities simplifies the implementation of the stochastic simulation algorithms. However, the efficiency is still not acceptable and no parallel implementation is available. Furthermore, the generality of split and join functions of beta-binders poses further difficulties to efficiently implement the calculus.

Qualitative versus quantitative descriptions. The most enhanced calculus of the second generation are beta-binders that decouple qualitative descriptions from quantitative ones. In fact, rates are no more merged with the qualitative descriptions, but are externally specified through the compatibility function between the types of the interfaces (see also Fig. 5). However, complex kinetics function cannot yet be incorporated within the models.

Fig. 7

The box enclosing Q acts as a sub-compartment of the other box in the figure. In fact, the binder x can only interact with the binder w assuming that the type v does not occur in any other place in the system. Therefore, the box enclosing Q can only interact internally or with its father compartment through x .

Space. Some preliminary attempt to code compartments and hence implicitly handle localization of molecules is emerging, but very limited computational support is available. For an example, see [Fig. 7](#).

Connection with standards. The situation is still the same as the previous generation of calculi.

Only limited activities have been performed (Ciocchetta et al. 2008b).

Predictive models. Something in this direction is obtained by beta-binders as a result of the higher level of nondeterminism within this calculus. However, the predictive capabilities of models specified through calculi are not yet satisfactory. In other words, one is only slightly ahead of ODEs.

Although the second generation of calculi improve the usage and scalability of the models, some relevant issues remain unresolved and no interoperability with mathematical modeling, (for example, ODEs) is available.

2.3 From Theoretical Calculi to Practical Modeling Languages

The very last step in the design of modeling formalisms is moving from theoretical calculi to real programming languages designed for biology. The most relevant platforms emerged from the two calculi discussed in the previous section. The BlenX (Dematté et al. 2008b) language inspired by beta-binders is considered here as an example, because it also incorporates the complex/decomplex features of κ -calculus. BlenX collects all features now available within modeling environments based on process calculi (see [Fig. 8](#)). Alternative efforts of BioPEPA (Ciocchetta and Hillston 2008) and BIOCHAM (see <http://contraintes.inria.fr/BIOCHAM/>) are also mentioned.

The driving principle to move from theoretical descriptions to practical modeling languages is sure to enrich the syntax of the calculi to facilitate the modeling process. This step must be performed by separating concerns as much as possible—that is, by keeping qualitative and quantitative descriptions distinct as well as using different syntactic categories and semantic actions to represent different fundamental biological principles. Finally, the run-time of the language should take into account, as much as possible, the basic dynamic principles of biological systems, like complexation and decomplexation. It would be useful to specify the minimum information that is needed to infer the dynamic interactions between entities.

The dynamic behavior of BlenX models is specified through three classes of actions:

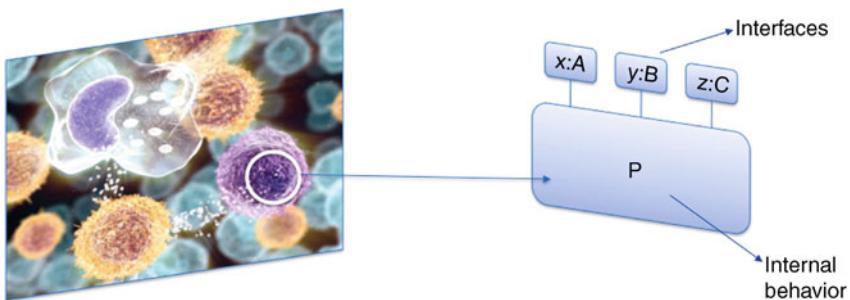

Monomolecular: actions that describe the evolution of single entities (see [Fig. 9](#))

Bimolecular: actions that involve two or more entities (see [Fig. 5](#))

Events: global rewriting rules of the environment that manipulate a set of entities as well as their structure (see [Fig. 10](#))

Fig. 8

BlenX is still based on boxes that are associated with biological entities. Boxes have typed and uniquely named interfaces and their internal behavior is specified similarly to beta-binders, although a richer set of primitives to manipulate interfaces is available and the restriction operator is no longer present, thus simplifying the theoretical development. The dynamics of systems are specified through three classes of actions: monomolecular, bimolecular, and events. Monomolecular actions affect a single box and can be either internal communications or internal primitives like *die* to destroy a box or interface manipulations. Bimolecular actions affect two or more boxes and can be either communications between boxes or complex/decomplex operations. Events are actions that are enabled when global conditions on the structure and cardinality of boxes are satisfied.

**Fig. 9**

BlenX provides many primitives to manipulate interfaces. Represented in the figure is the *expose* that creates a new interface on a box by ensuring that the name *x* is new (note the renaming to avoid clashes), the complementary actions of hiding and unhiding interfaces. There is also a primitive to let time pass without performing anything significant (*delay*) even if the time causes the choice between the alternatives to be performed. There are other two primitives not represented in the figure: *change(x:W)*, which alters the type of an interface named *x* to *W*, and *die*, which kills a box.

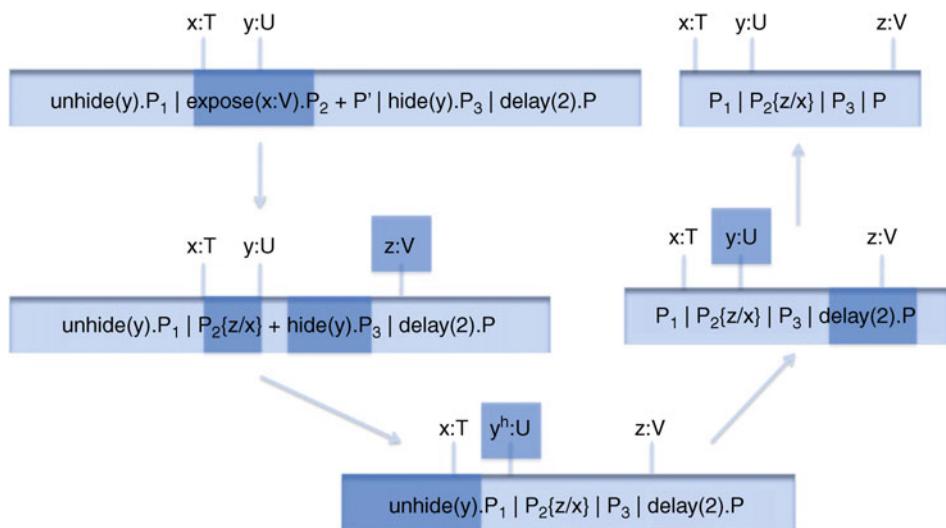

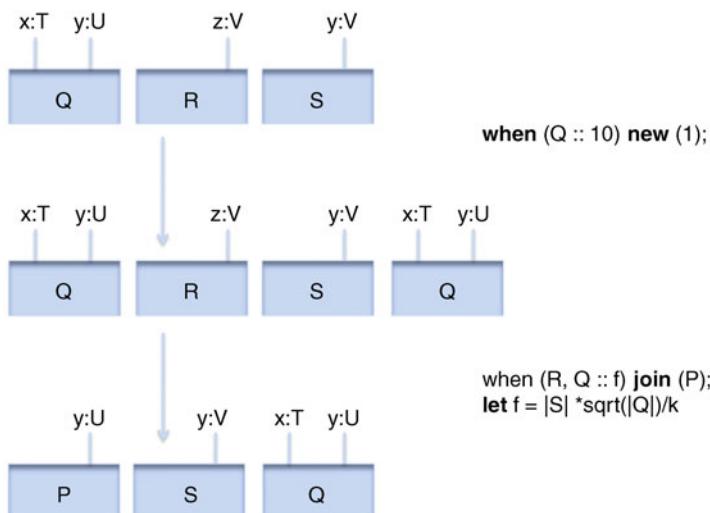

Fig. 10

Events in BlenX resemble conditional term rewriting systems. A condition on the structure of the system, on time, on the step of the simulation, or on the quantities of the species is tested after the keyword **when**. If the condition is satisfied, the event specified after the condition is enabled and participates in the selection of the next action through the stochastic simulation algorithm. The execution of a **new** or a **delete** event introduces or removes as many copies of boxes equal to the one in the condition as specified by their arguments (see first event in the figure for a **new** example). The execution of a **join** or a **split** event removes the boxes specified in the condition from the system and introduces the ones specified in the event action. For instance, the second event in the figure removes one **Q** and one **R** and introduces one box **P**. Conditions are also equipped with kinetic information. Finally, an **update** event action is provided to assign values to continuous or discrete variables associated with states of the system.

Events are very powerful modeling tools that also enable the execution of perturbative experiments over the models as is usually done in a laboratory. It can be specified that whenever a global condition, possibly time-dependent, is satisfied, a gene can be knocked-out, a drug injected in the system to study its interactions, or some components removed to see how they affect the overall behavior of the systems or, analogously, how robust a system is. Note that any event is associated with a rate and enters the race with all the other actions for selection by the simulation algorithm. Therefore, even if specified differently from the other interaction mechanisms, an event is a normal action of the system that does require modifications of the stochastic engine.

Note that the second event in [Fig. 10](#) is specified by a general mathematical function that does not only depend on the concentrations of the boxes affected by the event, but also on the concentrations of other components. Actually BlenX permits the specification of general kinetics by relying on mathematical functions. This is a useful generalization because it easily implements an interoperability with ODEs by translating them into BlenX models automatically. In this case, boxes coincide with variables and the dynamics emerge by simply copying the ODEs into functions associated with a very limited class of special events (see Mura et al. (2009)). As a consequence, the BlenX modeling approach can also handle smoothly hybrid

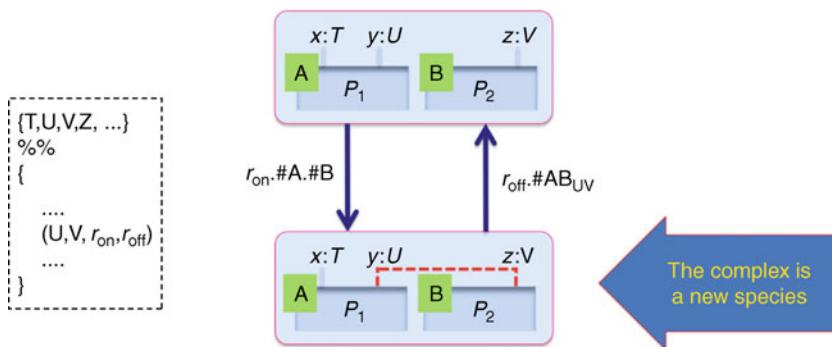

situations in which continuous and discrete aspects are fused. Finally, note that if one uses general distribution functions, the exactness of Gillespie's stochastic simulation algorithm is lost. However, this should not be a concern because most of Gillespie's hypotheses are not satisfied, being, for example, the interior of a cell crowded, not homogeneous and not well-stirred. Actually, the design of a good simulation algorithm for biological systems is an open issue.

Interoperability with mathematical modeling is also ensured in BlenX by the possibility of associating states of the system with discrete and continuous mathematical variables. These variables can be manipulated by events whose conditions are on the values of the state variables and the event action *update* provides the values for the new assignments. This feature can be used, for instance, to easily change the rate of a reaction dynamically depending on some conditions over time, space, or the structure of the system. The same can apply to the reaction volume that can change dynamically (e.g., cell growth).

BlenX includes the management of complexes in a way that specific actions of formation or destruction do not need to be specified (see Fig. 11). Because the formation of complexes and their destruction is a very primitive mechanism of interaction in biological systems, BlenX provides it in its runtime support so that the modeler can think of the basic biological components and their sensitivity without the need to program the interactions in detail. The positive result is an easier modeling approach on one side and a better predictive power of the models on the other. Here, predictive power refers to the set of observable behaviors by executing the systems. In fact, many actions are determined by the runtime of the language according to the compatibility of types and structure of boxes and to binders status. These conditions are dynamically checked and produce potential transitions at runtime that have

Fig. 11

In BlenX, it is not necessary to specify the interactions that form or destroy complexes. It is still the affinity between interfaces that determines whether a couple of boxes can complex or not. The parameters for the dynamics of complex formation are specified again in the separate file expressing compatibility. For instance, the tuple (U, V, r_{on}, r_{off}) in the figure means that two boxes having interfaces with types U and V can complex with a rate r_{on} and, once complexed, can detach each other with a rate r_{off} . The stochastic simulation algorithms also consider, at any step, the whole set of possible complexation and decomplexation among the enabled actions. As far as species are concerned, one should note that once two boxes are complexed, they form a new species in which a link between the interfaces complexed is created and visualized (the dashed red line in the figure).

not been coded by the programmer in the flow of control. The degree of freedom added to the runtime of the language increases the potential of observing behaviors, not considered at modeling time.

A BlenX model is made up of a static description of the system obtained by listing the entities of the initial configuration with their amount and specificity for interaction. Then, the execution of the model and the support of the language are in charge of determining, at any step, the possible actions to be performed. This approach enables a drag-and-drop library-based modeling: the modeler simply selects the components that must be considered in the system and then defines the sensitivity of interaction between them. After this step, only a little is needed to equip the boxes with their relevant internal behavior, if particular actions need to be implemented. The BlenX modeling process described above allows modelers to build scalable, modular, and compositional models. Finally, all the combinatorial effects are ruled out at modeling level, because the very same box represents all the possible states through which the corresponding biological entity can pass.

Almost all the concerns expressed in the previous sections for the first two generations of calculi for biology have been greatly reduced by the BlenX language. Some efforts are still ongoing to simplify the management of space and to improve the efficiency of the execution of systems both by parallelizing algorithms (Dematté and Mazza 2008) and by improving the efficiency of them, once contextual information is available (Kuwahara and Mura 2008) (Fig. 12).

Fig. 12

The figure summarizes the concerns and the characteristics of the calculi of the three generations described in the paper.

	1st generation π - calculus	2nd generation Beta-binders	3rd generation BlenX
Entities	Represented by processes, it is difficult to trace their identity	Encapsulated in boxes and hence easy to trace and count	Encapsulated in boxes and hence easy to trace and count
Complexes	Implicitly represented by scope of names and tricky manipulated through the restriction operator	Explicitly represented through the join/split of boxes or through dedicated links	Improved manipulation of complexes with conditions on their structure and state
Low-level programming	Thought for computing systems, all biological events must be encoded in the available primitives	Thought for biology, primitives closer to biological processes makes model simpler	Enriched and more natural set of primitives. A real programming language
Interaction	Exact complementarity of channel names	Compatibility of the types of the interfaces of boxes	Compatibility of the types of the interfaces of boxes
Incremental model building	Difficult: interconnection structure and affinity of entities hard-coded in the model.	Medium: affinity separated from model behavior and boxes allow easy identification of the connections between models	High: Affinity and complex formation separated from model behavior and handled through types. Boxes and different syntactic components identify connections between models
Implementation	Gillespie algorithm, counting through structural congruence	Gillespie algorithm, counting through structural congruence	Many simulation algorithms, efficient counting due to the design of the language
Qualitative versus quantitative	Exponential distributions with rates associated to channel names	Exponential distributions with rates associated both to typed interfaces and channel names	General distributions, rates as general functions, hybrid models with continuous variables
Space	Extremely limited support	Space can be encoded through tricks	Preliminary notions of space
Standards	Very limited import/export capabilities	Some import/export capabilities	Connection with SBML and ODE
Predictive power	Every interaction must be programmed	Many interactions are inferred by the execution engine	Many interactions are inferred by the execution engine

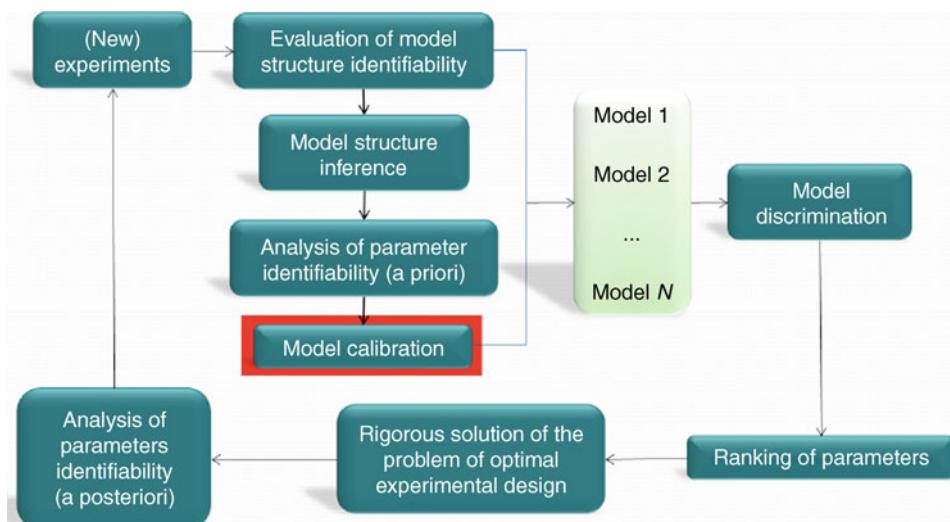

3 Knowledge Inference

Many efforts have been made toward the refinement of the modeling languages, and a reasonable level of easiness of use and generality to address most of the relevant biological problems has been reached. However, in order to execute these models, kinetic information is needed, which is often difficult to find. In particular, rates of interactions can be inferred from literature or database mining and sometimes directly by manipulating the outcome of wet laboratory experiments (e.g., time-course concentrations from microarrays or outcomes of NMR analyses). Therefore, it is essential, for a conceptual framework that aims at supporting biological research, to cover inference activities, both from a theoretical and computational perspective. Kinetics information inference is referred to here, although network structure inference is an important field as well. The tight integration of inference capabilities with a modeling framework is absolutely mandatory to make the framework practical. [Figure 13](#) shows how to integrate the inference of knowledge within a modeling cycle.

Here, one concentrates on model calibration (parameter estimation) since this is the most critical task in building an executable stochastic model following the algorithmic systems biology approach. Interaction networks can be estimated as well, but much more information on this aspect is available through various interactome projects and databases.

Fig. 13

A biological problem is usually modeled by describing the qualitative behavior constrained by quantitative information used to drive the dynamics. Starting from wet laboratory experiments, one needs to infer the parameters governing the kinetics of the reactions as well as the topology of the interaction network of the entities of the system at hand. By varying the parameters and the interaction network, one obtains a class of different models for the same phenomenon and one needs to discriminate between them according to some phenotypical fitness or statistic measures that allows one to rank the relevance of parameters. Once the main parameters are identified, it is possible to provide hints on the design of new experiments to gain the minimum knowledge one needs from the lab, in order to maximize the discrimination between the models. (Figure prepared by Alida Palmisano.)

Recent literature reports many examples of methodologies of parameter estimation both in deterministic and stochastic models, including Polisetti et al. (2006), Moles et al. (2003), Tian et al. (2007), and Chou et al. (2006), for example. Tools for parameter fitting, through regression or maximum likelihood methods, can be found as an integral part of simulation tools (e.g., Copasi (Hoops et al. 2006)), but there also exists stand-alone software, exclusively designed for that purpose, such as Splendid (Bashi et al. 2005) and PET (<http://mpf.biol.vt.edu/pet/contact.php>). Finally, Boys et al. (2008) and Golightly and Wilkinson (2008) developed Bayesian model-based inference techniques. Bayesian schemes offer some advantages over the maximum likelihood methods, such as when the volume of data is limited or the analytic form of the kinetic model makes the maximization of the likelihood difficult.

Most of the current tools for parameter estimation lack robustness to the noise as well as the absence of any estimates of experimental error in their outcome. Experimental uncertainties on parameters propagate from the measurements of the concentrations of the species. Inferring the parameters with an estimate of their uncertainty is essential if one wants to use the tool in the context of optimal experimental design. Moreover, most of the current tools based on optimization techniques suffer from the problem of univocally finding the solution by global optimization, and ask the user to provide a priori the optimization algorithm with the region of parameter space in which to perform the search for the global max/minimum.

A new approach has been recently proposed that enhances the state of the art in parameter estimation by relying on a completely new mathematical method (Lecca et al. 2009). The method is based on a probabilistic, generative model of the variations in reactant concentrations. The time-series concentrations of n reactant species are collected in n state vectors x_1, \dots, x_n . The method discretizes the law of mass action and provides a tool to predict the values of the variables x_i at time t , conditioned by their values at the previous time point. The variations of the concentration of the species, at different time points, are conditionally independent by the Markov nature of the discrete model of the law of mass action. Assuming the observation noise to be Gaussian with variance σ^2 , the probability of observing a variation for the concentration of species, between time t_{k-1} and t_k , is a Gaussian with variance depending on σ and the expectation value of the law of mass action under the noise distribution. The discretization of the law of mass action provides a model for the variations of species concentrations, rather than a model for the time-trajectory of species concentrations. This makes the evaluation of the expectation value of the law of mass action function more easily and analytically tractable. The rate coefficients and the level of noise are then obtained by maximizing the likelihood function defined by the observed variations.

This method produces the rate coefficients, the level of noise, and an error range on the estimates of rate constants. Its probabilistic formulation is key to a principled handling of the noise inherent in biological data, and it allows for a number of further extensions, such as a fully Bayesian treatment of the parameter inference and automated model selection strategies based on the comparison between marginal likelihoods of different models.

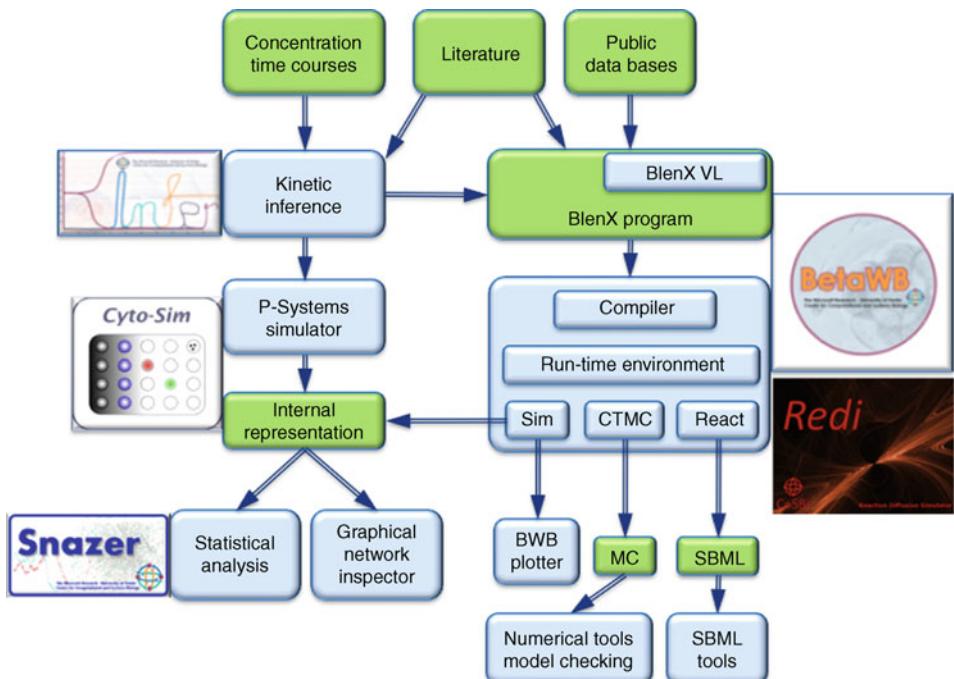

The implementation of this method in the tool KInfer (see next section) is used as an interface tool, connecting the outcomes of the wet lab activity for the concentration measurements and the software for the simulation of chemical kinetics. Finally, KInfer can also be used as a validation tool for models. If given a model, it is not possible to infer kinetic parameters that allow the model to reproduce the observed behavior in wet labs, it means that something is missing from the model or something is wrong.

4 CoSBI Lab: An Algorithmic Systems Biology Platform

The conceptual framework of algorithmic systems biology can become effective only if a suitable computational support that assists all phases in the life cycle of the modeling, simulation, and analysis of biological systems is implemented. At the time of writing, the algorithmic systems biology platform that covers most of the issues is CoSBI Lab, illustrated in Fig. 14, where the components of the platform and their connections are highlighted. CoSBI Lab is a software platform that implements a new conceptual modeling, analysis, and simulation approach to quantitative, dynamic systems primarily inspired by algorithmic systems biology. CoSBI Lab is intended to become a complete artificial laboratory in which it is possible to replicate, *in-silico*, all the activities that are usually performed in real wet labs. CoSBI Lab is centered around the new programming language, BlenX, that is the core of the formal modeling facilities. BlenX is directly derived from process calculi and hence has concurrency as a primitive feature that helps simplify models to avoid the combinatorial explosion of variables. CoSBI Lab

Fig. 14

CoSBI Lab, the algorithmic systems biology platform in the figure, provides support for quantitative model definition through both textual and graphical formalisms within the BetaWB set of tools. It allows for inference of kinetic rates via KInfer. The platform provides connection to simulators via the BetaWB, Cyto-sim, and Redi. Other kind of analyses on the models are allowed through exporting into Markov chains and SBML descriptions. Finally, Snazer provides support to visualize networks of reactions and annotate them. Snazer also implements a rich set of statistical analyses.

supports Gillespie-based simulations as well as spatial diffusion of entities. Export of models in the SBML format is allowed. CoSBi Lab implements inference procedures for quantitative parameters needed to feed the BlenX models and to drive the simulation engines. The inference starts directly from various sources of data, including the outcome of wet lab experiments that can be mapped (directly or through preprocessing transformations) into time courses of concentrations. CoSBi Lab offers a set of features to analyze the outcome of the experiments (simulations) that include the main statistical techniques as well as the visualization of networks of reactions and plots of concentrations.

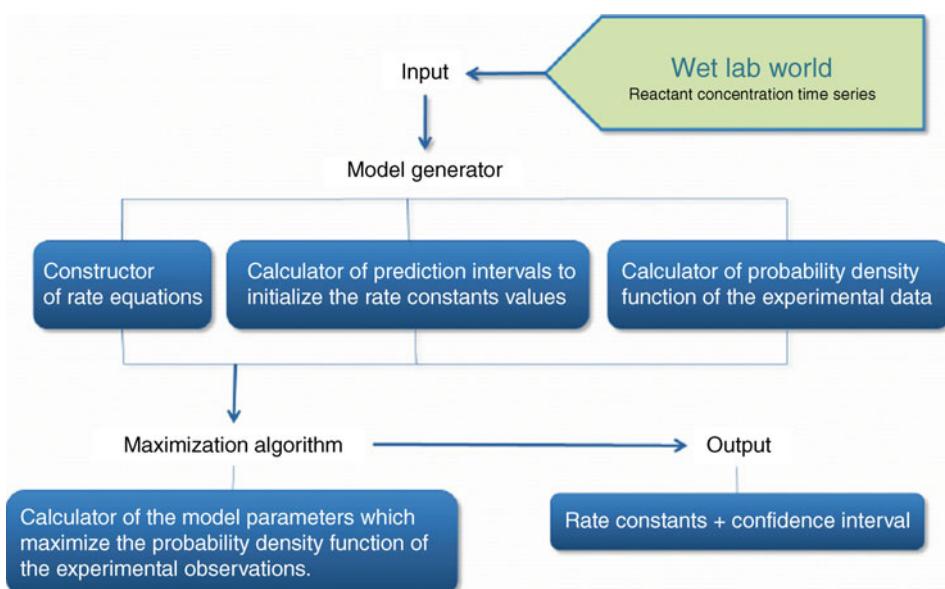

The main algorithmic tools populating the platform are now described.

BetaWB (http://www.cosbi.eu/Rpty_Soft_BetaWB.php) (Dematté et al. 2008b) is a collection of tools based on the programming language BlenX, explicitly designed to represent biological entities and their interactions. The BetaWB includes the BetaWB simulator, a stochastic simulator based on an efficient variant of the Gillespie stochastic simulation algorithm (SSA); the BetaWB designer, a graphical editor for developing models; and the BetaWB plotter, a tool to analyze the results of a stochastic simulation run. Generation of Markov chains and export into SBML is allowed.

KInfer (http://www.cosbi.eu/Rpty_Soft_KInfer.php) is a tool for estimating rate constants of biochemical network models from concentration data measured, with error, at discrete time points. A schema of KInfer is reported in **Fig. 15**. KInfer is inspired by the maximum

Fig. 15

KInfer starts from a time series concentration of entities and a list of reactions and automatically builds the mathematical model to be solved in order to estimate the rate constants describing the dynamics. Parameters are selected according to a fitting of the overall model toward some experimental observed data. KInfer also provides the user with a measure of the error performed in the calculation of the parameters, that is, the strength of the noise in the system that can be introduced by the experimental production of the time series. (Figure prepared by Alida Palmisano.)

likelihood estimation and assumes a discretized version of the law of mass action as a rate equation. The discretization of the rate equation makes the evaluation of its expectation value analytically tractable. The probabilistic formulation of the KInfer algorithm guarantees the noise-robustness and the possibility of extending it to a Bayesian treatment of the parameters. The principal features of the tools are:

1. Automatic generation of a generalized mass action model
2. Automatic estimation of the initial guesses and bounds for the parameter values
3. Estimation of the experimental errors on the inferred parameters
4. Estimation of the strength of noise in the input data

Redi (http://www.cosbi.eu/Rpty_Soft_RedI.php) (Lecca et al. 2008) is a reaction-diffusion simulator, built to test new diffusion models and algorithms. Redi simulates biochemical systems at the mesoscopic scale of interaction, employing a space discretized variant of the Gillespie SSA. Diffusion coefficients are not fixed, but are computed dynamically in a state-dependent way, inspired by the Maxwell–Stefan model of transport phenomena.

Cyto-Sim (http://www.cosbi.eu/Rpty_Soft_CytoSim.php) (Sedwards and Mazza 2007) is a stochastic simulator of biochemical processes in hierarchical compartments based on P-systems. The compartments may be isolated or may communicate via peripheral and integral membrane proteins. The native syntax is designed to be a compact and intuitive way of describing chemical systems. Arbitrary kinetic rate functions are permitted, allowing seamless import and export to SBML. Export to Matlab is also facilitated.

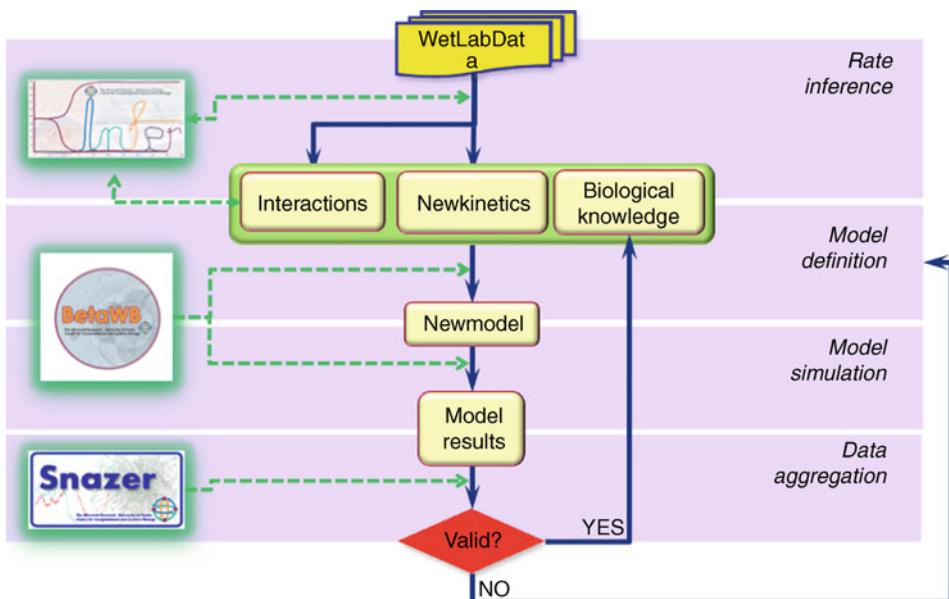

Snazer (http://www.cosbi.eu/Rpty_Soft_Snazer.php) (Mazza et al. 2010) is a modular tool designed to aid the processes of visualizing and manipulating reactive models, as well as to share and interpret time-course data produced by stochastic simulators or by any other means. Snazer upgrades the viewer of Beta Workbench and interfaces its output format. It loads biological networks encoded in SBML as well, and stores graph layouts in standard GraphML files. Moreover, it loads time-course data exported in CSV, and also compresses and prepares them for remote sharing and statistical processing. Finally, to enhance interoperability, it has been equipped with a public, XML-based schema to allow other tools both to encapsulate and structure their time-course data and to package their interaction networks, if any. A number of features are provided:

1. Import from Beta Workbench output, CSV, SBML, and (proprietary) XML file formats
2. Export to CSV, GraphML, and (proprietary) XML file formats
3. Interacting view of the chemical reactive networks
4. Color auto-tuning for color-blind users
5. Node importance highlighting (degree distribution)
6. Custom and MIRIAM-compliant annotation (see <http://www.ebi.ac.uk/miriam/>) support
7. Statistical analysis of simulated multi-traces
8. Statistical outcome export in support vector graphics (SVG)

The possible workflow depicted in  Fig. 16 highlights a relevant aspect of in-silico laboratories based on algorithmic descriptions of the dynamics of systems produced through computing languages. Most biological research is mainly driven by the availability of reactants, by technical capabilities of performing specific perturbation to the modeling organisms, and by the time needed to get the outcome of an experiment. In-silico replica of biological systems can instead exploit the power of algorithmic approaches to speed up experiments and to make thousands of them at a very low cost. The comparison of these in-silico experiments can

Fig. 16

A typical workflow supported by the algorithmic systems biology platform starts from the collection of the available biological knowledge and the inference from it of the relevant parameters through KInfer. The outcome of this step is used to feed the quantitative part of the models within BetaWB, that together with the algorithmic description of the behavior allows the simulation of the dynamics of the system. The result of the simulation can be inspected by Snazer and can suggest modifications to the model or new experiments to acquire new knowledge by iterating the cycle. Eventually this process can lead to the discovery of new biological insights. (Figure prepared by Ivan Mura.)

then drive the optimal design of new wet experiments. To make the approach described above practical, it is necessary to interpret the outcome of the execution of a model exactly as the outcome of a wet experiment and to make the same kind of inference on it that is usually done on the output of the bench. This is why the statistical analyses implemented in Snazer, directly on the outcome of multi-run simulations, provide an important added value to the algorithmic systems biology platform described so far.

This section concludes by noting that the described platform is the only integrated environment based on process calculi available. Other implementations are limited to simulators and various graphical tools to visualize the outcome of simulations. The first implementation of a biochemical stochastic π -calculus simulator was BIOSPI (Priami et al. 2001), followed by SPiM (Phillips and Cardelli 2007). A stochastic κ -calculus simulator is described elsewhere (Danos et al. 2007). The Kappa Factory (<http://www.lix.polytechnique.fr/krivine/kappaFactory.html>) is a graphical platform for the design, analysis, and simulation of biomolecular systems. Different kinds of analysis methods are supported, for example, static dependencies on rules and analysis of traces. Recently, an effort to integrate stochastic simulation with other analyses techniques, like model checking, has been done for BioPEPA (Ciocchetta et al. 2008a).

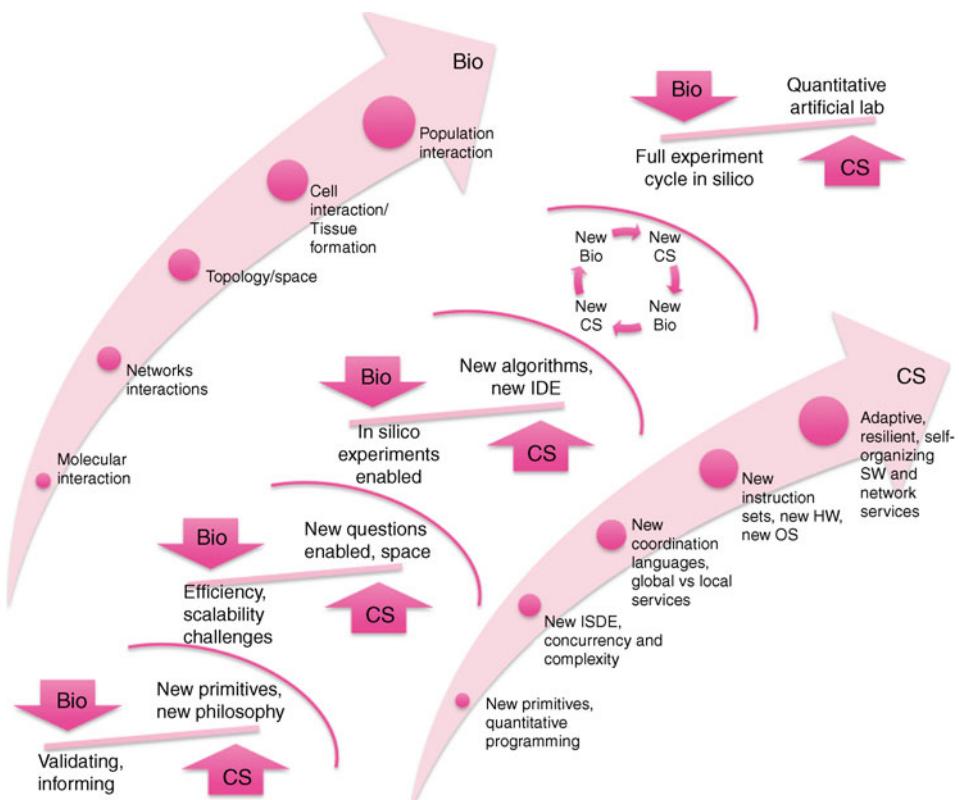

5 Conclusions

The integration of computer science and systems biology into algorithmic systems biology is a win-win strategy that impacts both disciplines from a scientific and technological perspective (Fig. 17).

The scientific impact of accomplishing the vision and the feedback from the biological understanding will be the definition of new quantitative theoretical frameworks that address the challenge of overcoming the increasing concurrency and complexity that is observed in the asynchronous, heterogeneous, and decentralized (natural/artificial) systems in a verifiable, modular, incremental, and composable way. Furthermore, the definition of novel quantitative

Fig. 17

Algorithmic systems biology can propel both biological and computer science research. The conceptual and computational framework developed to enhance biological capabilities of understanding basic principles allows biologists to address new and challenging questions (left arrow) whose answers provide the requirements for developing new and better computer science frameworks (right arrow). At the same time, the environment developed to address the biological challenges can turn computer science into a more quantitative science and can enable simulation-based research in all fields where the dynamics are driven by the interaction of entities (economic markets, social networks, etc.).

coordination and orchestration mechanisms of the loosely coupled components of the kind of complex systems being studied will produce new conceptual frameworks to cope with the growing paradigm of distributing the logics of applications between local software and global services. The definition of new logical and conceptual schemas to store data related to the dynamics of systems and the new query languages needed to retrieve and examine this new kind of records will create completely new perspectives to build the increasingly valuable data centers that provide added value to global services.

Another major scientific impact will be the definition of a new philosophical foundation of systems biology, which is algorithmic in nature and allows scientists to raise new questions that are out of reach for the current conceptual and computational support. An example of this would be the cross-talks (interaction) between pathways (cascades of interactions of biological entities). Actually the current interpretation of pathways (that do not exist per se in nature) is a reductionist approach (imposed by technological limitations) with respect to the system-level understanding of network behavior (a collection of interwoven pathways working simultaneously and interacting).

The technological impact of accomplishing the full merging of computer science and systems biology will be the design and implementation of artificial biology laboratories that allow many more experiments than the ones currently feasible in wet labs, at lower costs in terms of human and financial resources as well as time. These labs will allow biologists to design, execute, and analyze experiments to generate new hypotheses in a shorter time than needed in wet labs. The new findings in hierarchical networks of biological elements (molecules, cells, organs, and organisms) inform new technology actions coordinated by research requirements to develop novel, massive high-throughput tools. These actions should mainly address advances in experimental design, documentation, and interpretation as well as a deeper integration between dry and wet research. Furthermore, the artificial laboratories will be a main technology to move from single gene diseases to multifactorial diseases that are more than 90% of those affecting society. A deeper look at the causes of multifactorial diseases can positively impact their diagnosis and management. Health is not the only practical application of algorithmic systems biology; the comprehension of the basic mechanisms of life coupled with engineered design environments for synthetic biology will lead one toward the use of ad hoc bacteria to repair environmental damages as well as to produce energy.

Another major technological impact will be allowing computer scientists to properly address and master the challenges originated by the new HW design, which mainly exploit parallelism via many/multi-core architectures rather than the speed of single processors, through new integrated programming environments suitable to address concurrency and complexity.

Unraveling the very basic mechanisms adopted by living organisms to compute and manipulate information leads to the heart of computer science: computability. Life underwent billions of years of tests and was optimized during this time, and thus one can learn new computational paradigms to enhance the field. The same arguments apply to hardware architectures as well. Starting from the very basics, one can further build on top of them to enhance resource management and hence operating systems, primitives to instruct highly parallel systems and consequently (concurrent) programming languages, and also software development environments that ensure higher quality and better properties than current software applications. As a consequence, algorithmic systems biology can contribute to the future of computer science.

Algorithmic systems biology can also contribute to the future of natural and life sciences through connecting models and experiments by means of new conceptual and computational

tools integrated in a user-friendly environment equipped with templates of major biological components for drag-and-drop modeling of (artificial) organisms or populations and used by many life scientists to predict the behavior of multi-level, multi-scale biological systems in a modular, compositional, scalable, and executable manner.

Acknowledgments

The author thanks the CoSBi team for many inspiring discussions.

Abstract

Knowledge about life processes develops through the interplay of theoretical speculation and experimental investigation. Both speculation and experiments present several difficulties that call for the development of faithful and accessible abstract models of the phenomena investigated. Several theories and techniques born in computer science have been proposed for the development of models that rely on solid formal bases and allow virtual experiments to be carried out computationally *in silico*.

This chapter surveys the basics of *process calculi* and their applications to the modeling of biological phenomena at a system level. Process calculi were born within the theory of concurrency for describing and proving properties of distributed interacting systems. Their application to biological phenomena relies on an interpretation of systems as made of interacting components exhibiting a computational kind of behavior, “cells as computation.”

The first seminal proposals and the subsequent enhancements for best adapting computer science theories to the domain of biology (with particular reference to chemical, biochemical, and cellular phenomena) are surveyed.

1 Introduction

Knowledge about life processes and ultimately about oneself as a human being develops through the interplay of theoretical speculation and experimental investigation. Experiments have high costs, as materials and techniques are not easily available, may be lengthy, have speed that is determined by the speed of natural processes, pose ethical issues (for example, because they may be invasive), and have available investigation techniques that are not always sufficient to study the phenomena of interest.

A long-standing way of addressing such difficult investigations is to revert to models of the studied problem. As in any other scientific field, a model focuses on the essence of what is studied, abstracting away the unnecessary details so as to reduce complexity. Furthermore, a rigorous, formal description of natural phenomena permits reasoning on them at an abstract level. This is crucial for assessing the adequacy of the proposed model, which can then be used for formally checking aspects and properties of the modeled objects. Particularly relevant for an assessed model is its prescriptive capability, which in the realm of life sciences means that new facts can be discovered and hypotheses tested without resorting to actual experiments. This reduces the costs of the experimental work and drives those tests that remain essential for demonstrating these findings.

The use of formal methods in biology has been advocated for some time. A seminal exploration appeared in Schrödinger’s “*What is Life?*” (Schrödinger 1946), which contains *in nuce* a quest for a description of living matter in terms of the mathematics and the techniques used in physics. Biophysics is a fascinating and effective discipline, originally influenced by that book.

Beyond physics and mathematics, computer science also contributes to the development of biology, which becomes more and more a multi-disciplinary research field. On the one hand, computer science has traditionally provided mankind with the information technology infrastructure needed to store the vast amount of data we acquire about biological phenomena and to organize it, as well as with several methods and effective tools to search, retrieve, and reason on these data. On the other hand, more recently, computer science has been

fostering the development of *executable* formal models of biology, for which several theories born in computer science are being exploited.

One of the most successful and widely known examples of this is the modeling of DNA as a string and the application of several string-based algorithms in the quest for DNA sequencing. A large body of research has been done on algorithms for mining recurrent patterns for a better understanding of the *structure* of the DNA double chain.

Broadly speaking, these results in representing and searching genomic structures follow from a reductionist approach, which focuses on the single aspects of the components of a biological system, namely the sequential structure of the DNA. However, these efforts seem inadequate for explaining the overall *functioning* of a complex system and the properties emerging from its behavior when considered in its dynamical evolution. Clearly, the complete knowledge of the DNA structure is not enough to describe its metabolic and regulatory functionalities, which rather depend on the interactions among genes, the proteins they code, and also the environment in which these interactions happen.

In the words of Kitano:

- ▶ To understand biology at the system level, we must examine the structure and dynamics of cellular and organismal function, rather than the characteristics of isolated parts of a cell or organism. . . many breakthroughs in experimental devices, advanced software, and analytical methods are required. (Kitano 2002)

Such a systemic approach has been embraced by the recently developing *systems biology* research field.

This chapter focuses on the role that theories, models, and analysis techniques born in computer science may have within systems biology. More specifically, theories from the field of *concurrency*—that is, the study and analysis of the interactions happening within computer systems—are considered. This approach relies on interpreting biological systems as interactive computational systems. In both contexts, a potentially vast number of components (for example, biochemical molecules vs. software applications) cooperate together in a similar manner (for example, by chemical reactions vs. communications over a computer network) toward a common goal (for example, sustaining a cell vs. managing a flight control system). This approach was clearly suggested by Regev and Shapiro in their seminal paper (Regev and Shapiro 2002):

- ▶ We believe that computer science can provide the much-needed abstraction for biomolecular systems. . .the ‘molecule-as-computation’ abstraction, in which a system of interacting molecular entities is described and modelled by a system of interacting computational entities. Abstract computer languages, . . . enable simulation of the behaviour of biomolecular systems, . . . supporting qualitative and quantitative reasoning on these systems’ properties.

The mentioned abstract computer languages considered here are *process calculi*. In the form of an algebraic representation, they describe the dynamics of an interacting system. This representation is *formal*, that is, mathematically precise, and the modeler can choose the desired *level of abstraction*; it is largely *compositional*, that is, separate subparts of a system can easily be assembled together; it is *executable*, that is, it supports automated simulation; and it offers a repertoire of tools and techniques for a mechanical *verification* of properties.

Process calculi offer their users the possibility of representing both *qualitative* information, (for example, checking whether a metabolite is or is not produced by a cell) and *quantitative* information (for example, the stochastic time-course of specific metabolites along a pathway).

In recent years, various process calculi designed for modeling network distributed applications and their analysis tools have been used to describe the dynamics of biological systems (for example, biochemical pathways and even whole cells). However, it became clear that, as they are, these calculi lack descriptive power under several pragmatic aspects. Then, new process calculi were defined in order to properly take into account biological features, such as the specific structures or the complex interactions that occur within and on membranes and compartmentalized systems (Regev et al. 2004; Cardelli 2004; Priami and Quaglia 2004). These extensions also call for related enhancements in the formal theory that supports them, and so started a new research subfield across concurrency theory and life sciences. In particular, one has to rethink the way the dynamics of systems is specified (that is, their semantics), so as to comprise relevant biological aspects at different levels of detail (for example, the stochastic nature of various phenomena), starting from Hillston (1996) and Priami et al. (2004). This task is not easy at all, and also raises the formal question of the expressivity of the resulting calculi from a theoretical point of view, typically whether they express all the computable functions.

Beyond the mentioned features and despite its early stage, the process calculi for biology often are adequately descriptive and computationally efficient compared with other traditionally adopted modeling techniques, such as those based on the differential calculus. A crucial distinction is that a model in this approach turns out to be, roughly, a computer program that can be executed to *generate* a formal representation of the biological behavior, rather than *being* itself a description of the behavior, as offered, for example, by a system of differential equations. So, it might be easier to build the model, as well as to study the model under different conditions (for example, by varying and tuning parameters, looking for emergent properties, etc.) because each run can be seen as a *virtual* experiment.

Process calculi and the algebraic approach lie in a much bigger effort of defining formal (and executable) models of living matter and to reason on them, ultimately aiming at defining new formal languages for biology. References are only provided for some of these approaches, as completeness would be impossible. Among the various rule-based formalisms presented in the literature, one can find the λ -calculus (Fontana and Buss 1994), Biocham (Calzone et al. 2006), the κ -calculus (Danos et al. 2007), Moleculizer (Larry and Roger 2005), the pathway logic (Eker et al. 2002), the calculus of looping sequences (Milazzo 2008), and closer to formal languages, P-systems (Paun et al. 2007). Formalisms introduced for reactive systems have also been used to model biological entities (Damm and Harel 2001; Sadot et al. 2008). Petri nets offer a graphical framework for formally describing biological networks, and have been widely used (Reddy et al. 1993). The surveys collected in Bernardo et al. (2008) can help to complete the vast picture of the numerous contributions to this field, which cannot be properly summarized in the limits of this chapter.

Synopsis. Process calculi are illustrated in [Sect. 2](#), where their main features are recapitulated, along with some simple examples of applications taken from biology. In particular, the syntax and the semantics of a simple calculus are introduced, then there is a discussion on how to extend them with quantitative information and illustrate some features that make the modeling of membranes easier. In [Sect. 3](#), a representation of chemical facts through process calculi is discussed and some expressivity results are surveyed. Classical techniques for analyzing the behavior of processes are in [Sect. 4](#). Finally, [Sect. 5](#) surveys a few examples of biological systems that have been modeled and investigated within the approach based on process calculi.

2 Process Calculi for Computational Models of Bio-systems

Process calculi have been defined within concurrency theory to formally represent the behavior of a system made of interacting components, also called *processes*. The represented behavior is an abstraction of the actual behavior of the components at the desired level of abstraction. This abstraction is also referred to as *observable behavior*, suggesting that the aspects of interest that an external observer can perceive are considered, neglecting internal mechanisms or details deemed irrelevant. Process calculi are based on an algebraic notation whose main ingredients are

- (i) The basic *actions* that components can perform together with a set of operators for defining *processes* by composing basic actions and simpler processes;
- (ii) A *semantics* describing the possible dynamics of a process according to the actions it is enabled to do. Often the semantics is operational and consists of a *labelled transition system (LTS)*. LTS have *states*, roughly processes themselves, and *transitions*, that is, a relation between a state and the next one the process can move to. A transition may have *labels* recording its observable behavior, to keep track of the relevant information about the step. LTS are usually defined compositionally by inductive rules over the structure of the components of a process (SOS rules (Plotkin 2004)). A *trace* is a sequence of transitions, such that the target state of a transition in the sequence is the source of the next one. A trace represents a possible computation of the process in the source of its first transition;
- (iii) *Properties*, *methodologies*, and (mechanical) *tools* to analyze process behavior. Examples of properties can be equivalence relations, such as bisimulations, or reachability properties, such as checking whether a process can reach a given state of interest. Examples of mechanical analysis tools are model checkers, used for verifying whether an LTS can fulfill a logical formula expressing the property of interest, and static analysis tools, which check properties of an LTS by reasoning on an abstraction of it.

Below a simple calculus, called BCCS after basic CCS, will be introduced. It consists of a (restriction- and value passing-free) subset of CCS, an exemplary calculus (Milner 1989). This introduction to process calculi aims at presenting their use in systems biology and is definitely not exhaustive. The interested reader is referred to Milner (1980, 1999) and Bergstra et al. (2001) and citations therein.

Two extensions that have been demonstrated to be relevant for systems biology are then presented. The first one takes into consideration quantitative data. Many biological phenomena need to be understood in terms of the quantities, and their variations, of the elements involved. Often, these are continuous variations derived from deterministic laws. However, at certain scales and levels of abstraction, the phenomena are essentially discrete, as each single element may cause specific behavior to emerge globally. Furthermore, they are better described in a stochastic manner, as the dynamics of the system cannot be fully reduced to deterministic mechanisms (Wilkinson 2006). Process calculi have been equipped with stochastic semantics suitable for studying the performance of computer systems in the presence of events with a probabilistic distribution over time, for example, user requests and queued incoming messages (Hillston 1996; Priami 1995). Stochastic process calculi offer then natural means for formal quantitative modeling of biological phenomena.

The second extension concerns the development of calculi designed to account for a certain form of interaction that peculiarly happens within biological systems. In particular, the focus will be on a few calculi designed to express the notion of membraned components

and the behavior that can be expressed by the membranes themselves. The capability of describing intra- and extracellular processes show the versatility of the approach in modeling phenomena at different scales with the desired level of abstraction.

2.1 Process Calculi for Systems Biology

BCCS is illustrated here. Essentially, the processes may perform basic actions that are inputs and outputs over a communication channel. Channels may be seen as the interface of a process with its environment.

Formally, one can assume a set of channels Ch , upon which one can define the set of actions $Act = \{a, \bar{a} : a \in Ch\}$ (one can feel free to use the same letter to denote a channel and an action along it). Actions a and \bar{a} represent complementary input/output actions over channel a (with $\bar{\bar{a}} = a$). Additionally, $\tau \notin Act$ is a distinguished action called *internal action*.

Basic actions can be put in sequence within a process, and their execution will take place in the prescribed order. More interestingly, processes can be built by composing (sub)processes, running in parallel. Two (sub)processes in parallel may proceed independently of each other, or they can synchronize when ready to perform a complementary pair of input/output actions over a channel they share. Furthermore, (sub)processes may also be composed so as to represent mutually exclusive behavior chosen non-deterministically.

More precisely, BCCS is defined by its syntax and its SOS operational semantics, given in Fig. 1. The syntax is in the first line and defines (through the symbol $::=$) the various forms a process P may assume, separated by $|$. The semantics is specified in a logical style, through inference rules that define the transitions of the calculus, actually its LTS – technically, the minimal transition relation that shall be taken among processes fulfilling the rules in Fig. 1. A transition has the form $P \xrightarrow{\alpha} Q$, where P is its source process, Q its target, and $\alpha \in Act \cup \{\tau\}$ is its label, recording the activity performed by the transition.

The inference rules are now briefly commented upon. Each of them consists of some premises and a conclusion, written above and below the line, respectively.

The empty process 0 does nothing, so there is no need for any rule governing its behavior.

The rule *pref* specifies the temporal ordering of actions to occur. It has no premise, and directly justifies the transition for any process in the form $\alpha.P$, in words, P prefixed by action α (P plays here the role of process variable, to be instantiated to an actual process). The process $\alpha.P$ becomes P by performing α , which is recorded in the label of the transition.

The parallel composition of two processes is represented by the $|$ operator. Rule *par* says that if a process P can perform an action α , then $P|R$ can also perform the same action

Fig. 1

Syntax and operational semantics of BCCS.

$$P, Q ::= 0 | \alpha.P | P | Q | P+Q | N \doteq P$$

$$\frac{}{\alpha.P \xrightarrow{\alpha} P} (\textit{pref}) \quad \frac{P \xrightarrow{\alpha} Q}{P|R \xrightarrow{\alpha} Q|R} (\textit{par}) \quad \frac{P \xrightarrow{\alpha} Q}{P+R \xrightarrow{\alpha} Q} (\textit{cho})$$

$$\frac{P_1 \xrightarrow{\alpha} Q_1 \quad P_2 \xrightarrow{\bar{\alpha}} Q_2}{P_1|P_2 \xrightarrow{\tau} Q_1|Q_2} (\textit{comm}) \quad \frac{A \doteq P \quad P \xrightarrow{\alpha} Q}{A \xrightarrow{\alpha} Q} (\textit{def})$$

with Q staying idle. More generally, if the (instantiated) premises of the rule (top row) are themselves justified, possibly by applying other rules, the bottom transition is justified as well. A further comment is in order. As is often the case, processes are considered up to some structural properties of the operators, so the same rule governs the behavior of any process whose structure matches (up to the structural properties) the source of the transition in the conclusion. Here, it is assumed that the parallel operator is associative (i.e., $(P|Q)|R = P|(Q|R)$), commutative ($P|Q = Q|P$), and has the inactive process 0 as the neutral element ($P|0 = P$). Then, the rule *par* also applies to $P|R = R|P$, with R moving and P staying idle.

The second rule governing the parallel operator is *comm*. It states that whenever any two subprocesses P_1 and P_2 in parallel are ready to perform complementary actions, they can synchronize: $P_1|P_2$ becomes $Q_1|Q_2$ (note that this rule has two premises, and both need to be justified to deduce the conclusion). The observable behavior of a synchronization is τ . This use of the internal action is a means of modular information hiding, not disclosing to the environment the details of the synchronization that happened among P_1 and P_2 . Technically, it also forces synchronization to be binary, because τ has no complementary action to be used in further synchronizations.

Rule *cho* allows $P + R$ to move as P does, and R is discharged. Also $+$ is associative, commutative, and with 0 as neutral element, and so this rule also prescribes that $R + P$ moves as R and P is discharged. Note that the choice among the two alternatives is purely nondeterministic.

The last syntactic definition permits a process to be denoted by a name, taken from a given set $N = \{A, B, \dots\}$. A process name can be used to identify a specific fragment of behavior: rule *def* specifies that the process A , standing for P , can move to any process Q to which P moves. Actually, using this feature one can define recursive processes accounting for the repetition of the same behavior. In a recursive definition, the name of the process being defined occurs within the definition itself. For example, the process $N = a.N + 0$ can perform an unbound number of a actions and then become the process 0.

It is worth underlining the *compositional* flavor of these rules. For instance, the behavior of $P|Q$ is defined in terms of the behavior of its components P and Q . This is *abstractly represented* in terms of the mere observable behavior of P and Q respectively, without any reference to their internal structure.

Example 1 (LTS) The simple process $a.0|b.0|\bar{a}.\bar{b}.0$ consists of three parallel sub-processes, the last of which can communicate in a precise order with the other two. This behavior is specified by the following trace:

$$a.0|b.0|\bar{a}.\bar{b}.0 \rightarrow_{\tau} b.0|\bar{b}.0 \rightarrow_{\tau} 0.$$

The first transition is justified by recalling that $a.0|b.0|\bar{a}.\bar{b}.0 = a.0|\bar{a}.\bar{b}.0|b.0$; hence rule *comm* can be applied since both its premises hold: $a.0 \rightarrow_a 0$ (by rule *pref*) and $\bar{a}.\bar{b}.0|b.0 \rightarrow_{\bar{a}} \bar{b}.0|b.0$ (by rules *par* and *pref*). Being 0 the neutral element for $|$, it can be elided. The last state 0 has no further possible transition.

Differently, the process $P = a.0|b.0|(\bar{a}.0 + \bar{b}.0)$ has the two traces

$$a.0|b.0|(\bar{a}.0 + \bar{b}.0) \rightarrow_{\tau} b.0 \rightarrow_b 0 \quad \text{and} \quad a.0|b.0|(\bar{a}.0 + \bar{b}.0) \rightarrow_{\tau} a.0 \rightarrow_a 0$$

both making available to the environment an action to synchronize with.

Finally, an example of (mutually) recursive processes can be represented by a quite abstract specification of the acquisition/release of energy by the *ATP/ADP* molecules (one can omit here the involved inorganic *ortho*-phosphate). The process representing *ATP* transforms into *ADP* by performing an internal action τ , which needs no synchronization and is executed autonomously. This action represents the mechanisms for the exchange of energy by actually abstracting them away. Analogously, *ADP* performs the inverse process through another τ action.

$$ATP = \tau.ADP \quad ADP = \tau.ATP$$

A trace of a system made of the simple process *ATP* is

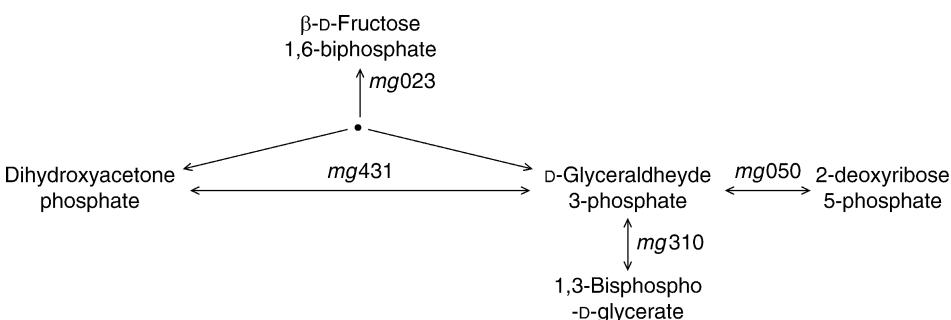

$$ATP \rightarrow_{\tau} ADP \rightarrow_{\tau} ATP \rightarrow_{\tau} \dots$$

The basic calculus introduced comprises several of the ingredients needed to model relevant biological phenomena. Below, another example is considered at the biochemical level and model a fragment of the *Glycolysis* pathway. Recalling the described approach, “cells as computation” metabolites are represented as BCCS processes. The interaction points of metabolites are abstractly represented by channels. Two molecules that may react are then modeled as two processes sharing a channel a , and the reaction between them as a synchronization along a . Indeed, at this level of abstraction, reactions are often understood as binary phenomena after the consideration that the probability that more than two reactants interact at the very same instant is practically negligible. Hence, calculi based on basic binary interaction operators, such as the one introduced, have been often used. Also, reactions are represented that consider the number of reactants present in the system, rather than the more usual concentrations; this point will be addressed later.

Example 2 Consider the small fraction of glycolysis shown in Fig. 2. We use long names for metabolites (IUPAC convention) and codes (as in Fraser et al. (1995), to which we refer the reader) for enzymes: (i) *mg023* for fructose-bisphosphate aldolase, (ii) *mg431* for phosphoglycerate mutase, (iii) *mg301* for glyceraldehyde 3-phosphate dehydrogenase, and (iv) *mg050* for 2-deoxyribose-5-phosphate aldolase. We represent the catalytic effects of enzymes in an abstract way: their contribution is simply recorded with a label attached to the τ actions. In this way we do not explicitly represent enzymes as processes, although this would be possible with a specification at a finer level of detail. Note, however, that the labels of transitions are enough to trace the enzymatic activities along the dynamics of the pathway. The freedom

Fig. 2

A fragment of the glycolysis pathway.

in selecting what will be the focus and what will be represented more abstractly is a feature of process calculi.

The metabolite β -D-fructose-1,6-biphosphate, reacting with the enzyme *mg023*, splits into Dihydroxyacetone phosphate and D-Glyceraldehyde 3-phosphate. In turn, Dihydroxyacetone phosphate, catalyzed by the enzyme *mg431*, becomes D-Glyceraldehyde 3-phosphate. This can become (i) the metabolite 1,3-Bisphospho-D-glycerate via *mg301*, or (ii) Dihydroxyacetone phosphate via *mg431*, or (iii) 2-deoxyribose 5-phosphate via *mg050*, or finally, (iv) it can reconstitute β -D-fructose-1,6-biphosphate via a reverse reaction with respect to the one that has generated it.

The topmost reaction of Fig. 2 can be described by defining the behavior of the involved metabolite as follows:

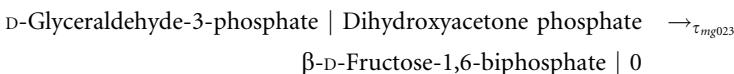

where the prefix consisting of the internal action represents the biochemical mechanisms driven by the *mg023* enzyme that triggers the reaction. In this case, the enzyme action is independent of any metabolite other than β -D-fructose-1,6-biphosphate.

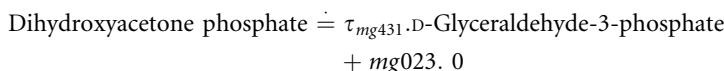

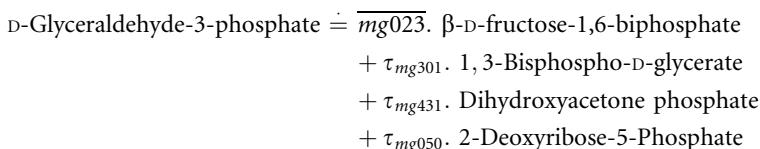

The reverse interaction arises from the specification of the interaction capabilities of D-Glyceraldehyde-3-phosphate and of Dihydroxyacetone phosphate. The first offers a synchronization on the channel (representing the) enzyme *mg023*, and then becomes β -D-Fructose-1,6-bP; similarly, the second is willing to accept a synchronization on *mg023*, and will then disappear, becoming 0.

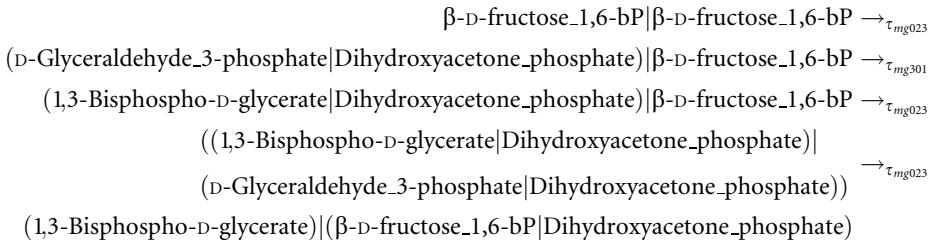

The *adolase* reaction then spawns from the parallel composition of the two metabolites, modeled by the synchronization “catalyzed” by *mg023*:

The one specified above is not the only interaction in which D-Glyceraldehyde-3-phosphate is involved. Its behavior can be incrementally specified by adding the other alternatives to its nondeterministic behavior. Beyond interacting with Dihydroxyacetone-phosphate through the *mg023* channel/enzyme, it can: (i) execute a τ_{mg301} becoming 1,3-Bisphospho-D-glycerate, or (ii) execute a τ_{mg431} becoming Dihydroxyacetone phosphate, or (iii) execute a τ_{mg050} becoming 2-Deoxyribose 5-phosphate. Similarly, the behavior of Dihydroxyacetone phosphate can be completed by its possibility of becoming D-Glyceraldehyde-3-phosphate

The following is a trace of a system made of two copies of β -Fructose 1,6-bisphosphate:

2.2 Adding Quantitative Information

The need to embed quantitative information into process calculi has been put forward for studying the performance of systems. Time was the first quantitative dimension that came into play, although it is easy to recognize that other quantities also have to be considered. Indeed, in a distributed system several of the aspects, typically task completion time, that affect performance have a probabilistic nature, as they depend on the probability distribution of the incoming requests, among other factors.

A probabilistic formal model for the study of system performance, depending on the possible occurrence of events, was first defined in Hillston (1996) and Priami (1995) by embedding stochastic aspects into process calculi. This is realized by associating a random variable to each action. The random variable models the delay of action execution, according to the idea that, for each action, it is necessary to consider a completion time that is probabilistic in nature. In other words, the random variable represents the probability, drawn from a given distribution, that the action will be executed within a delay.

Often, the adopted distribution is a negative exponential distribution $1 - e^{-rt}$, meaning that the probability of completing the considered action before time t is $1 - e^{-rt}$. This distribution guarantees that the probability of a system to go from a state to the next via a transition only depends on the current state and not on the way this state has been reached, namely the system enjoys the Markov, or memory-less property. This property has a good correspondence with the modeled reality, because the current state of a distributed system is generally sufficient to determine the next one. Additionally, the memory-less property fosters good semantic definitions.

More formally, the actions Act of the calculus are annotated with a rate r , the parameter of the probability distribution associated with the random variable relative to the action. Basic actions hence consist of pairs (α, r) . Compositional operators and process construction work as standard. The stochastic machinery clearly reflects on the semantics. The inference rules label the transitions with actions and rates, for example,

$$\frac{}{(\alpha, r). P \xrightarrow{(\alpha, r)} P} (pref)$$

Noticeably, the meaning of choice is no longer purely nondeterministic. Rather, we have a probabilistic choice between weighted alternatives:

$$\frac{P \xrightarrow{(\alpha, r)} Q}{P + R \xrightarrow{(\alpha, r)} Q} (cho)$$

Furthermore, synchronization also needs to be rethought, as it is clearly related to the probability of the completion time of actions. This point has been heavily debated; see for example, Hillston (1994) and Bradley (1999). A natural choice would be to consider the slowest of the distributions of two synchronizing actions as the distribution of the synchronization, but min/max operations on exponential distributions do not yield an exponential distribution. A suitable solution to compute the rate r is using a function proposed by Hillston (2005), which is written as a side-condition of the rule below:

$$\frac{P_1 \xrightarrow{(\alpha, r_1)} Q_1 \quad P_2 \xrightarrow{(\bar{\alpha}, r_2)} Q_2}{P_1 | P_2 \xrightarrow{(\tau, r)} Q_1 | Q_2} \text{ with } r = \frac{r_1}{r_\alpha(P_1)} \frac{r_2}{r_\alpha(P_2)} \min(r_\alpha(P_1), r_\alpha(P_2))$$

Above, it is written $r_\alpha(P_i)$, namely the *apparent rate* of α within P_i , $i = 1, 2$, to denote the sum of all the rates associated with the α 's in P_i ready to be performed. The apparent rate takes into account the many possible different ways in which the subprocess P_i offers to its partner a synchronization, which clearly influences the probability of which to occur.

The other rules are straightforward extensions of the usual ones, for example, of (*par*) and (*def*) in  Fig. 1 for BCCS.

As mentioned above, the use of exponential distributions helps in defining and in exploiting the semantics of a stochastic process calculus. Actually, the operational semantics originates a continuous time Markov chain (CTMC), on which several statistical analyses can be made; for more details, the interested reader should refer to Hillston (2005).

One of the most influential calculi with the stochastic features mentioned above is PEPA (Hillston 1993), which was specifically designed for generating Markov processes that could be solved numerically for performance evaluation. This calculus combines the CCS operations discussed above with others, taken from csp. As above, PEPA has actions with a duration, represented by a random variable with a negative exponential distribution; in the choice $P + Q$, the first process completing its activity is taken and the other is discarded. Different from the above, processes are composed in parallel through a cooperation operator, indexed by a set of cooperation activities L , much in the csp style (Hoare 1985). Roughly, the set L determines those activities on which the cooperands are forced to synchronize, and the observable behavior is the activity itself, rather than a τ . This provides one with the possibility of a multi-way synchronization between components: further processes, performing the same actions, can be engaged in the synchronization. Asynchrony occurs when a process performs an action not in L . From csp, PEPA also inherits the additional operator of hiding, also indexed by a set L , written P/L . When such a process performs an activity belonging to L , it becomes a τ , thus preventing other processes from synchronizing and making the activity internal or private to the process P . Starting from an operational definition, the semantics of PEPA is defined as a CTMC, which can be exploited for extracting performance measures.

Besides being used in the performance evaluation of computer system, Bio-PEPA (Ciocchetta and Hillston 2006) has been recently proposed, which extends PEPA to model various biochemical aspects of living matter, including general kinetic laws.

As a matter of fact, stochastic process calculi have been fruitfully exploited for describing biological phenomena, which generally require quantitative models to be better understood. Consider for instance the biochemical level. System dynamics defines and is affected by the amounts of the reactants produced and consumed. Other measurable quantities, such as temperature and time, play a determinant role in the overall picture. Furthermore, the dynamics of biochemical reactions present a stochastic behavior, just like most natural phenomena.

Although CTMCs exhaustively represent the semantics of interest, they pose computational difficulties, because the interplay of states and transitions over time exponentially increases the size of the model, making the approach computationally intractable. This is particularly important for the models taken into consideration, because they often formalize rather complex biological entities, thus leading to systems with huge dimensions.

A more efficient, computationally successful alternative is using stochastic process calculi for simulation purposes. Instead of considering the whole model of all the possible states, transitions and their probabilities, a single trace, called the *trajectory*, is simulated. This consists of one of the possible time courses of the system whose steps are chosen according to the given probability distribution, obviously obeying the semantics of the calculus.

Pushing further the “cells as computation” analogy, one can see a trajectory as an experiment *in silico*. A simulation starts from the description of the initial state of the system in terms of the number of processes that are initially present (see [Sect. 3](#) for a discussion on the number of components vs. their concentrations). Recall that processes represent at the desired level of abstraction the components of the biological system specified, and that the models are discrete (and abstract from temperature, pressure, etc.). The initial state above represents then the initial conditions of the biological entity under experimentation.

Trajectory simulation can be repeated, yielding possibly different outcomes: different experiments are carried out, and various behavioral or statistical analysis are possible on the collected “virtual” results.

Technically, trajectories are computed by including Gillespie’s stochastic simulation algorithms (SSA) in the semantics of the calculus, which will be outlined in [Sect. 3](#). Roughly, SSA stochastically selects the pair of complementary actions in the whole process, which are ready to fire. Also, it determines the time at which the resulting synchronization will occur, namely its apparent rate. Note that synchronizations correspond to reactions, so the actions that occur along a channel a will have all the same rate, often called the *basal rate*. As will be clear later on, SSA then suitably manipulates basal rates to compute the apparent rates of transitions, taking into account all the synchronizations possible (besides a couple of random numbers).

Several simulation tools have been developed, such as the Stochastic Pi-calculus Machine (Phillips and Cardelli 2007), to cite one. These tools represent a viable computational support for the simulation of phenomena at a sufficiently detailed level of description. See [Sect. 5](#) for details.

Next, the results of an experiment carried out by using a tool that implements (a variant of) the stochastic version of BCCS are illustrated.

Example 3 Consider again the fragment of Glycolysis in [Example 2](#), which is taken from the specification of almost all the metabolic pathways of a virtual cell, called VICE (Chiarugi et al. 2007), which is discussed in more detail in [Sect. 5](#). As said, to obtain a quantitative description of a metabolic pathway, it is necessary to link each transition, and in particular its apparent rate, to a measurable biological parameter. The underlying idea is to associate a channel with a basal rate drawn from the specific (microscopic) rate constant of the described biochemical reaction.

In the original paper (Chiarugi et al. 2004), these basal rates were estimated starting from the constants of Michaelis–Menten kinetics (Fersht 1999; Hammes and Shimmel 1970), and taking care of the control strength of the enzymes involved in a pathway (Fell 1997). These values proved accurate enough, as confirmed also by recent findings (Zhao et al. 2008). The

simulation *in silico* of VICE showed, for example, that it reaches its steady state, which is resistant to nonshocking changes in the external environment, for example, in the feeding regimen. This property mimics the homeostatic capability, typical of real cells, which require it in order to regulate their internal medium. Homeostatic biological systems oppose external environment change to maintain their internal equilibrium and succeed in reestablishing their balance, while nonhomeostatic ones eventually stop functioning.

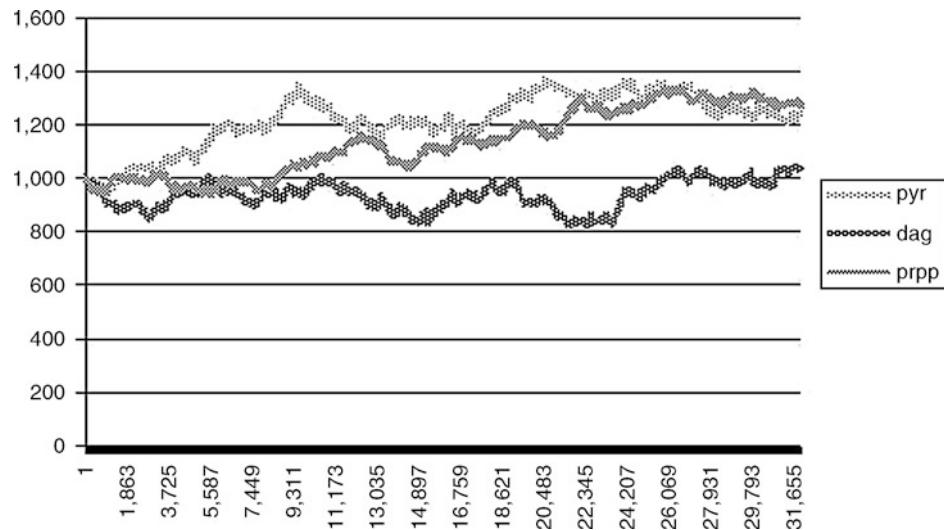

The steady state is manifest when the time course distribution of metabolites reaches a plateau after a certain initial period of time, *in silico* after some transitions. This is shown for VICE in **Fig. 3** for three selected metabolites, whose behavior is rather informative, because they represent critical nodes in the entire metabolic network. Note that **Fig. 3** is affected by white Gaussian noise, because the whole model is stochastic, as it embodies Gillespie's SSA.

The first model of a biological system based on a stochastic process calculus, namely the Stochastic Pi-calculus, is in Priami et al. (2004). It extends the Pi-calculus (Milner 1999), associates rates with channels, and enhances its semantics as sketched above (Hillston 1996; Priami 1995).

The Pi-calculus is a nominal calculus that models systems of concurrent communicating processes whose communication network may change in time. Nominal calculi have the distinguished notion of *name*, roughly an identifier that denotes a shared resource, possibly a channel itself. A process that possesses a name can communicate it to another process across the system, but disclosing a name is constrained by *visibility rules*. Typically, a name, say n , is often private to a group of processes, so the resource it denotes can be referred to only by them; for example, when n denotes a channel, it is the mean for each member of the group to communicate with the others. Instead, a process P not belonging to the group cannot use n , unless the group is enlarged and n communicated to P . Technically, this is done by carefully handling the visibility scope of the name n , so to avoid any possible mismatch or ambiguity or leaking of n to other processes. A name n is declared private to a (group of processes) Q by writing $(vn)Q$; in words,

Fig. 3

Time course distribution of pyruvate (pyr), diacylglycerol (dag), phosphoribosylpyrophosphate (prpp). The concentration of metabolites is plotted vs. the number of transitions.

n is restricted within Q (more precisely, v acts as a binder for n , whose scope is Q , with some *caveat* (Milner et al. 1992), among which α -conversions to avoid name captures).

Clearly, communications are not simple synchronizations, like in BCCS, but also exchange information. As the semantics of the calculus is very rich, instead of giving the details, only a couple of examples are shown.

Notationally, $\bar{n}\langle m \rangle$ is the output action of the name m , through the channel denoted by n ; with $n(x)$ one can represent reading a name that replaces the place-holder x . So, a process $\bar{n}\langle m \rangle.Q \mid n(x).P$ will perform a communication that also has the effect of binding within P (suitable occurrences of) the place-holder x to the received name m . If m denotes a channel, the communication additionally alters the interconnection topology of the system. As a matter of fact, now P , rather P with x instantiated to m , is linked to channel m as well, even though m originally was not a channel in the interface of P .

To exemplify the disclosure of a restricted name, consider the process $(vm)(\bar{\ell}\langle m \rangle.R \mid m(x).P(x))$ in which the name m is restricted, so both processes in parallel can use it (as a short-hand, one can write $P(x)$ to indicate that the place-holder x occurs within P). Consider now the following trace, starting from the above process, in parallel with two other processes $T = \ell(y).\bar{y}\langle n \rangle.0$ and Q , neither of which can know m . The first transition is a communication of m to T , and it enlarges the scope of the restriction to include $\bar{m}\langle n \rangle.0$ (the *extruded* name is highlighted), but not Q . A further communication on the channel denoted by m is now possible, between processes under the restriction, that is, *within* the same group.

$$\begin{aligned} & (vm)(\bar{\ell}\langle m \rangle.R \mid m(x).P(x)) \mid \ell(y).\bar{y}\langle n \rangle.0 \mid Q \xrightarrow{\tau} (vm)(R \mid m(x).P(x) \mid \bar{m}\langle n \rangle.0) \mid Q \xrightarrow{\tau} \\ & (vm)(R \mid P(\bar{n})) \mid Q \end{aligned}$$

The system described in Priami et al. (2004) consists of a gene regulatory network with positive feedback. It involves two genes, RNA transcription and degradation, and positive feedback. Name machinery plays an important part in the positive feedback of protein A onto protein TF , both coded by the genes of the system. Actually, a complex is formed by the disclosure of the private channels (backbones) of A to TF , basically through the same extrusion mechanism mentioned above. Then, A and TF can interact along newly shared, highly efficient channels, boosting the role of TS in the reciprocal promotion, thus originating the positive feedback. The results of computational simulations clearly show the expected uprise of A in the presence of TF , confirming experimental data.

Sharing restricted channels can be conceived as a natural mechanism for implementing a notion of compounded complex, as is often the case in computer system modeling. However, this seems to be neither completely satisfactory in biological systems modeling, nor expressive enough to faithfully and directly describe compounds, compartmentalized cells, and membranes. In the next subsection, a few calculi will be illustrated with operators explicitly for these features.

2.3 Membrane Systems

Distributed computational paradigms often consider software applications that can move around through the interconnection network, crossing environmental boundaries and interacting at different locations – think of the Internet applications that move along the net and enter/exit from sites where they are executed. The concept of *distributed ambient* has been

formalized in the AMBIENT calculus (Cardelli and Gordon 1998). A process P is wrapped within a named environment, called *ambient*, resulting in $n[P]$. Within the ambient n , the process P may contain other (nested) ambients and standard communications actions. Processes can move along the nested ambients by executing the actions *in* n and *out* n , and also dissolve through *open* n . The ambient name referred to by the actions implements a capability discipline: The name of an ambient must be known in order to interact with that ambient. Communication happens only within the same ambient. The premiseless rules in the upper part of Fig. 4 are part of the semantics of the calculus.

Quite naturally, ambients may be interpreted as membraned components, for example, cells. Indeed, a system of membraned components has a nested structure and its components often move, interact, and also transform, for instance by dissolving or inglobing membranes.

A first proposal in this direction is the BIOAMBIENT calculus (Regev et al. 2004), which extends the ideas of AMBIENT in several directions to better suit biological interaction; a stochastic version of it is in Brodo et al. (2007), which exploits the SSA algorithm. In BIOAMBIENT, communications can cross ambients in a controlled way, as happens in intra-membrane interaction. The actions for ambient interaction occur synchronously through different channels/modalities, and merging of ambients/membranes has been introduced. Two rules of the operational semantics are in Fig. 4, which may help in understanding its peculiarities. Just as in nominal calculi, communication actions have “directions,” for example, $\bar{a}(m)$ represents sending the name m through channel a , while $a(x)$ is the complementary action of receiving, but they are controlled to mimic membrane permeability. See, for example, the parent-to-child communication rule ($p2c$), where the output with modality $p2c$ matches the input with modality $c2p$. Two ambients can also merge, giving rise to a new ambient, by modeling the analogous activity on membranes. This is specified by the rule (mrg) in Fig. 4, where the name c associated with the actions $merge+ c$ and $merge- c$ identifies the two membranes that will fuse together. The “direction” $+/-$ (yet another usage of $+ !$) names the resulting membrane m , as $merge +$ occurs within m .

The pragmatics of BIOAMBIENT have been illustrated through several proof of concept examples, such as transport layers, protein complexation, and reversible enzyme activity, (Regev et al. 2004). The last one will be briefly surveyed below.

Example 4 Suppose one has the following parallel composition of membraned components corresponding to the enzyme and the substrate molecule:

$$\text{enzyme}[E] | \dots | \text{enzyme}[E] | \text{molecule}[S] | \dots | \text{molecule}[S]$$

The enzyme E either accepts within its ambient the substrate membrane or an already

Fig. 4

An extract of AMBIENT and BIOAMBIENT semantics.

$$\begin{array}{c}
 \frac{m[in\ n.Q|R]\ | \ n[P] \rightarrow_{\tau} n[m[Q|R]|P]}{n[m[out\ n.Q|R]\ | \ P] \rightarrow_{\tau} m[Q|R]\ | \ n[P]} \quad (in) \qquad (out) \\
 \frac{n[P]\ | \ open\ n.Q \rightarrow_{\tau} P\ | \ Q}{m[merge+\ c.P|Q]\ | \ n[merge-\ c.R|S] \rightarrow_{\tau} m[P|Q|R|S]} \quad (open) \qquad (mrg) \\
 \frac{n[p2c\ \bar{a}(b).P\ | \ m[c2p\ a(x).Q(x)]] \rightarrow_{\tau} n[P]\ | \ m[Q(b)]}{n[P]\ | \ m[Q|R|S]} \quad (p2c)
 \end{array}$$

transformed product molecule. Accordingly, it can then either expel the product, or the original substrate and revert to the original state:

$$\begin{aligned} E &::= \text{accept e-s-bind}.ES + \text{accept e-p-bind}.ES \\ ES &::= \text{expel unbind}.E + \text{expel react}.E \end{aligned}$$

The substrate S can initially only enter the enzyme environment (becoming X), and then, synchronizing with the enzyme, it can either revert to the substrate or exit as the product P . In turn, the product can again be re-processed by the enzyme.

$$\begin{aligned} S &::= \text{enter e-s-bind}.X \\ X &::= \text{exit unbind}.S + \text{exit react}.P \\ P &::= \text{enter e-p-bind}.X \end{aligned}$$

Given a single enzyme and substrate molecule, a possible trajectory (abstracting from the stochastic machinery) follows, in which the substrate transforms into the product:

$$\begin{aligned} &\text{enzyme}[E] \mid \text{molecule}[S] \rightarrow \\ &\text{enzyme}[\text{accept e-s-bind}.ES + \text{accept e-p-bind}.ES] \mid \text{molecule}[\text{enter e-s-bind}.X] \rightarrow \\ &\text{enzyme}[(\text{expel unbind}.E + \text{expel react}.E) \mid \text{molecule}[\text{exit unbind }.S + \text{exit react}.P]] \rightarrow \\ &\text{enzyme}[E] \mid \text{molecule}[P] \end{aligned}$$

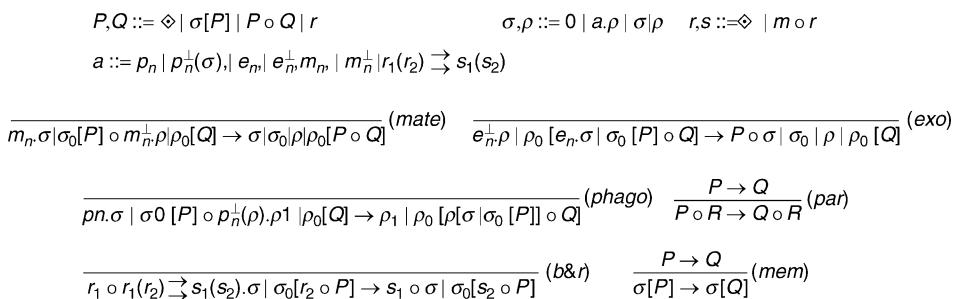

A further step in the direction of modeling membranous components and the interaction mediated by membranes are the BRANE calculi (Cardelli 2004; Miculan and Bacci 2006). These are a modular set of process calculi expressing different details of membrane activity, and associated logics for describing system properties. An important novelty is that membranes themselves exhibit a behavior.

For brevity, a reduced instance of BRANE, namely sBRANE, is considered below. Its (simplified) syntax is in the topmost part of Fig. 5, which also displays the rules of its qualitative semantics (neither quantities of reactants nor stochastic rates are considered).

A few comments are in order. In sBRANE, membrane complexes (P, Q, \dots) and membrane behavior (σ, ρ, \dots) are kept apart. The complex $\sigma[P]$ consists of an (active) external membrane layer σ and of a complex P contained inside the membrane. The symbol \diamond denotes the null membrane complex.

Fig. 5

Syntax and operational semantics of sBRANE, a simplified BRANE calculus.

The complex $P \circ Q$ is obtained by putting in parallel P and Q , while $m_1 \circ \dots \circ m_k$ is the complex consisting of a multiset of molecules (r, s, \dots) .

Membrane complexes interact through the membrane layer σ . This can either perform no action if it is 0, the empty one; or perform an action prefixing a layer a . σ ; or behave as two parallel layers $\sigma|\rho$ (other structure can also be added). Here, one can consider the actions $phago_n$ (in brief p_n) and exo_n (in brief e_n), together with the coactions $p_n^\perp(\sigma)$ and e_n^\perp ; the name n therein constrains the occurrence of these actions in communications, like in BIOAMBIENTS. Moreover, action m_n and coaction m_n^\perp model *cell merging* (although this can be expressed by (*phago*) and (*exo*), only (Cardelli 2004)).

A membrane complex $\sigma[P]$ can enter another complex $\rho[Q]$, if σ can execute a phago p_n action and ρ the corresponding coaction $p_n^\perp(\rho)$ with the same n (see rule (*phago*)). As a result, $\sigma[P]$ is enclosed within a membrane with part ρ . A nested membrane complex $\rho[\sigma[P] \circ Q]$ allows the subsystem P to leave the $\rho[\dots]$ membrane complex if σ and ρ are ready to execute e_n and e_n^\perp , respectively, as dictated by rule (*exo*). Membranes and their contents merge according to rule (*mate*). A membrane complex can also proceed autonomously in a system or within a membrane (rules (*par*) and (*mem*)). As standard, $|$ and \circ are associative and commutative with 0 and \Diamond as neutral elements.

Finally, rule (*b&r*) illustrates a kind of membrane permeability. Being molecules r_1 and r_2 outside and inside the complex, respectively, and being the membrane sensitive to them (they appear in the membrane specification as arguments of the \Rightarrow operator), then the rule can be applied and its effect is to bring inside the complex the molecule s_2 (also an argument of \Rightarrow), while r_1 and r_2 are consumed.

The next example illustrates the use of the chosen calculus in modeling the behavior of systems with membranous components. One can consider (the first steps of) a reference model of viral infection.

Example 5 Via phagocytosis, the virus enters the cell wrapped by a membrane. The external membrane of the virus then merges with a component of the cell, the *endosome*. Finally, through an exocytosis, the viral *nucleocapsid* and the viral RNA it contains are directly released in the *cytosol* of the cell. These first steps on the viral infection can be modeled as follows:

$$\begin{array}{lll} virus = p_a.e_a [nucap] & nucap = capsid[vRNA] & capsid = p_b \mid bud \mid disasm \\ cell = p_a^\perp(m_a) \mid e_b^\perp [cytosol] & cytosol = endosome \circ CC & endosome = m_a^\perp \mid e_a^\perp [\Diamond] \end{array}$$

The virus membrane is ready to execute a phago p_a and an exo e_a action. Its content *nucap* will take part in later stages, and in turn has a membrane *capsid* that contains the RNA of the virus. The membrane *capsid* is ready to execute a phago action p_b , and two further actions *disasm* and *bud* that are not relevant for the initial steps of the viral infection. The cell membrane is ready for a phago $p_a^\perp(m_a)$ and an exo e_b^\perp action, with the latter modeling the reproduced virus that eventually leaves the cell. What is inside the membrane, *cytosol*, consists of two parts. The first is the endosome, which is a membrane complex that can merge, via an action m_a^\perp , with what has been “eaten” by the cell through a phago action. The endosome can also uncoat its content, via e_a^\perp , as soon as the virus provides a suitable coaction. The second component, *CC*, is not relevant here.

The initial configuration of the system is a complex composed by the virus and the cell. The following trace shows an endocytic pathway, consisting of phagocytosis, merging, and exocytosis. As expected, its last state shows that the genetic material of the virus floats within the cell (recall that *nucap* is defined as *capsid*[*vRNA*]).

$$\begin{aligned}
 p_a \cdot e_a[nucap] &\circ p_a^\perp(m_a) | e_b^\perp[m_a^\perp | e_a^\perp[\Diamond] \circ CC] \rightarrow \\
 e_b^\perp[m_a[e_a[nucap]]] &\circ m_a^\perp | e_a^\perp[\Diamond] \circ CC \rightarrow \\
 e_b^\perp[e_a^\perp[e_a[nucap]]] &\circ CC \rightarrow \\
 e_b^\perp[0[\Diamond] \circ nucap \circ CC]
 \end{aligned}$$

The last membrane and compartment oriented calculus that is surveyed is BETA BINDERS (Priami and Quaglia 2004), which builds over the Pi-calculus. It has a notion of ambient, called *box*, so a process has the form $B[P]$; boxes cannot be nested. The component B is a set of so-called *BETA BINDERS*, and represents the possibly modifiable interface of the box. The process P is a Pi-calculus process with standard communication actions, and with some additional actions that manipulate the interfaces. The description of a biological system is then rendered as a set of boxes in parallel.

More technically, a BETA BINDER $\beta(x : \Gamma)$ associates with the name x a set of channels through which the box can communicate with another box, and represents the interaction sites of the modeled membrane. A binder can be either active $\beta^h(x : \Gamma)$ or hidden $\beta^h(x : \Gamma)$, that is, either ready for or temporarily unavailable for interaction. The interfaces are manipulated through the actions $hide(x)$, $unhide(x)$, and $expose(x, \Gamma)$, the semantics of which is in Fig. 6 (the rule for *unhide* and some details are omitted). The first action hides the name x , rather the binder for x in the interface; the second activates a hidden x ; the third action makes x available for interaction by creating a binder for it in the interface (name captures are avoided).

A process P is essentially a Pi-process, and communication within a box is standard. Interaction between boxes is instead peculiar: it still occurs on a given channel, but it is not necessary to explicitly say on which. Suppose that one box has in its interface the BETA BINDER $\beta(x : \Gamma)$ and the other has the BETA BINDER $\beta(y : \Delta)$. The two boxes communicate along x and y provided that the sets Γ and Δ are compatible, according to a given notion. The simplest requires that Γ and Δ contain at least one common channel, that is, $\Gamma \cap \Delta \neq \emptyset$. This simple definition of compatibility contains the rule (*inter*) of the operational semantics in Fig. 6; besides this, others conditions can be given.

Here two further actions that can be used to implement a variety of membrane interactions of interest for biological modeling, namely splitting and joining boxes, are not discussed, and the interested reader is directed to refer to the original presentation (Priami and Quaglia 2004) for a discussion on their definition and usage.

The interested reader can find a stochastic semantics for BETA BINDERS in Degano et al. (2006).

Examples of virus infection, similar to the one presented for the sBRANE calculus, have also been modeled in Priami and Quaglia (2004). These illustrate a natural and expressive way of using the loose communication mechanism offered by BETA BINDERS to define which virus can interact with which cells.

Fig. 6

Some rules of BETA BINDERS.

$$\overline{B\beta(x : \Gamma)[hide(x).P|Q] \rightarrow B\beta^h(x : \Gamma)[P|Q]}^{(hide)} \quad \overline{B[\mathbf{expose}(x : \Gamma).P|Q] \rightarrow B\beta(x : \Gamma)[P|Q]}^{(exp)}$$

$$\overline{B\beta(x : \Gamma)[x(w).P|Q] \mid B\beta(y : \Delta)[y(z).R(z)|S] \rightarrow B\beta(x : \Gamma)[P|Q] \mid B\beta(y : \Delta)[R(w)|S]}^{(inter)} \text{ with } \Gamma \cap \Delta \neq \emptyset$$

3 Artificial Chemistry

In this section, the focus is on a process calculi-based representation of chemistry. First, some classical notions, in particular those connected with quantitative and stochastic modeling, are briefly discussed.

The dynamics of a chemical system are usually described by transformation rules annotated with quantities, known as Generalized Mass Action Laws (GMA) (Segel 1987). These rules define and are affected by the amounts, traditionally measured as concentrations, of the reactants produced and consumed. Remarkably, GMA deterministically govern the changes in a chemical system. For instance, the reversible interaction of molecules of species A and B generating molecules of species C is described as

This stands for the fact that quantities of A and B transform themselves into quantities of C with a rate k_1 (note the different use of $+$ with respect to the nondeterministic operator of the algebra of processes). The rate represents here a proportional constant that determines the amount of quantity transformed in the time unit, in proportion to the joint amount of A and B . Vice versa, C decays back into its constituents, proportionally to the amount of C and the rate k_2 . This reaction happens by the spontaneous activity of C . Generally, GMA model systems in terms of variations of continuous *concentrations* of species A , often represented as $[A]$.

Being $[A(t)]$, $[B(t)]$, and $[C(t)]$ the molecular concentrations (numbers of molecules per unit volume) at time t , the following system of ordinary differential equations (ODEs) corresponds to the above kinetic schema:

$$\frac{d[C]}{dt} = k_1[A][B] - k_{-1}[C] \quad \frac{d[A]}{dt} = -k_1[A][B] + k_{-1}[C] \quad \frac{d[B]}{dt} = -k_1[A][B] + k_{-1}[C]$$

Given initial conditions, the solution of the above system provides $[A(t)]$, $[B(t)]$, and $[C(t)]$. In the case of the spontaneous decay $C \xrightarrow{k} 0$, one can have $\frac{d[C]}{dt} = -k[C(t)]$, hence $[C(t)] = e^{-kt}[C_0]$, which is the well-known exponential law of decay, with $[C_0]$ as the initial concentration.

An extensive treatment of ODEs modeling chemical reactions is dealt with in Voit (2000). Although a valuable and widespread description tool, ODEs present methodological difficulties and rely on assumptions that do not suit all possible scenarios of interest.

Among the first ones, ODEs rarely can be solved analytically; numerical solutions are typically computationally expensive (beyond few tens of variables); and models can hardly be constructed in a compositional manner (the introduction of a new variable/molecule/reaction typically requires the redefinition of the whole model).

As for the necessary assumptions, in many phenomena it happens that extremely low concentrations, up to few molecules in a given volume unit, are responsible for relevant behavior emerging at the whole system level. Moreover, such limited amounts perturb the system so that it behaves in a way that is difficult to interpret deterministically, as is done for concentration variations. In the words of Wilkinson (2006), the deterministic approach fails to capture the nature of chemical kinetics, which at low concentrations is discrete and stochastic. (See also Wolkenhauer for a critical analysis on the adequacy of deterministic ODEs descriptions and the relationships between the continuous deterministic approach and the stochastic discrete one.)

A model accounting for the stochastic aspects of system dynamics can be defined analogously to GMA; its result is particularly suitable for modeling small volumes where only few

molecules interact (Gillespie and Petzold 2006; Van Kampen 1992; Gardiner 2001; Wilkinson 2006; Gillespie 1977). The model describes the *stochastic* time-course of *discrete* quantities, that is, the actual number of involved molecules, where rates represent the distribution probability that a selected reaction occurs at a given time-point. This approach leads to the definition of the chemical master equation (CME) (Voit 2000), which describes the interactions of N well-stirred chemical species S_1, \dots, S_N . By naming $x_i(t)$ the number of molecules of S_i at time t , one wants to model the time evolution of the vector $X(t) = (x_1(t), \dots, x_N(t))$ (sometime written X) from a given initial condition $X(t_0) = X_0$. Species interact by M uni- or bimolecular chemical reactions R_1, \dots, R_M . Each reaction R_i is characterized by two quantities: $a_i(X)$ and v_i , namely the *propensity function* and the *state-change vector*, respectively. The system changes because of the reaction R_i with a probability defined by $a_i(X)dt$. This probability is defined on top of a probability rate constant c_i , such that c_idt represents the probability that any two, or one, molecules that are randomly chosen among those reacting according to R_i will react in the time interval dt . By knowing c_i and summing over all the possible distinct combinations of R_i reacting molecules (addition law of probability), we can immediately see that if R_i is a unimolecular reaction $S_j \rightarrow products$, then $a_i(X) = c_i x_j$, while if R_i is a bimolecular reaction $S_j + S_p \rightarrow products$, then $a_i(X) = c_i x_j x_p$. When the reaction R_i occurs, the state vector $X(t)$ becomes $X(t + dt) = X(t) + v_i$.

The CME defines the variations of the probability associated with state changes of the system, which basically corresponds to the probability of reaching the state of interest X from any other possible state minus the probability, being in X , of leaving the state. A possible formalization is the following (see Voit (2000) for further details):

$$\frac{\partial P(X, t | X_0, t_0)}{\partial t} = \sum_{j=1}^M [a_j(X - v_j)P(X - v_j | X_0, t_0) - a_j(X)P(X, t | X_0, t_0)]$$

The CME consists of as many coupled differential equations as all the possible molecular reactions within the system, a number that is almost always prohibitively large. Additionally, even for very simple systems, the numerical solution of the CME is computationally hard, given that the transition probability matrix becomes rapidly untractable because of its dimensions (Smith 2005; Ermentrout 2002).

The stochastic formulation of the biochemical intracellular processes of the CME can be simulated by a Monte Carlo method, as proposed by Daniel Gillespie with his stochastic simulation algorithm (SSA) (Gillespie and Petzold 2006; Gillespie 1977). The algorithm determines a numerical realization of $X(t)$ as a function of t , called the *trajectory*, according to the probability values in the system. This realization has been proven to give an exact simulation of the CME. The SSA relies on homogeneous volume hypotheses and models reactions, but not diffusion.

Roughly, the idea behind Gillespie's algorithm can be recapitulated as follows (see provided references for technical details). Assume $P(t, \mu)dt$ is the probability that R_μ will be the next reaction and it will occur in the interval $(t_0 + t, t_0 + t + dt)$, with t_0 the current time. Then, one can get $P(t, \mu) = P_1(t) \times P_2(\mu, t)$, where $P_1(t)dt$ is the probability that the next reaction will occur in the interval $(t_0 + t, t_0 + t + dt)$, and $P_2(\mu, t)$ is the probability that the next reaction will be of type R_μ . Gillespie showed that $P(t, \mu) = a_\mu(X)^{-a_0(X)t}$, where $a_0(X) = \sum_{k=1}^M a_k(X)$ represents the sum of the probabilities of all possible reactions. Then the time of the next reaction is $t = (1/a_0(X)) \times \ln(1/r_1)$ and the next occurring reaction R_μ is identified by μ as the smallest integer satisfying the relation $\sum_{k=1}^\mu a_k(X) > r_2 a_0(X)$. Here r_1 and r_2 are two random numbers that make the system stochastic. Summing up the application of SSA consists of repeating the steps (2–4) below as many times as needed, after the initialization step (1):

- (1) Initialize the initial time t_0 and initial conditions of the system X_0
- (2) Evaluate all the $a_k(X)$ and $a_0(X)$
- (3) Generate t and μ as indicated above
- (4) Replace the time t_0 with $t_0 + t$ and the number of molecules X with $X + v_\mu$

Since $P(t, \mu)dt$ follows an exponential distribution, system dynamics is memory-less. Importantly, the next reaction and time determined are *exactly* coherent with the probability distributions considered. Once the time and type of the next reaction are determined, time and quantities are updated as prescribed by the reaction and the algorithmic selection of the next reaction and time can be iterated.

As mentioned in [Sect. 2.2](#), the stochastic extensions of process calculi are generally based on SSA and its variations. As said, in those settings SSA determines, beyond the elapsed time, the processes that will interact next. The operational semantics then rules the steps of the system. This amounts to saying that SSA and the operational semantics select a trajectory, exactly mimicking the probability distributions described by the rates of the model.

A thorough investigation about the feasibility of a computational modeling of chemistry, and also of biochemistry, is in the work by Cardelli ([2009](#), [2008](#)). A shallow survey follows, in particular considering some examples showing how to model typical chemical reactions, which are often taken literally from the above papers. These examples also describe how some phenomena are best captured by stochastic approaches. Then, some results about the relations between stochastic and deterministic modeling are mentioned. Also, the use of some new features added to the calculi seen so far, which are needed for modeling certain forms of complexation and decomplexation typical of biochemistry, will be illustrated. Finally, the computational expressiveness of the calculi adopted shall be discussed from a theoretical point of view. This allows one to characterize which class of behavior can be expressed by the programs in that formalism and which cannot, and which properties can be mechanically proved about that class.

Cardelli introduces *interacting stochastic automata* to represent species and their capabilities in a graphical notation. For brevity, some of their features will be discarded here, and their *simple* version is expressed as stochastic BCCS processes, each modeling a (state of) a molecule (in their full form interacting stochastic automata exhibit a dynamical interface of communication capabilities, similarly to nominal calculi, mentioned in [Sect. 2.2](#)).

The reactions of kind $A \xrightarrow{r} B$ are *first order*, those like $A + B \xrightarrow{r} C$ are *second order*. Concentrations follow the mass action law $\frac{d[A]}{dt} = -r[A]$ in first-order reactions, and $\frac{d[A]}{dt} = -r[A][B]$ in second-order reactions, under the assumption of working with a fixed interaction volume and a *well-stirred* solution (diffusion effects are then neglected because they are immaterial; refer also to the assumptions of SSA). Once the volume is fixed, the conversion between numbers of molecules and concentration is mediated by Avogadro's number. Three-way reactions are not considered here because they are unlikely to occur.

A molecule performing a first-order reaction waits for a delay, according to a negative exponential distribution, and then reacts. Technically, in this setting, such an action cannot reduce to a synchronization between two processes, because it is performed by a process in isolation. Usually, one assumes there is an internal action annotated with a suitable rate, representing an *ad hoc* stochastic delay construct (note that rates are here associated also with internal actions, and not only with channels). For instance, the decaying process $C \xrightarrow{r} 0$ can be modeled by the process

$$C \xrightarrow{\cdot} \tau_r.0$$

Second-order reactions, for example, $A + B \xrightarrow{r} C$, follow the above mentioned law of mass action, and can be represented as standard processes, for example, $A \doteq a.0$ and $B \doteq \bar{a}.C$ with the rate r associated to the channel a . Note that the choice of A becoming 0 and B becoming C is arbitrary. A case that requires a bit of care is a second-order reaction within a homogeneous population, for example, $A + A \xrightarrow{r} C$. In this case, each A can interact in two symmetric ways with other A 's, for example,

Since two A 's are transformed by each reaction, one can have $\frac{d[A]}{dt} = -2r[A]^2$.

Other examples of reproducible behavior at different levels of abstraction are oscillators, feedbacks, and even operators of the Boolean algebra (see Cardelli (2009) for details). Also zero-order reactions are considered, which obey a law of mass action independent of concentrations, for example, $\frac{d[A]}{dt} = r$. These represent a sort of constant growth of a population, and have no straightforward chemical correspondence, although they show a dynamic similar to that of saturated enzymes.

Some examples facilitate the intuitive understanding of how far one can go with the process-based representation of chemistry. By analyzing the *collective* behavior of large populations of processes/reactants, it is easy to observe stochastically emerging behaviors due to a small number of specific processes spawned in the large populations. One can also observe emerging behavior that can be assimilated to continuous and deterministic variations, as they concern the fluctuations of large populations.

Consider the so-called *celebrity* kind of behavior:

As soon as any two A 's synchronize on a , one of the two decides to become B , snobbishly “differentiating” itself. Analogously, as soon as any two B 's synchronize, one of them differentiates by becoming A again. The overall behavior of a system of an equal number of A and B , with equals rates for channels a and b , exhibits a dynamical equilibrium, with the expected stochastic fluctuations. The results are in [Fig. 7](#), and were obtained using SPiM, the Stochastic Pi-calculus Machine (Phillips and Cardelli 2007).

Similarly, *groupies* try to maintain their state as far as they are able to synchronize with others in the same state:

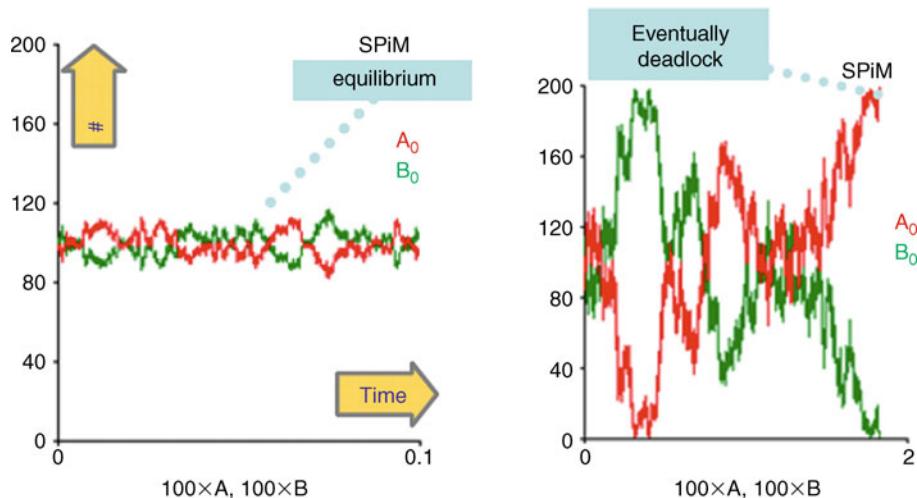

Under the quantities assumed, rates and number of molecules, the overall behavior tends to uniformity where eventually all the groupies end up in the same state, either A or B , where no further reaction is possible.

It is quite instructive to observe the behavior of the same population of groupies with just one celebrity, [Fig. 8](#). The presence of a *single* molecule influences the macroscopic behavior of the system that passes through a deadlock-free random walk: Whenever all groupies get uniform, the celebrity distinguishes itself, followed by some imitating groupie.

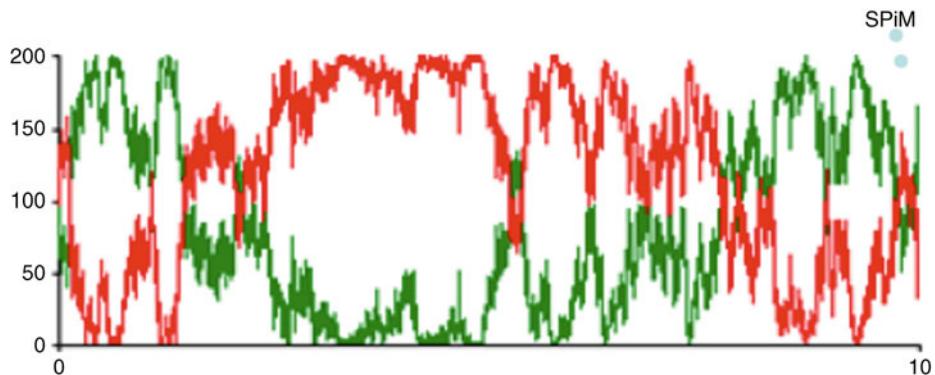

In order not to underestimate the differences between stochastic and deterministic models, it is worth comparing ODEs and process calculi-based models on systems with minimal quantities of “destabilizing” molecules. [Figure 9](#) compares some ODEs (top row) with processes (bottom row). The leftmost column refers to the example of [Fig. 8](#), which exhibits the most evident differences. The other two cases deal with similar examples, in which the number of molecules increases moving rightward, and the groupies offer growing resistance

Fig. 7

Celebrities (left) and groupies (right) (from Cardelli 2009).

**Fig. 8**

Groupies and one celebrity (from Cardelli 2009).

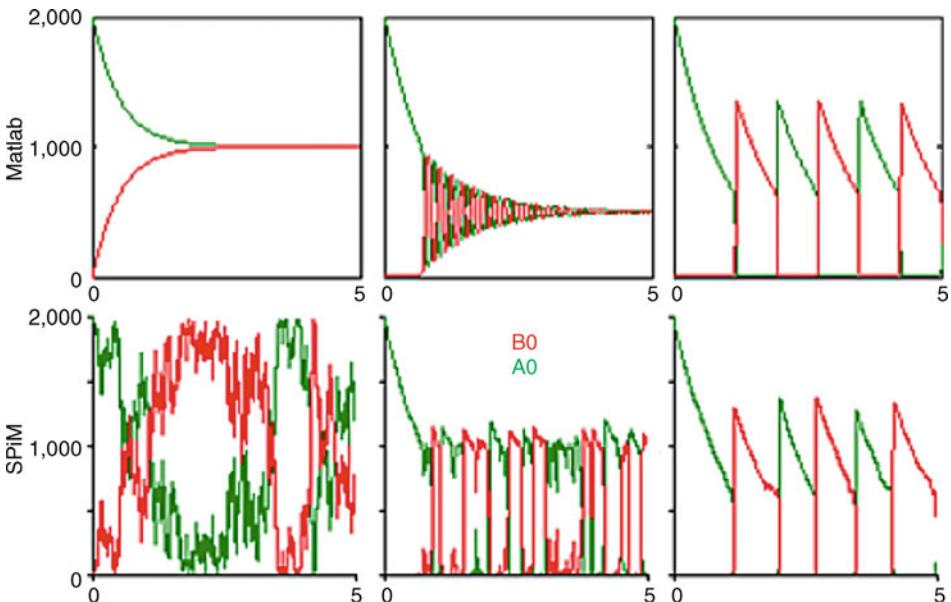

to changes. Consequently, the stochastic behavior tends to assimilate to the continuous case, and the differences between the two approaches blur moving towards the right. As a matter of fact, some phenomena are inherently discrete and stochastic and cannot be faithfully modeled by continuous and deterministic methods.

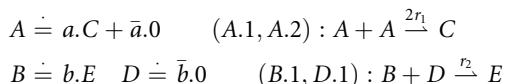

It is now interesting to link the usual representation of chemical reactions with the process-based representation, through a correspondence between the semantics of the two representations. This involves giving both deterministic (ODEs) and probabilistic (CTMC) semantics to chemistry, as done in Cardelli (2008), starting from a formalization of the language of chemical reactions. Note that while the chemical notation is “reaction centric,” that is, the single reactions are listed, the process notation is “reactant centric,” as it consists of a list of reactants with an associated behavior. Then, a mapping is needed from processes to the

Fig. 9

Stochastic and deterministic models are not the same (from Cardelli 2009).

chemical reactions they represent, and backward. We illustrate it through the following example. Consider the processes in the left column below, which will be put in correspondence with the second-order reactions in the right column:

Here r_1 is the rate of channel a and r_2 the rate of channel b (recall that $+$ has a different meaning in reactions and in processes). As part of the mapping, reactions are annotated with information about the reactants/processes that generate them: here the label $(A.1, A.2)$ denotes the two different actions of the same process A . This defines the reaction as occurring among homogeneous reactants, and hence the rate can properly be determined as $2r$. For passing from processes to reactions, these can be labeled with a name that, when translating to processes, may well become the name of the channel representing that specific reaction. This implies that each channel occurs within two processes only (and hence the set of processes is somewhat larger than the set of reactions).

Having defined a language for reactions and one for processes and a way for passing from one to another, one is obliged to prove a correspondence between them. This requires some technical machinery and will not be detailed here. The relevant steps are only sketched here.

For the discrete interpretation of the models, both reactions and processes can be given a CTMC as semantics. This can be straightforwardly derived once the initial conditions are fixed, that is, the number and the species of reactants/processes initially present in a system. For processes, the CTMC semantics follows from the LTS (which turns out to be a graph) associated with the initial state, that is, the initial set of processes composed in parallel. For

reactions, the CTMC semantics follows from a graph representing the possible dynamics of the system of reactions. Relying on a sufficiently analogous structure, the two semantics are then proven equivalent under a suitable equivalence notion. This guarantees that the translation from reactions to processes and vice versa is correct with respect to discrete semantics.

The semantics of the continuous interpretation of the models is the set of ODEs determined according to the Generalized Mass Action Laws. As seen above, once a standard interaction volume is fixed, it is possible to read the number of interacting processes and of reactants as (continuous) concentrations. This requires one to consider the initial conditions as concentrations and to suitably convert rates. Other technical considerations are needed for the hypothesis of continuity in the variation of concentrations. Finally, it has been proven that the continuous semantics for processes is equivalent to the ODEs one.

One can stress again that the often neat correspondence between processes and ODEs models outlined above should not make one believe that the two approaches are freely interchangeable. Indeed, it has been seen that examples of phenomena are intrinsically discrete and stochastic, while others are better modeled by continuous approaches.

We now have a very quick overview of biochemistry and the features required to model it, following Cardelli (2009). Typical biochemical reactions include the creations of complexes, which are best modeled with calculi more expressive than BCCS. A *complex* is obtained by two molecules that interact through complementary reaction sites, a shared channel in these terms, and bind together. As a consequence, those reaction sites are no longer available for further complexations. Furthermore, a complex can split back into the original components, making reaction sites available again. Relevant examples of complexation and decomplexation came from enzymatic activity. Typically, this consists of bounding the enzyme with the substrate, and then splitting the obtained compound either back into enzyme and substrate or, much more likely, into enzyme and product.

Such a notion of composition that preserves the identities of the components cannot be easily represented by BCCS, as so far defined. However, it is sufficient to add a naming mechanism, similar to that of Pi-calculus mentioned in [Sect. 2.2](#), to obtain the needed expressiveness. Processes of such a calculus are a basic ingredient of the so-called *polyautomata*. These have explicit complexation and decomplexation channels and rates, and they also maintain a state with information about performed complexation actions. When two processes synchronize on a complexation channel, the channel is recorded in a binding list that prevents us reusing it. Moreover, these communications associate a brand new name, say n , with the synchronizing processes, so n exactly identifies the two. Then, only the two processes that have been bound together can further synchronize through the unique name n , by performing a decomplexation action that restores the original components.

Other than complexation and detailed enzymatic activity, processes corresponding to polyautomata have been used to model polymerizations as well.

From the computer science point of view, a natural question to ask now is whether the additional expressive power obtained through the naming machinery is only a matter of pragmatics or if it has an intrinsic computational meaning. More precisely, it is interesting to know whether BCCS is Turing-complete, and if not which extensions are required. Roughly, a Turing-complete, or *universal*, formalism can compute through its programs all the functions that the programs of any other formalism can, often called *the computable* functions (typically, a function is such if it is computed by a Turing machine). Note that the programs are all finite, are made of a fixed finite number of symbols, and can be mechanically executed, with no limitations on the number of steps or on the size of the data they operate on.

This is the case with the programs, viz. the processes. A well-known result of computability theory is that there exist functions that are not computable in this sense. In particular, one cannot mechanically decide, in a finite amount of time, if the execution of a program will never halt, by only looking at the text of the program itself (the so-called *halting problem*).

The question of the formal expressive power of chemistry was first addressed by Magnasco (1997), and then studied by Busi and Gossieri (2006) for the BRANE calculus, by Soloveichik et al. (2008) using the different formalism of Minsky's register machine, and by Cardelli and Zavattaro (2008) for calculi such as those discussed above. Briefly, a first answer is that (a variant of) BCCS is *not* universal, in spite of the intuitions of Magnasco (1997). In chemical terms, this can be rephrased by saying that chemistry can implement, with a finite number of species, no Turing-complete formalism. It cannot thus be used to compute all the computable functions. Intuitively, the reason is that one can decide in finite time whether a certain molecule will be produced, so contradicting the undecidability of the halting problem. (Instead, chemistry with an *unbound* number of species is Turing-complete, but clearly its "programs" are no longer finite, nor do they use a finite number of symbols – nor are they very realistic, either!)

When enhanced with the association and dissociation actions discussed above, BCCS becomes universal (Cardelli and Zavattaro 2008). (Note in passing, these two actions cannot therefore be encoded in BCCS, while they can be encoded in the full CCS, which is known to be Turing-complete.) In other words, biochemistry, which includes operations of complexation and decomplexation formalized as polyautomata, is universal.

4 Formal Analysis of Models

One of the distinguishing features of the presented calculi is that a process can be *executed*, and more generally, *automatically processed*. An example of the first modality is the *simulation* of the modeled reality, of which a few examples have been shown. An example of the second kind is *reasoning* on a process, so as to investigate, prove, or disprove some of its properties, which hopefully are in correspondence with some properties of the modeled reality.

A few techniques that can be fully automated or supported by mechanical tools are briefly reported here. These techniques have been largely investigated in computer science in order to provide means for proving properties of software and hardware systems, and they can usually be smoothly applied also to the formalisms for modeling biological entities. Traditionally, these are techniques based on qualitative models, for example, for checking whether a given condition, a deadlock, or an error condition can ever occur in a system. More recently, and particularly following the development of the quantitative models for systems biology, there are proposals that take into account quantitative models, too.

Theorem proving consists in devising a *proof* for a given fact within a formal system. It often requires human supervision and has been generally applied to well-defined contexts, like restricted topics of mathematics and other sciences. It requires a precise domain knowledge, as well as nontrivial search and heuristic strategies implementing some forms of reasoning, for example, induction. It has not generally been applied to system biology and it will not be discussed any further; for an example, see Paulson (1989).

Model checking is instead a technique that can be carried out in a largely automated way. It was defined independently by Clarke and Emerson (Clarke et al. 1986) and Sifakis (1982) in the early 1980s. In its general formulation, model checking consists of verifying whether a

(finite) structure is a *model* for a given property, expressed in a suitable logic. The result can either be positive or negative, in which case a counterexample is returned.

In this case, it consists of checking whether the semantics of a process—that is, its LTS—fulfills a property of interest.

Generally, the logic-expressing properties predicate over LTS; hence, they can also have predicates referring to events that may happen during system evolution, besides the classical Boolean operators such as conjunction, disjunction, and the like. A few operators of the *computation tree logic (CTL*)* (Emerson and Sistla 1983), a well-known logic of this kind, will be considered. A formula f can be an atomic proposition p (which usually depends on the application context), the negation $\neg f$ or the conjunction $f_1 \wedge f_2$ of formulas. A formula holds for a specific state s of the given LTS (the semantics of the logic is a Kripke structure):

$$s \models f$$

Formulas then grow by using modal operators: X is a “next state operator” and is used together with the quantifiers A , always, and E , exists. For example, one can write the formula

$$s \models A X f$$

which is true if and only if f holds in all the states s' reachable after a single transition from s , in symbols if and only if $\forall s'. s \rightarrow s' \ s' \models f$.

The method to verify if the above simple formula is true suggests how to automatize the process of checking whether a given structure is a model for the formula at hand. One mechanically builds the relevant LTS, exploiting the operational semantics. The formula is then verified, often by proceeding by structural induction on it and by exploring the LTS, as done for the formula above. The need to visit the LTS (or to incrementally generate pieces of it when needed) is even more evident for formulas with an “eventually”-like operator $\Diamond f$: there will be a state in the future fulfilling f (see below for a formal definition).

Different working hypotheses, like the finiteness of the LTS and the choice of the logical operators available, lead to different decidability results. This kind of logic is generally nonconclusive in its full formulation (there is not a general algorithmic procedure to check every possible formula against every possible structure).

In Micalan and Bacci (2006), a modal logic for reasoning over qualitative BRANE CALCULI models was introduced, and states are direct processes. Beyond classical Boolean operators, it also consists of operators that predicate over the structure and, like CTL, over the behavior of BRANE (see [Sect. 2.3](#)) processes. Skipping a few technical details, there are structural formulae, like $f_1[f_2]$, the intuition of which is that a complex consists of a membrane fulfilling f_1 and of an internal complex fulfilling f_2 ; the already seen $\Diamond f$, a process can evolve to a state where f is fulfilled; and a modal formula over the structure $\star f$, a process has a sub-term that fulfills f :

$$P \models f_1[f_2] \text{ iff } P = \sigma[Q] \wedge \sigma \models f_1 \wedge Q \models f_2$$

$$P \models \Diamond f \text{ iff } \exists Q. P \rightarrow^* Q \wedge Q \models f$$

$$P \models \star f \text{ iff } \exists Q. P \downarrow^* Q \wedge Q \models f$$

with $P \rightarrow^* Q$ indicating a state Q reachable in zero or more transitions, and \downarrow^* defining a suitable notion of sub-term, typically Q can occur anywhere within P .

An example of use of the logic follows. In settings similar to those of [Example 5](#) about viruses and cells, the following statement can be verified by model checking:

$$\text{Infectable_cell} \models \text{Virus} \triangleright (\diamond \text{Infected_cell})$$

Here *Infectable_cell* is a process modeling a cell that can be infected, *Virus* is a formula fulfilled by processes modeling a given virus (e.g., a formula representing its structure, say), and *Infected_cell* is a formula satisfied by processes modeling infected cells.

Overall, the above formula expresses the fact that an infectable cell of the specified type can eventually become infected if exposed to a virus of the specified type. (Intuitively, the formula $f_1 \triangleright f_2$ is fulfilled by all the processes that, whenever composed with a process fulfilling f_1 , form together a complex fulfilling f_2 .)

The full logic is not decidable, but subsets of it can be chosen that are decidable, hence allowing for fully automated model checking (under the hypothesis of finiteness of the LTS).

Other approaches involving model checking for biological systems are those based on a combination of qualitative and quantitative properties, where quantities are understood as probability values and time. One example is in Kwiatkowska et al. (2008): the reference LTS has associated probabilities, and properties are expressed in suitable temporal logics with probabilities, for example, Aziz et al. (2000) and Baier et al. (2003). The kind of expressible properties talk about the “probability that an event *eventually* occurs” or the “probability that an event occurs within t time units.” Experiments can be done using the PRISM probabilistic model checker (Hinton et al. 2006).

It is worth pointing out that model checking appears to be a mature verification technique, although a full quantitative verification is still an open research topic. Thus, this technique appears adequate to be fruitfully exploited in systems biology. A successful example is shown by the work of Fages and Soliman (2008), which however is carried on a rule-based and reaction-centric approach, rather than the reactant-centric approach surveyed in this paper. A system is given three different semantics, based on ODEs, discrete stochastic processes and Boolean. The last semantics is a sort of “flat” quantitative semantics that only admits the presence or the absence of a component. It is fruitfully used, for example, in checking causal relations among the metabolites of a pathway. Properties can also be expressed by a kind of temporal logic that can express standard qualitative properties (so considering the Boolean semantics) and semiquantitative properties (exploiting discretized ODE-based semantics). The properties are then model checked by verifying the model in hand. Remarkably, the results of model checking permit its user to determine unknown parts of the model, such as reaction rates.

Static techniques refrain from considering the state space a system/process can pass through, as done by model checking. Rather, they analyze “statically” the text of the system, without actually executing it. A typical use of static analysis is in optimizing the code of computer programs, for example, determining from the program code that a variable is dead, that is, it would never be used. In general, these techniques are efficient, being low polynomial in time, but they only give approximate results that err on the safe side. Back to the example above, it may happen that a variable predicted to be used will be never used at execution time (approximation), but it will never happen that a variable is predicted to be dead when it will actually be used (sound).

An example of a static technique used in systems biology is *control flow analysis*, originally proposed for BioAMBIENT in Nielson et al. (2004a) and further developed in Nielson et al. (2004b),

and used for BETA BINDERS in Bodei (2009). For example, properties concerning the nesting of membranes are investigated by considering the set of “possible” interactions as they emerge from process definitions. The approximation comes from the fact that some interactions are statically predicted, but they may be mutually exclusive in the dynamics of the system.

Another problem largely investigated within concurrency is that of establishing the *equivalence* of (the behavior of) processes (Sangiorgi 2004). Behavioral equivalence is at the basis of component interchangeability. Indeed, one can replace a part of a system with an equivalent one, which additionally enjoys a property of interest, or also proceed in incrementally building systems, by replacing (abstract) components with equivalent, more detailed ones. So far, most of the studies have been carried out on qualitative semantics, but proposals for addressing quantitative aspects have been put forward, like notions of stochastic equivalence (see, for example, Doberkat (2007)). Although not yet widely explored, the application of notions of equivalence for biological systems appears of interest, especially for defining equivalences that reflect interchangeability of molecules or of pathways.

The interest in the automated processing of process calculi models has called for the development of a range of computational support, from simulation tools for calculi, like the cited SPiM (Phillips and Cardelli 2007), to extended modeling environments that integrate various analysis tools, both quantitative and qualitative, and support various semantics.

BioPEPA (Ciocchetta and Hillston 2006) builds upon the theory of PEPA (● Sect. 2.2). The essential algebraic representation of calculi is substituted by a richer language. Relevant biological aspects can be explicitly represented, for example, the stoichiometric matrix that summarizes quantitative information about reactions, which is implicitly defined by the overall process interaction in PEPA. Interaction rates are functions that dynamically determine their values according to the current state of the modeled system. Furthermore, the level of detail of the representation can be varied upon according to need, such as by modeling abstract (or non-fully known) interactions involving more than two reactants. Typically, this is done by explicitly associating quantities to reactants, and by assigning a role to actions, such as *activator*, *product*, *reactant*, etc. The semantics consists of an LTS enriched with quantitative information, which has a direct correspondence with CTMCs, as usual. A range of diverse kinetic laws can be applied to model the system. Furthermore, the analysis can be carried out through different approaches, like ODE-based descriptions or Gillespie’s simulations (with a bit of care depending on the kinetic adopted).

BlenX (Dematté et al. 2008) is explicitly presented as a programming language, with a stochastic execution support based on an efficient variant of Gillespie SSA. It builds upon BETA BINDERS (● Sect. 2.3) and consists of a modular architecture, among the modules of which there are the CTMC generator, the one that traces reactions and reagents involved, statistical tools, as well as a graphical user interface and a graphical output module. The programming language includes some mathematics, declarations, binder representations, and its control part relies on (an extended representation of) BETA BINDER processes. Process behavior can also be determined by events, for example, environmental conditions, that may trigger actions, like “no molecules are left of a given species.” BlenX supports modeling of a range of phenomena, such as enzymatic reactions, Michaelis–Menten kinetics, oscillatory behaviors, and self-assembly. As far as analysis is concerned, it features the capability of keeping trace of the species that have played an active role during a system simulation and the specific reactions in which they have taken part.

5 Case Studies

In this section, some case studies that show how suitable process calculi help in constructing *in silico* models of biological phenomena will be reported.

The already mentioned virtual cell experiment VICE (Chiarugi et al. 2004) addresses the biological problem of determining a genome as minimally as possible, and checking whether a hypothetical organism possessing it is able to live or not. The starting point was a hypothetical minimal genome (minimal gene set, MGS) (Mushegian and Koonin 1996), obtained by functionally comparing the genomes of two simple bacteria and eliminating duplicated or functionally identical genes.

To check the viability problem of a MGS-based prokaryote, Chiarugi et al. first specified *in silico* its metabolic pathways, using a process calculus very similar to BCCS. Then, they performed dynamic simulations, that is, virtual experiments of cellular metabolic activities, in order to check whether the MGS-prokaryote was able to reach some equilibrium state and to produce the necessary biomass, as these two properties are enjoyed by any living organism. The simulations clearly showed that MGS does not express an organism able to live, as it cannot reach any equilibrium.

Next, some genes were discarded, others added or replaced upon a functional analysis, and the various genomic sets obtained in this way checked for viability. The virtual experiments were made of about 10^8 transitions/reactions and involved up to 10^7 processes. Using a matrix-based interpreter (Chiarugi et al. 2008), a few minutes each were enough on a medium-sized PC.

After several iterations, a genome composed of 187 elements was selected. It expresses a virtual organism that exhibits homeostatic capabilities and produces biomass in the expected manner. Moreover, the steady-state distribution of the concentrations of virtual metabolites that resulted was similar to that experimentally measured in bacteria, as anticipated in **Example 3**. At least *in silico*, the virtual cell VICE is able to live.

It might be interesting to compare the above results with those of some authors who recently used a wet-lab approach to characterize the minimal gene set necessary to sustain bacterial life (Glass et al. 2006). Their experimentation consisted of knocking out *Mycoplasma genitalium* genes, which are supposed to form a set close to a minimal one. The difference between the genome proposed after *in silico* experimentations and the one obtained *in vitro* is about 10% (while the difference is about 30% with MGS).

A process-based model of pharmacodynamics was proposed in Dematté et al. (2007), to study the effects of drugs controlling the hypertension. A typical therapy consists of acting on the vascular tone, the degree of constriction experienced by a blood vessel relative to its maximally dilated state. The vascular tone is primarily dependent on a protein called myosin light chain kinase (MLCK), which is deeply influenced by intracellular calcium concentration.

Dematté et al. fully specified the nitric oxide-cGMP pathway, through which it is possible to modulate several signal transduction mechanisms that control the level of active MLCK in a cell. To study its effects, the considered drug is also represented as a set of processes.

A main contribution of Dematté et al. (2007) is the definition of the *effective index*, which formally gives sensible measures of the effects of a drug, as well as of the dose-response curve. More precisely, an effective index gives the expectation to reach a state, in the transition system

of the pathway and the drug, which is safe with respect to an observable property, defined as a logical formula. Remarkably, effective indexes are mechanically computed by relying on Markov process theory (Norris 1970).

Summing up, this case study proves the feasibility of an automatic and system-level decision support in drug discovery and analysis, based on process calculi.

The illustrated framework Bio-PEPA (Ciocchetta and Hillston 2006) has been used to investigate a number of phenomena. A repressilator, that is, a synthetic gene regulatory network with oscillating behavior, is analyzed in Ciocchetta and Hillston (2008). Three genes are connected in a feedback loop, where the protein coded by one inhibits the transcription of another one. The model comprises mRNA transcription, protein synthesis and degradation (the first is regulated by the Hill kinetics and the others by the GMA law). Starting from data in the literature, the biological parameters and initial conditions of the experiments are set. Then, exploiting the facilities of Bio-PEPA, both deterministic and stochastic analysis are carried out. The first consists of ODE-based simulations and reveals the expected oscillatory behavior of the three proteins considered. The second consists of a SSA-based simulation that, when averaged over a number of trials, tends to attenuate the oscillations. This phenomenon is explained by a stochastic difference of phases in the oscillations of each trial, which hence tend to cancel each other. Such a behavior underlines how analysis results may require further interpretations and the utility of frameworks like Bio-PEPA, which smoothly allow a phenomenon to be observed under different viewpoints, especially when there is no privileged viewpoint for all the situations.

Gene regulation networks and their feedback-determined behavior have been long appreciated as test-bed examples of the adequacy of the defined models. It is worth recalling here that the first phenomenon modeled within the process calculus approach is the gene regulatory network described and discussed in [Sect. 2.2](#).

In cooperation with two neuroscientists, Bracciali et al. (2008a, b) developed the first stochastic and discrete model of the calyx of Held, a big glutamatergic neuronal synapse in the auditory pathway of the mammalia. The synapses are the places of functional contacts between neurons, where the information is stored and transmitted from one neuron to another. A particular feature of the calyx of Held is its sensitivity to very small quantities of calcium ions, and this makes the continuity assumptions of its ODE-based models not very realistic.

We specified the pre- and the postsynaptic phases in the Stochastic Pi-calculus, starting from existing kinetic models based on ODEs of some sub-components of the synapse, integrating other data from the literature and making some assumptions about non-fully understood processes. A delicate point was determining the stochastic rates of the channels used in processes, starting from the deterministic ones; a similar problem was addressed and solved in Ihewkawa et al. (2007).

In silico experiments have confirmed the coherence of the model with known biological data, also validating the assumptions made. Sensitivity analysis over several parameters of the model has provided results that help to clarify the dynamics of synaptic transmission and explain short-term plasticity mechanisms that are supposed to be at the basis of memory.

It is worth remarking that the compositionality typical of process calculi has permitted us to specify separately, experiment on, and tune the models of the pre- and postsynaptic traits, and then to connect them in a plain and straightforward way.

Acknowledgments

The authors are deeply indebted to Luca Cardelli who kindly gave them permission to reuse here parts of his work, as well as Davide Chiarugi and Roberto Marangoni for joint previous work on VICE. The authors thank Enrico Cataldo for helpful comments and suggestions. The first author wishes to thank all the people at the Microsoft Research—University of Trento Centre for Computational and Systems Biology.

Abstract

A reaction–diffusion computer is a spatially extended chemical system, which processes information by transforming an input concentration profile to an output concentration profile in a deterministic and controlled manner. In reaction–diffusion computers, the data are represented by concentration profiles of reagents, information is transferred by propagating diffusive and phase waves, computation is implemented via the interaction of these traveling patterns (diffusive and excitation waves), and the results of the computation are recorded as a final concentration profile. Chemical reaction–diffusion computing is among the leaders in providing experimental prototypes in the fields of unconventional and nature-inspired computing. This chapter provides a case-study introduction to the field of reaction–diffusion computing, and shows how selected problems and tasks of computational geometry, robotics, and logics can be solved by encoding data within transient states of a chemical medium and by programming the dynamics and interactions of chemical waves.

1 Introduction

The field of natural computation (sometimes “unconventional computation,” “nonclassical computing,” and “nonstandard computation” can be used as well, depending on the context and personal preferences) is concerned with the design of computing paradigms, architectures, and experimental implementations of novel computing devices. These devices are based around the principles of information processing in chemical, physical, and biological systems and the implementation of conventional algorithms in nonstandard, non-silicon substrates (Adamatzky and Teuscher 2006; Adamatzky et al. 2007; Akl et al. 2007). The majority of the results published in natural computation (up to 99% of papers related to natural computation are theoretical) deal with algorithms, methodologies, or theories of computing based on paradigms or, occasionally very distant, analogies with biological, physical, and chemical processes. Only a few experimental prototypes of unconventional natural computers have been implemented in laboratories over the last few decades. These prototypes include examples of reaction–diffusion chemical processors (Adamatzky et al. 2005b; Adamatzky and De Lacy Costello 2002b; Tóth and Showalter 1995; Steinbock et al. 1996; Gorecki et al. 2003; 2005; Gorecka and Gorecki 2003; Motoike et al. 2001; Ichino et al. 2003), extended analog computers (Mills 2008), micro-fluidic circuits (Fuerstman et al. 2003), and plasmodium computers (Nakagaki et al. 2001; Shirakawa et al. 2009). This tendency is worrying because it looks like living in a world populated with combustion scientists but no car mechanics, aerodynamic engineers but no pilots. Bearing in mind that there are plenty of “talkers” but on the evidence just a few “doers” in this developing field we decided to focus this chapter entirely on experimental prototypes developed by the authors and coworkers/collaborators (just a couple of illustrations assisted by numerical experiments are included).

The chapter is structured as follows. ➤ [Section 2](#) is a short excursion into the history of reaction–diffusion computing and lists the main achievements in the field. A classification of reaction–diffusion computers is provided in ➤ [Sect. 3](#). In ➤ [Sect. 4](#), chemical recipes are provided for the preparation of the basic types of reaction–diffusion processors: precipitating palladium processors and excitable chemical media in the form of the Belousov–Zhabotinsky (BZ) reaction. Specialized chemical processors for computational geometry and robot control are discussed in ➤ [Sect. 5](#). In ➤ [Sect. 6](#), how to implement basic logical gates

in a sub-excitable chemical medium is shown. A few thoughts on the future developments in the field are outlined in [Sect. 7](#).

This chapter is only able to give a brief introduction to the field of reaction-diffusion computing; for this reason, the existence of working prototypes and some notable practical implementations are mainly stated without going far below the surface. Therefore, the interested reader is strongly encouraged to consult the book by Adamatzky et al. ([2005b](#)) for further details on the realization of chemical processors and also the implementation of the reaction-diffusion paradigm in silicon devices.

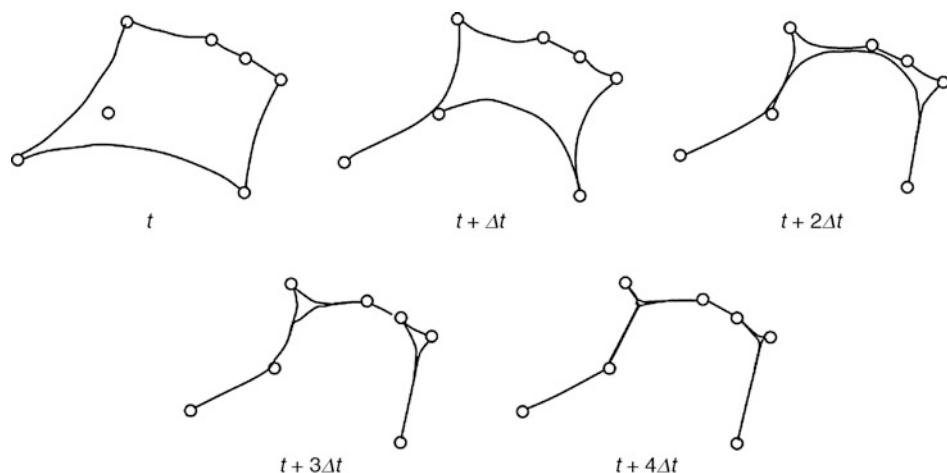

2 History and Milestones of Reaction-Diffusion Computing

The idea of physics-based computation can be attributed to Joseph Plateau, see references in Courant and Robbins ([1941](#)), who thought about methods to devise an experimental solution to the problem of calculating the surface of smallest area bounded by a given closed contour in space. Given a set of planar points, connect the points by a graph with the minimal sum of edge lengths (it is allowed to add more points, however the number of additional points should be minimal). Plateau's solution is simple yet nontrivial: mark the given planar points on a flat surface, insert pins in the points, place another sheet on top of the pins, briefly immerse the device in a soap solution, wait till the soap film dries, then record the topology of the dried soap film. The dried soap film represents a minimal Steiner tree spanning the given planar points ([Fig. 1](#)).

Due to surface tension, the soap film between the pins, representing points, naturally tries to minimize the total surface area. A length-minimizing curve enclosing a fixed-area region consists of circular arcs of positive outward curvature and line segments (Saltenis [1999](#)). The curvature of the arcs is inversely proportional to the pressure. By gradually increasing the pressure ([Fig. 1](#)) arcs can be transformed to straight lines, and thus a spanning tree is calculated.

Fig. 1

Several steps of spanning tree constructions by soap film (Saltenis [1999](#)).

The soap film does not involve diffusion or reaction; however, the operation is somewhat analogous to chemical reaction–diffusion computers. Initial data sites are represented by local perturbations of the system’s state. Information is transferred between the sites by propagating patterns. The computation is implemented via interaction of the propagating patterns and the result of the computation is represented by a final spatial configuration of the system. After the work of Plateau, it would be another hundred years until the Belousov–Zhabotinsky (BZ) reaction (Zaikin and Zhabotinsky 1970) became widely known and Kuhnert published his pioneering results (Kuhnert 1986a, b; Kuhnert et al. 1989) on implementation of memory devices and basic image processing procedures using a light-sensitive BZ medium. These first BZ processors did not employ the propagation of excitation waves but relied on global switching of the medium between excited and nonexcited states termed phase shifts. In a light sensitive analogue of the BZ reaction, the timing of these phase shifts could be coupled to the projected light intensity due to the light sensitivity of the catalyst used in the reaction. However, the publications encouraged other researchers to experiment with information processing in excitable chemical systems. The image processing capabilities of BZ systems were further explored and the research results were enhanced in Agladze et al. (1995), Rambidi (1997, 1998, 2003), Rambidi and Yakovenchuk (2001), and Rambidi et al. (2002).

In the mid-1990s, the first results concerning the directed, one-way, propagation of excitation waves in geometrically constrained chemical media was announced (Agladze et al. 1996). This led to a series of experimental studies concerning the construction of Boolean (Tóth and Showalter 1995; Steinbock et al. 1996; Motoike and Yoshikawa 2003) and three-valued (Motoike and Adamatzky 2004) logical gates and eventually led to the construction of more advanced circuits (Gorecka and Gorecki 2003; Gorecki et al. 2003; Ichino et al. 2003; Motoike and Yoshikawa 1999) and dynamical memory (Motoike et al. 2001) in the BZ reaction. The BZ medium was also used for one optimization task – shortest path computation (Steinbock et al. 1995; Agladze et al. 1997; Rambidi and Yakovenchuk 2001).

The studies in reaction–diffusion computing were boosted by algorithms of spatial computation in cellular automata, when the first automaton model for Voronoi diagram construction was designed (Adamatzky 1994, 1996). The algorithm was subsequently implemented under experimental laboratory conditions using a precipitating chemical processor (Tolmachiev and Adamatzky 1996; Adamatzky and Tolmachiev 1997), and later a variety of precipitating chemical systems were discovered to be capable of Voronoi diagram approximation (De Lacy Costello 2003; De Lacy Costello and Adamatzky 2003; De Lacy Costello et al. 2004a, b). The precipitating systems also proved to be efficient in the realization of basic logical gates, including many-valued gates (Adamatzky and De Lacy Costello 2002b).

In the early 2000s, the first ever excitable chemical controller mounted on-board a wheeled robot was constructed and tested under experimental laboratory conditions (Adamatzky and De Lacy Costello 2002a; Adamatzky et al. 2003, 2004), and also a robotic hand was interfaced and controlled using a Belousov–Zhabotinsky medium (Yokoi et al. 2004). These preliminary experiments opened the door to the future construction of embedded robotic controllers and other intelligent reaction–diffusion processors.

As for computational universality, sub-excitable analogues of chemical media have been proved by experiment to be powerful collision-based computers, capable of the implementation of universal and arithmetical logical circuits via the collision of propagating wave-fragments (Adamatzky 2004; Adamatzky and De Lacy Costello 2007; Toth et al. 2007).

3 Classification of Reaction–Diffusion Processors

In reaction–diffusion processors, both the data and the results of the computation are encoded as concentration profiles of the reagents. The computation *per se* is performed via the spreading and interaction of wave fronts.

This can be summarized using the following relationships between architecture or operation and implementation:

- Component base, computing substrate → Thin layer of reagents
- Data representation → Initial concentration profile
- Information transfer, communication → Diffusive and phase waves
- Computation → Interaction of waves
- Result representation → Final concentration profile

Reaction–diffusion computers are parallel because the chemical medium’s micro-volumes update their states simultaneously, and molecules diffuse and react in parallel. The architecture and operations of reaction–diffusion computers are based on three principles (Margolus 1984; Adamatzky 2001):

- Computation is dynamical: physical action measures the amount of information
- Computation is local: physical information travels only a finite distance
- Computation is spatial: their nature is governed by waves and spreading patterns

Potentially, a reaction–diffusion computer is a super-computer in a goo. Liquid-phase chemical computing media are characterized by

- Massive parallelism: millions of elementary – 2–4 bit – processors in a small chemical reactor
- Local connectivity: every micro-volume of the medium changes its state depending on the states of its closest neighbors
- Parallel I/O: optical input – control of initial excitation dynamics by illumination masks, output is parallel because the concentration profile representing the results of computation is visualized by indicators
- Fault tolerance and automatic re-configuration: because if some quantity of the liquid phase is removed, the topology is restored almost immediately

As far as reusability is concerned, there are two main classes of reaction–diffusion processors: reusable and disposable. Excitable chemical media are one of a family of reusable processors because given an unlimited supply of reagents, unlimited lifetime of the catalyst and the removal of any by-products, the system can be excited many times and at many simultaneous points on the computing substrate. The excitation waves leave almost no trace a certain time after the propagation. Precipitating chemical systems on the other hand are disposable processors. Once a loci of the substrate is converted to precipitate, it stays in the precipitate state indefinitely and therefore this processor cannot be used again within a realistic timeframe.

With regard to the communication between the domains of the computing medium the chemical media can be classified into either broadcasting or peer-to-peer architectures. Excitable chemical media and most precipitating systems are broadcasting. When a single site of a medium is perturbed the perturbation spreads in all directions, as a classical circular wave. Thus, each perturbed site broadcasts. However, when diffusion or excitation in the medium is limited, for example, the sub-excitable Belousov–Zhabotinsky system, no circular waves are

formed but instead self-localized propagating wave fragments are formed (chemical relatives of dissipative solitons). These wave-fragments propagate in a predetermined direction, therefore they can be seen as data packets transferred between any two points of the computing medium.

Broadcasting chemical processors are good for image processing tasks, some kinds of robot navigation and path computation. They are appropriate for all tasks when massive spatially extended data must be analyzed, modified, and processed. The circular-wave-based communication becomes less handy when one tries to build logical circuits: It is preferable to route the signal directly between two gates without affecting or disturbing nearby gates.

When one uses an excitable medium to implement a logical circuit, the propagation of the excitable waves must be restricted, for example, by making conductive channels surrounded by nonconductive barriers, or via the use of localized excitations in a sub-excitatory chemical medium. Reaction-diffusion processors where the computing space is geometrically inhomogeneous are called geometrically constrained processors. Sub-excitable chemical media, where wave-fragments propagate freely are called collision-based (because the computation is implemented when solution-like wave-fragments collide) or architecture-less/free-space computers (because the medium is homogeneous, regular, and uniform).

Further, examples of architecture-less chemical processors acting in either broadcasting or peer-to-peer modes are provided.

4 Recipes of the Chemical Processors

In this chapter, only three kinds of chemical reaction-diffusion processors are described: the precipitating palladium processor, and two chemical processors: an excitable Belousov-Zhabotinsky (BZ) medium and a light-sensitive sub-excitable analogue of the BZ reaction. Below we show how to prepare the reaction-diffusion processors in laboratory conditions.

4.1 Palladium Processor

A gel of agar (1.5% by weight, agar select Sigma-Aldrich Company Ltd., Poole, Dorset, UK) containing palladium chloride (Palladium (II) chloride 99%, Sigma-Aldrich Company Ltd.) in the range 0.2–0.9% by weight (0.011–0.051 M) is prepared by mixing the solids in warm deionized water. The mixture is heated with a naked flame and is constantly stirred until it boils to ensure full dissolution of the palladium chloride and production of a uniform gel (on cooling). The boiling liquid is then transferred to Petri dishes or alternatively spread on acetate sheets to a thickness of 1–2 mm and left to set. One can favor the use of Petri dishes because the reaction process is relatively slow and drying of the gel can occur if kept open to the atmosphere. The unreacted gel processors are then kept for 30 min although they remained stable for in excess of 24 h provided drying was controlled. A saturated solution (at 20°C) of potassium iodide (ACS reagent grade, Aldrich Chemical Co.) is used as the outer electrolyte for the reactions. Drops of outer electrolyte are applied to the surface of the gel to initiate the reaction process.

4.2 BZ Processor

A thin layer Belousov-Zhabotinsky (BZ) medium is usually prepared using a recipe adapted from Field and Winfree (1979): an acidic bromate stock solution incorporating potassium

bromate and sulfuric acid ($[BrO_3^-] = 0.5\text{ M}$ and $[H^+] = 0.59\text{ M}$) (solution A); solution of malonic acid (solution B) ($[CH_2(CO_2H)_2] = 0.5\text{ M}$); and sodium bromide (solution C) ($[Br^-] = 0.97\text{ M}$). Ferroin (1,10-phenanthroline iron-II sulfate, 0.025 M) is used as a catalyst and a visual indicator of the excitation activity in the BZ medium. To prepare a thin layer of the BZ medium, one can mix solutions A (7 ml), B (3.5 ml), C (1.2 ml), and finally when the solution becomes colorless, ferroin (1 ml) is added and the mixture is transferred to a Petri dish (layer thickness 1 mm). Excitation waves in the BZ reaction are initiated using a silver colloid solution.

4.3 Light-Sensitive Sub-excitatory BZ Processor

The recipe is quoted from Toth et al. (2007). A light-sensitive BZ processor consists of a gel impregnated with catalyst and a catalyst-free solution pumped around the gel. The gel is produced using a sodium silicate solution prepared by mixing 222 ml of the sodium silicate solution with 57 ml of 2 M sulfuric acid and 187 ml of deionized water (Toth et al. 2007). The catalyst $Ru(bpy)_3SO_4$ is recrystallized from the chloride salt with sulfuric acid. Pre-cured solutions for making gels are prepared by mixing 2.5 ml of the acidified silicate solution with 0.6 ml of 0.025 M $Ru(bpy)_3SO_4$ and 0.65 ml of 1.0 M sulfuric acid solution. Using capillary action, portions of this solution were quickly transferred into a custom-designed 25 cm long, 0.3 mm deep Perspex mold covered with microscope slides. The solutions are left for 3 h in the mold to permit complete gelation. After gelation, the adherence to the Perspex mold is negligible leaving a thin gel layer on the glass slide. After 3 h, the slides with the gel on them are carefully removed from the mold and placed into 0.2 M sulfuric acid solution for an hour. Then they are washed in deionized water at least five times to remove by-products. The gels are 26 mm \times 26 mm, with a wet thickness of approximately 300 m. The gels are stored under water and rinsed just before use.

The catalyst-free reaction mixture is freshly prepared in a 30 ml continuously fed stirred tank reactor, which involves the *in situ* synthesis of stoichiometric bromomalonic acid from malonic acid and bromine generated from the partial reduction of sodium bromate. This reactor is continuously fed with fresh catalyst-free BZ solution in order to maintain a nonequilibrium state. The final composition of the catalyst-free reaction solution in the reactor is the following: 0.42 M sodium bromate, 0.19 M malonic acid, 0.64 M sulfuric acid, and 0.11 M bromide.

A light projector is used to illuminate the computer-controlled image. Images are captured using a digital camera. The open reactor is surrounded by a water jacket thermostated at 22°C. Peristaltic pumps are used to pump the reaction solution into the reactor and remove the effluent.

In some cases, the regular structure of illumination is applied onto the BZ chemical reactor. Four light levels can be used: black (zero light level), at which level the reaction BZ oscillates; dark (0.035 mW cm^{-2}), which represents the excitable medium in which a chemical wave is able to propagate; white (maximum light intensity: 3.5 mW cm^{-2}), the inhibitory level; and finally the light level (1.35 mW cm^{-2}) corresponding to the weakly excitable medium, where excitation just manages to propagate.

Waves were initiated by setting the light intensity to zero within a small square at specific points on the gel surface. A black oscillating square is used to initiate waves periodically. The waves are then directed from source into a weakly excitable area (controlled by projecting a light intensity of 1.35 mW cm^{-2}) such that only small fragments are able to propagate.

5 Specialized Processors

As their name suggests, specialized processors are designed to solve just one possible computational task (or family of very similar tasks). In this section, examples of specialized processors for computational geometry, image processing, and robotics are provided.

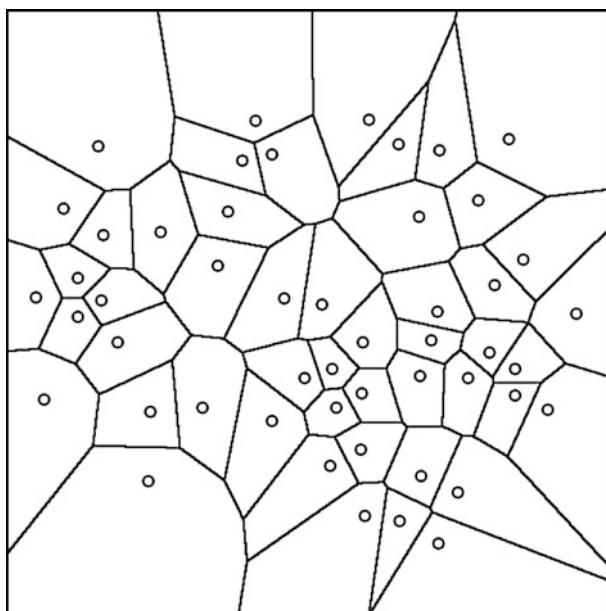

5.1 Voronoi Diagram and Skeletonization

Let \mathbf{P} be a nonempty finite set of planar points. A planar Voronoi diagram of the set \mathbf{P} is a partition of the plane into such regions, so that for any element of \mathbf{P} a region corresponding to a unique point p contains all those points of the plane which are closer to p than to any other node of \mathbf{P} . A unique region $vor(p) = \{z \in \mathbb{R}^2 : d(p, z) < d(p, m) \forall m \in \mathbf{P}, m \neq p\}$ assigned to point p is called a Voronoi cell of the point p . The boundary of the Voronoi cell of a point p is built of segments of bisectors separating pairs of geographically closest points of the given planar set \mathbf{P} . A union of all boundaries of the Voronoi cells determines the *planar Voronoi diagram*: $VD(\mathbf{P}) = \cup_{p \in \mathbf{P}} \partial vor(p)$. A variety of Voronoi diagrams and algorithms of their construction can be found in Klein (1990). An example of a Voronoi diagram is shown in [Fig. 2](#).

Voronoi cells of a planar set represent the natural or geographical neighborhood of the set's elements. Therefore, the computation of a Voronoi diagram based on the spreading of some "substance" from the data points is usually the first approach of those trying to design massively parallel algorithms in chemical nonlinear systems.

Fig. 2

Voronoi diagram of 50 planar points randomly distributed in the unit disc.

The “spreading substance” can be represented by a potential or an oscillatory field, or diffusing or phase waves, or simply by some traveling inhomogeneities or disturbances in the physical computing medium. This idea was first explored by Blum, Calabi, and Hartnett in their “grass-fire” transformation algorithm (Blum 1967, 1973; Calabi and Hartnett 1968). A fire is started at planar points of a given data set, the fire spreads from the data points on a substrate (that constitutes the computing medium) and the sites where the fire fronts meet represent the edges of the Voronoi diagram of the planar data set.

Quite similarly, to construct the diagram with a potential field one puts the field generators at the data points and then detects sites where two or more fronts of the field waves meet. This technique is employed in the computation of a Voronoi diagram via repulsive potential and oscillatory fields in homogeneous neural networks (Hwang and Ahuja 1992; Lemmon 1991). These approaches are “natural” and intuitive and their simplicity of implementation made them an invaluable tool for massively parallel image processing. The weakness of the approach is that a stationary structure is formed as a result of the computation and the meeting points of the colliding wave fronts must be detected by some “artificial” or extrinsic methods. This disadvantage is eliminated in the reaction–diffusion technique as demonstrated.

To compute a Voronoi diagram of planar points, each point is represented by a unique drop of outer electrolyte. The configuration of the outer electrolyte drops corresponds to the configuration of the data to be subdivided by the Voronoi diagram. Data objects (to be separated) are represented using a clear solution of potassium iodide. The potassium iodide diffuses from the sites of the drops or from the edges of planar shapes into the palladium chloride loaded gel. The potassium iodide reacts with the palladium chloride to form iodo-palladium species. The palladium chloride gel is light yellow colored while iodo-palladium species are dark brown. Thus, during the process of computation, the growth of dark-brown patterns emanating from the initial data sites can be observed. At sites where two or more diffusive fronts meet each other almost no precipitate is formed; these sites therefore remain uncolored, and they represent the bisectors of a Voronoi diagram, generated by the initial geometrical configuration of data objects (☞ Fig. 3a).

Voronoi diagrams of other geometric shapes can be constructed by substituting the drops of the outer electrolyte for pieces of absorbent materials soaked in the electrolyte solution and applying these to the gel surface (☞ Fig. 3b, c).

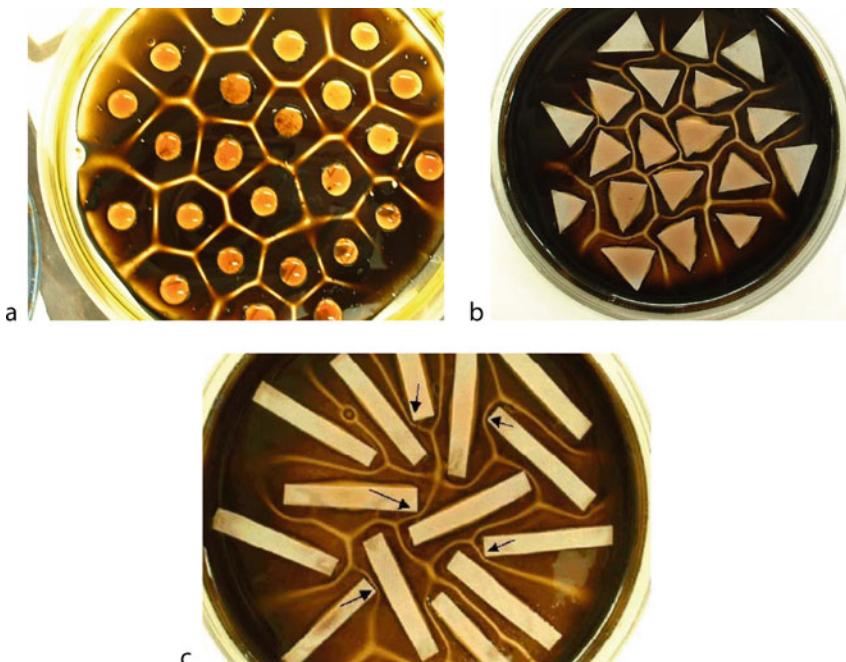

The processor starts its computation as soon as drops/shapes with potassium iodide are applied; the computation is finished when no more precipitate is formed. Configurations of drops/filter-paper templates of potassium iodide correspond to the input states of the processor; the resulting two-dimensional concentration profile of the precipitate (iodo-palladium species) is the output state of the processor. The processor can be seen as a preprogrammed or hardwired device because the way in which the chemical species react cannot be changed.

It should be noted that the “palladium processor” is just one of a huge number of chemical-based processors capable of Voronoi diagram calculation. Some others, particularly those based on gels containing potassium ferrocyanide and mixed with various metal salts, are discussed in Adamatzky et al. (2005b). Reagents with differing diffusion on the same substrate and differing chemical reactivities to the gel substrate can be used to form a number of generalized weighted Voronoi diagrams.

It is also interesting to note that in these chemical systems, the more data inputted in a given area the faster the computational outcome. The limit of the processors is currently determined by the gel thickness and the integrity and the ability to accurately input data points – but these are just design issues that can realistically be overcome and do not limit the

Fig. 3

Voronoi diagram of planar points/discs (a), triangles (b) and rectangles (c) computed in the palladium processor (from Adamatzky et al. 2005b).

theoretical capabilities of the systems. Also, these systems can be practically used to implement three-dimensional Voronoi tessellations. For example, algorithms of classical computation of Voronoi diagram of planar points and planar objects are very different because when arbitrary-shaped objects are involved, one needs to employ algebraic curves to produce bisectors, which increases complexity. In chemical processors, it does not matter what shape data objects have, the time of computation is determined only by the maximum distance between two geographically neighboring objects.

Skeletonization ([Fig. 4](#)) of the planar shapes in a reaction-diffusion chemical processor is yet further proof of the correctness of the proposed mechanism, namely, the wave-velocity-dependent bisector formation. During skeletonization, there are no interactions of wave fronts emanating from different sources; there is only one front, generated at the edges of the closed planar shape. Concave parts of the shape produce bisectors; however, the further the bisecting sites are from the given shape the larger the width of the bisectors and the more precipitate they contain (this is because the velocity of the fronts corresponding to the concave parts reduces with time) (Adamatzky and De Lacy Costello [2002c](#)).

5.2 Collision-Free Path Calculation

A BZ parallel processor (Adamatzky and De Lacy Costello [2002a](#)) that computes a collision-free path solves the following problem. Given a space with a set of obstacles and two selected

Fig. 4

Computation of the skeleton of a planar shape in the palladium processor (from Adamatzky and De Lacy Costello 2002c).

sites, find the shortest path between the source and the destination such that every site of the path is as far from the obstacles as possible. This is not only a classical problem in mathematical optimization but one heavily relied on in robotics, logistics, electronic design, etc.

The problem has already been tackled in a framework of wave-based computing. Three experimental prototypes exist, where BZ processors have been designed to compute the shortest paths:

- extraction of an optimal path in a labyrinth from excitation wave-front dynamics in the labyrinth (Steinbock et al. 1995); the path is extracted from time-lapsed snapshots of the wave-front motion;
- collision-free path using the BZ medium, where obstacles are represented by drops of KCl or strong illumination (Agladze et al. 1997); a path is extracted from the motion of excitation waves;
- approximation of a path on a tree in a light-sensitive BZ-medium (Rambidi and Yakovenchuk 2001); this technique is rather complicated because a data tree is represented by gradients of the medium and the image-processing routines were implemented at every step of the medium's development.

A BZ processor coupled with a two-dimensional cellular automaton has been designed, the hybrid system computes the shortest path by first approximating a distance field generated by the obstacles (BZ medium) and then calculating the shortest path in the field (cellular automaton) (Adamatzky and De Lacy Costello 2003).

A configuration of obstacles (☞ Fig. 5a) is represented by an identical configuration of silver wires parallel to each other and perpendicular to the surface of the BZ medium. Each circular obstacle is represented by a unique wire positioned exactly at the center of the obstacle. To start the computation in the BZ processor, the tips of all the wires are briefly immersed into the BZ mixture (in the reduced steady state). Immersing silver wires at specific points of the BZ mixture reversibly removes bromide ions from these sites. Bromide ions act

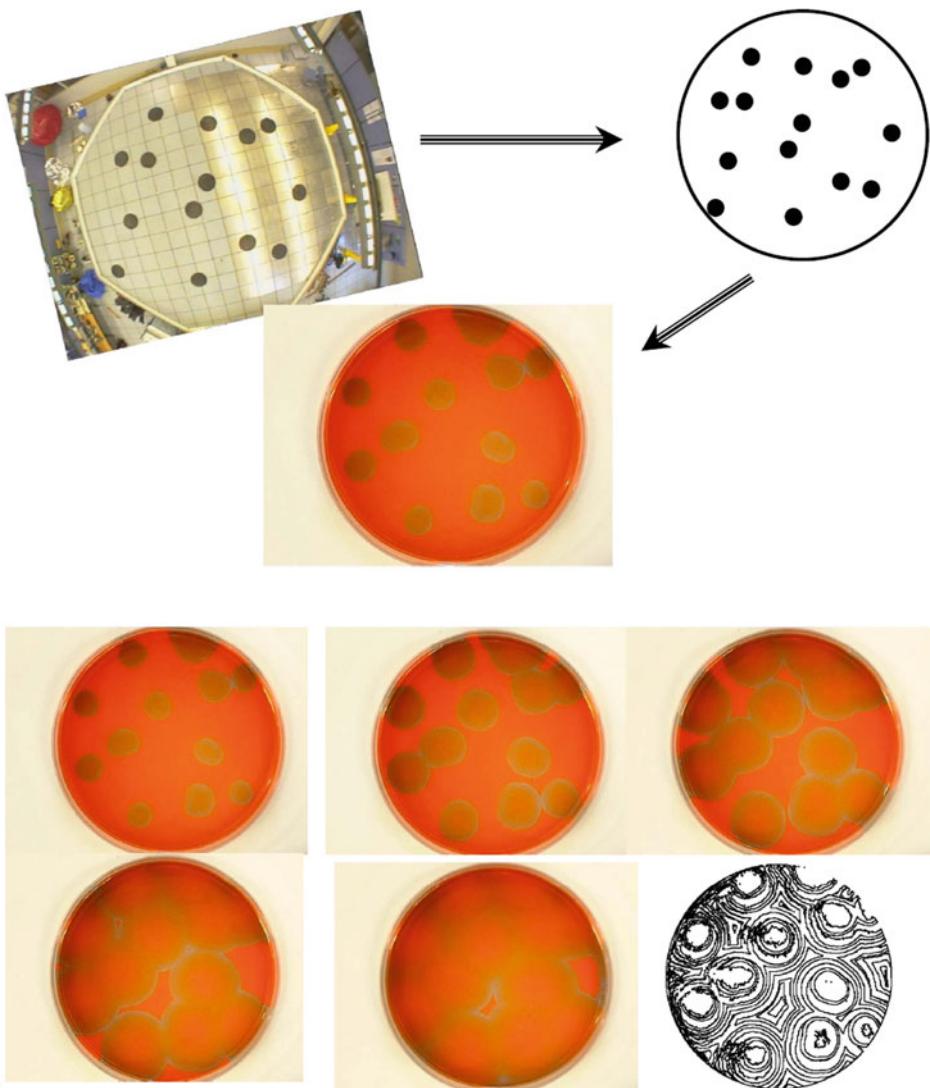

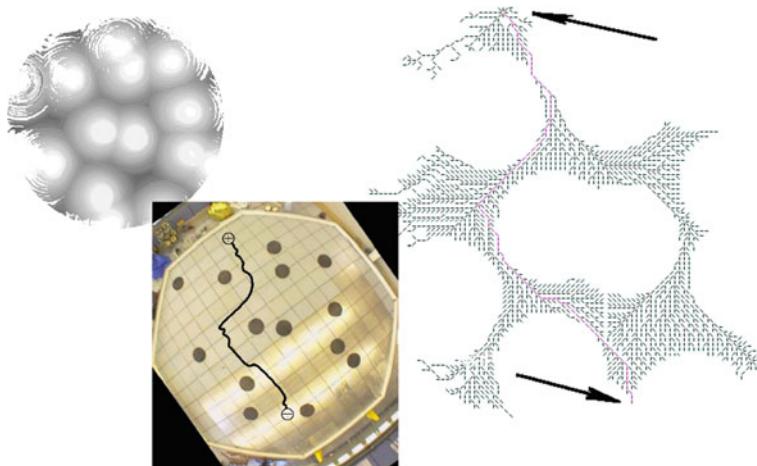

Fig. 6

Extraction of the shortest collision-free path (from Adamatzky et al. 2005b).

as primary inhibitors of the autocatalytic reaction in the BZ medium, therefore local removal of bromide ions stimulates wave generation. The digital images of the BZ medium were taken at certain intervals until all primary wave fronts had been annihilated (► Fig. 5b). Then we could transform a series of color snapshots taken to a gray-level matrix, which represents a distance scalar field derived from a configuration of obstacles (► Fig. 6, on the left).

The distance matrix is mapped to a two-dimensional excitable cellular automaton, which calculates the shortest path between any two points of the experimental arena, labeling the path with the local pointers (► Fig. 6, on the right). The configuration of the local pointers, representing the shortest collision-free path, can be communicated to a mobile robot that navigates the experimental arena (► Fig. 6, center).

5.3 Taxis

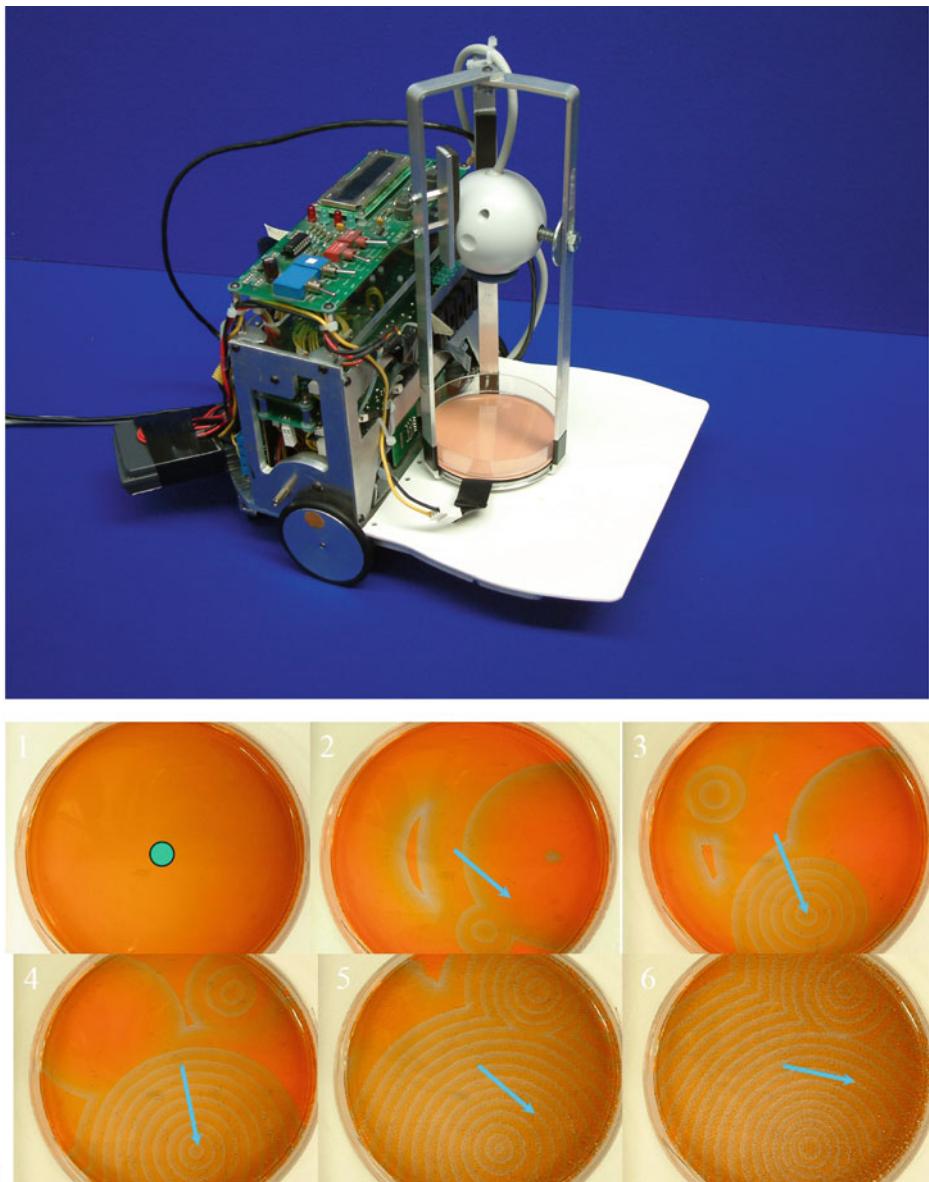

The Belousov–Zhabotinsky reaction is capable of assisting in the navigation of a mobile robot in a real-life environment (Adamatzky et al. 2004). Given an onboard thin-layer chemical reactor with the liquid-phase Belousov–Zhabotinsky medium, one can apply intermittent stimulation of the medium to sensibly guide the robot.

To make a BZ robotic taxis controller, a thin layer Belousov–Zhabotinsky (BZ) reaction is prepared using a recipe adapted from Field and Winfree (1979). Excitation waves in the BZ reaction are initiated using a silver colloid solution, which is added to the medium by a human operator. The chemical controller is placed onboard a wheeled mobile robot (► Fig. 7a). The robot is about 23 cm in diameter and able to turn on the spot; wheel motors are controlled by a Motorola 68332 onboard processor. The robot features a horizontal platform, where the Petri dish (9 cm in diameter) is fixed, and a stand with a digital camera Logitech QuickCam (in 120 × 160 pixels resolution mode), to record excitation dynamics. The robot controller and the camera are connected to a PC via serial port RS-232 and USB 1.0, respectively.

Because vibrations affect processes in BZ reaction systems, the movements of the robot are made as smooth as possible, thus in the experiments the robot moves with a speed

Fig. 7

Wheeled robot controlled by BZ medium (a) and snapshots of excitation dynamics with robot's velocity vector extracted (b) (from Adamatzky et al. 2004).

of circa 1 cm s^{-1} . It was found that rotational movements were particularly disruptive and caused spreading of the excitation waves from the site of the existing wave fronts faster than would be seen if the process was just diffusion. Therefore, to minimize this effect, the robot was made to rotate with a very low speed of around 1°s^{-1} .

To enhance the images of the excitation dynamics, the Petri dish is illuminated from underneath by a flexible electroluminescent sheet (0.7 mm thick) cut to the shape of the dish. The sheet, powered through an inverter from the robot's batteries, produces a cool uniform blue light not affecting (at least in conditions of the experimental setup) the physicochemical processes in the reactor. It was found preferable to implement experiments in dark areas to avoid interference of daylight and lamps with the light from the luminescent sheet.

When the medium is excited with a silver wire, a local generator of target waves is formed (Fig. 7b). The robot extracts the position of the stimulation point, relative to the center of the chemical reactor, from the topology of the excitation target waves. The robot adjusts its velocity vector to match the vector toward the source of stimulation. To guide the robot more precisely one can excite the chemical medium in several points (Fig. 7b). It should be noted that eventually it was intended that environmental interaction would become the source of stimulation for the excitation waves. The forced stimulation was simply to test the algorithms on board with real chemical controllers and to learn about any problems coupling chemical reactors and robots. Something that was identified as a problem, physical disruption of chemical waves, could actually turn out to be advantageous as it may feed back both direction, velocity, and even rotational movement of the robot.

5.4 Control of Robotic Hand

In the previous sections, we described the designs of chemical controllers for robots, which can calculate a shortest collision-free path in the robotic arena and guide the robot toward the source of stimulation (taxis). However, the controllers described lacked feedback from the robot. In a set of remarkable experiments undertaken by Hiroshi Yokoi and Ben De Lacy Costello (Yokoi et al. 2004), it was demonstrated that when a closed-loop interface between the chemical controller and the robot is established, the behavior of the hybrid systems becomes even more intriguing.

In the chemical controller of the robotic hand (Yokoi et al. 2004) the excitation waves propagating in the BZ reactor are sensed by photodiodes, which in turn trigger finger motion. When the bending fingers touch the chemical medium glass, “nails” fitted with capillary tubes release small quantities of colloidal silver into the solution and this triggers additional circular waves in the medium (Adamatzky et al. 2005b) (Fig. 8). Starting from any initial configuration, the chemical-robotic system always reaches a coherent activity mode, where fingers move in regular, somewhat melodic patterns, and just a few generators of target waves govern the dynamics of the excitation in the reactor (Yokoi et al. 2004).

5.5 Parallel Actuators

How can a reaction-diffusion medium manipulate objects? To find out the answer, a simulated abstract parallel manipulator (Adamatzky et al. 2005a) can be coupled with an experimental Belousov-Zhabotinsky (BZ) chemical medium. The simulated manipulator is a two-dimensional array of actuating units, each unit can apply a force vector of unit length to the manipulated objects. The velocity vector of the object is derived via the integration of the results of all local force vectors acting on the manipulated object.

Fig. 8

Robotic hand interacts with Belousov–Zhabotinsky medium (from Yokoi et al. 2004).

Coupling an excitable chemical medium with a manipulator allows one to convert experimental snapshots of the BZ medium to a force vector field and then simulate the motion of manipulated objects in the force field, thus achieving reaction–diffusion medium controlled actuation. To build an interface between the recordings of space–time snapshots of the excitation dynamics in the BZ medium and simulated physical objects, one can calculate the force fields generated by mobile excitation patterns and then simulate the behavior of an object in this force field (Skachek et al. 2005).

The chemical medium used to perform the actuation is prepared following the typical recipe, see Field and Winfree (1979), based on a ferroin catalyzed BZ reaction. A silica gel plate is cut and soaked in a ferroin solution. The gel sheet is placed in a Petri dish and the BZ solution is added. The dynamics of the chemical system is recorded at 30 s intervals using a digital camera.

The cross-section profile of the BZ wave-front recorded on a digital snapshot shows a steep rise of red color values in the pixels at the wave-front's head and a gradual descent in the pixels along the wave-front's tail. Assuming that excitation waves push the object, local force vectors generated at each site – a pixel of the digitized image – of the medium should be oriented along local gradients of the red color values. From the digitized snapshot of the BZ medium, an array of red components is extracted from the snapshot's pixels and then the projection of a virtual vector force at the pixel is calculated.

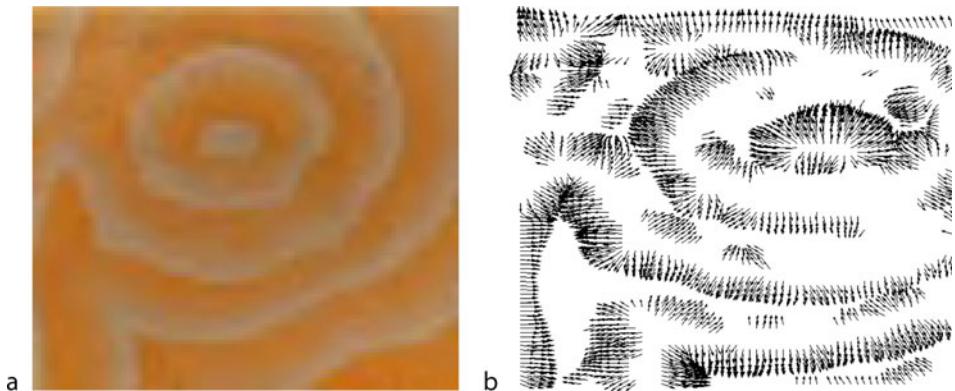

Force fields generated by the excitation patterns in a BZ system (Fig. 9) result in tangential forces being applied to a manipulated object, thus causing translational and rotational motions of the object (Adamatzky et al. 2005a).

It was demonstrated that the BZ medium controlled actuators can be used for sorting and manipulating both small objects, comparable in size to the elementary actuating unit, and larger objects, with lengths of tens or hundreds of actuating units.

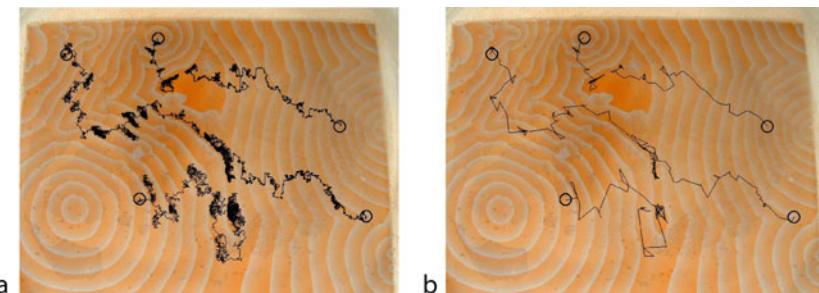

Pixel-objects, due to their small size, are subjected to random forces, caused by impurities of the physical medium and imprecision of the actuating units. In this case, no averaging of forces is allowed and the pixel-objects sensitively react to a single force vector. Therefore, one can adopt the following model of manipulating a pixel-object: If all force vectors at the 8-pixel neighborhood of the current site of the pixel-object are nil then the pixel-object jumps to

Fig. 9

Force vector field (**b**) calculated from BZ medium's image (**a**) (Adamatzky et al. 2005a).

**Fig. 10**

Examples of manipulating five pixel-objects using the BZ medium: (a) trajectories of pixel-objects. (b) Jump-trajectories of pixel-objects recorded every 100th time step. Initial positions of the pixel-objects are shown by circles (Adamatzky et al. 2005a).

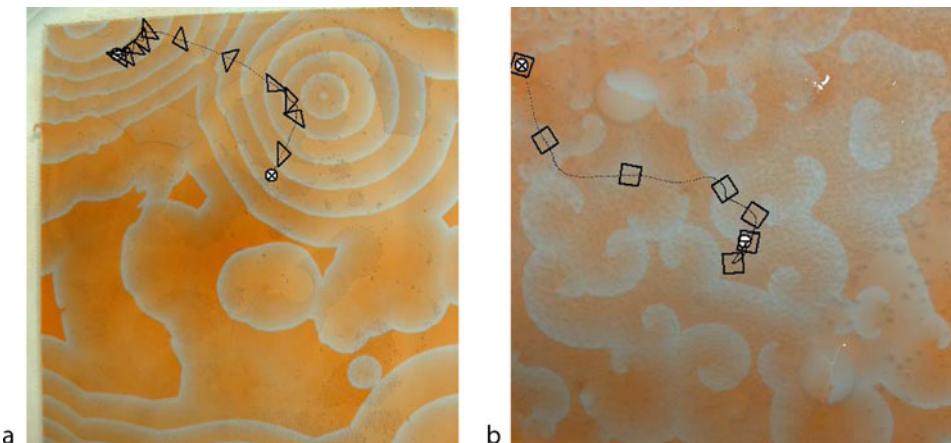

a randomly chosen neighboring pixel of its neighborhood, otherwise the pixel-object is translated by the maximum force vector in its neighborhood.

When placed on the simulated manipulating surface, pixel-objects move at random in the domains of the resting medium; however, by randomly drifting each pixel-object eventually encounters a domain of co-aligned vectors (representing the excitation wave front in the BZ medium) and is translated along the vectors. An example of several pixel-objects transported on a “frozen” snapshot of the chemical medium is shown in [Fig. 10](#). Trajectories of pixel-objects ([Fig. 10a](#)) show distinctive intermittent modes of random motion separated by modes of directed “jumps” guided by traveling wave fronts. Smoothed trajectories of pixel-objects ([Fig. 10b](#)) demonstrate that despite a very strong chaotic component in manipulation, pixel-objects are transported to the sites of the medium where two or more excitation wave fronts meet.

The overall speed of pixel-object transportation depends on the frequency of wave generations by sources of target waves. As a rule, the higher the frequency the faster the objects are transported. This is because in parts of the medium spanned by low-frequency target waves

Fig. 11

Manipulating planar object in BZ medium. (a) Right-angled triangle moved by fronts of target waves. (b) Square object moved by fronts of fragmented waves in sub-excitatory BZ medium. Trajectories of center of mass of the square are shown by the dotted line. Exact orientation of the objects is displayed every 20 steps. Initial position of the object is shown by \ominus and the final position by \otimes (Adamatzky et al. 2005a).

there are lengthy domains of resting states, where no force vectors are formed. Therefore, a pixel-sized object can wander randomly for a long time until climbing the next wave front (Adamatzky et al. 2005a).

Spatially extended objects follow the general pattern of motion observed for the pixel-sized objects. However, due to the integration of many force vectors, the motion of planar objects is smoother and less sensitive to the orientation of any particular force vector.

The outcome of the manipulation depends on the size of the object, with increasing size of the object – due to larger numbers of local vector forces acting on the object – the objects become more controllable by the excitation wave fronts (Fig. 11).

6 Universal Processors

Certain families of thin-layer reaction–diffusion chemical media can implement sensible transformation of the initial (data) spatial distribution of the chemical species concentrations to the final (result) concentration profile (Adamatzky 2001; Sienko et al. 2003). In these reaction–diffusion computers, computation is realized via the spreading and interaction of diffusive or phase waves. Specialized, intended to solve a particular problem, experimental chemical processors implement basic operations of image processing (Kuhnert 1986b; Rambidi 1998; Rambidi et al. 2002; Adamatzky et al. 2005b), computation of optimal paths (Steinbock et al. 1995; Agladze et al. 1997; Adamatzky et al. 2005b), and control of mobile robots (Adamatzky et al. 2005b).

A device is called computationally universal if it implements a functionally complete system of logical gates, for example, a tuple of negation and conjunction, in its space–time dynamics.

A number of computationally universal reaction–diffusion devices were implemented, the findings include logical gates (Tóth and Showalter 1995; Sielewiesiuk and Gorecki 2001) and diodes (Kusumi et al. 1997; Dupont et al. 1998; Motoike and Yoshikawa 1999) in the Belousov–Zhabotinsky (BZ) medium, and an XOR gate in a palladium processor (Adamatzky and De Lacy Costello 2002b).

So far, most known experimental prototypes of reaction–diffusion processors exploit the interaction of wave fronts in a geometrically constrained chemical medium. The computation is based on a stationary architecture of the medium’s inhomogeneities. Constrained by stationary wires and gates, reaction–diffusion chemical universal processors provide little computational novelty and no dynamical reconfiguration ability because they simply imitate the architectures of conventional silicon computing devices. To appreciate in full the inherent massive-parallelism of thin-layer chemical media and to free the chemical processors from the imposed limitations of fixed computing architectures, an unconventional paradigm of architecture-less, or collision-based, computing has been adopted. An architecture-based, or stationary, computation implies that a logical circuit is embedded into the system in such a manner that all elements of the circuit are represented by the system’s stationary states. The architecture is static. If there is any kind of “artificial” or “natural” compartmentalization, the medium is classified as an architecture-based computing device. Personal computers, living neural networks, cells, and networks of chemical reactors are typical examples of architecture-based computers.

A collision-based, or dynamical, computation employs mobile compact finite patterns, mobile self-localized excitations or simply localizations, in active nonlinear medium. The essentials of collision-based computing are as follows.

Truth values of logical variables are given by either the absence or presence of the localizations or other parameters of the localizations. The localizations travel in space and perform computation when they collide with each other. There are no predetermined stationary wires, a trajectory of the traveling pattern is a momentary wire. Almost any part of the medium space can be used as a wire. Localizations can collide anywhere within the overall space of the medium, there are no fixed positions at which specific operations occur, nor location-specified gates with fixed operations. The localizations undergo transformations, form bound states, annihilate, or fuse when they interact with other mobile patterns. The information values of the localizations are transformed as a result of the collisions and thus a computation is implemented (Adamatzky et al. 2005b).

The paradigm of collision-based computing originates from the technique of proving the computational universality of the Game of Life (Berlekamp et al. 1982), conservative logic and the billiard-ball model (Fredkin and Toffoli 1982) and their cellular automaton implementations (Margolus 1984).

Solitons, defects in tubulin microtubules, excitons in Scheibe aggregates, and breathers in polymer chains are most frequently considered candidates for the role of information carrier in nature-inspired collision-based computers, see the overview in Adamatzky (2001). It is experimentally difficult to reproduce all these artifacts in natural systems; therefore, the existence of mobile localizations in an experiment-friendly chemical media opens new horizons for the fabrication of collision-based computers.

The basis for the material implementation of the collision-based universality of reaction–diffusion chemical media was discovered by Sendiña-Nadal et al. (2001). They experimentally proved the existence of localized excitations – traveling wave fragments that behave like quasiparticles – in a photosensitive sub-excitable Belousov–Zhabotinsky medium.

6.1 Basic Gates in Excitable Chemical Medium

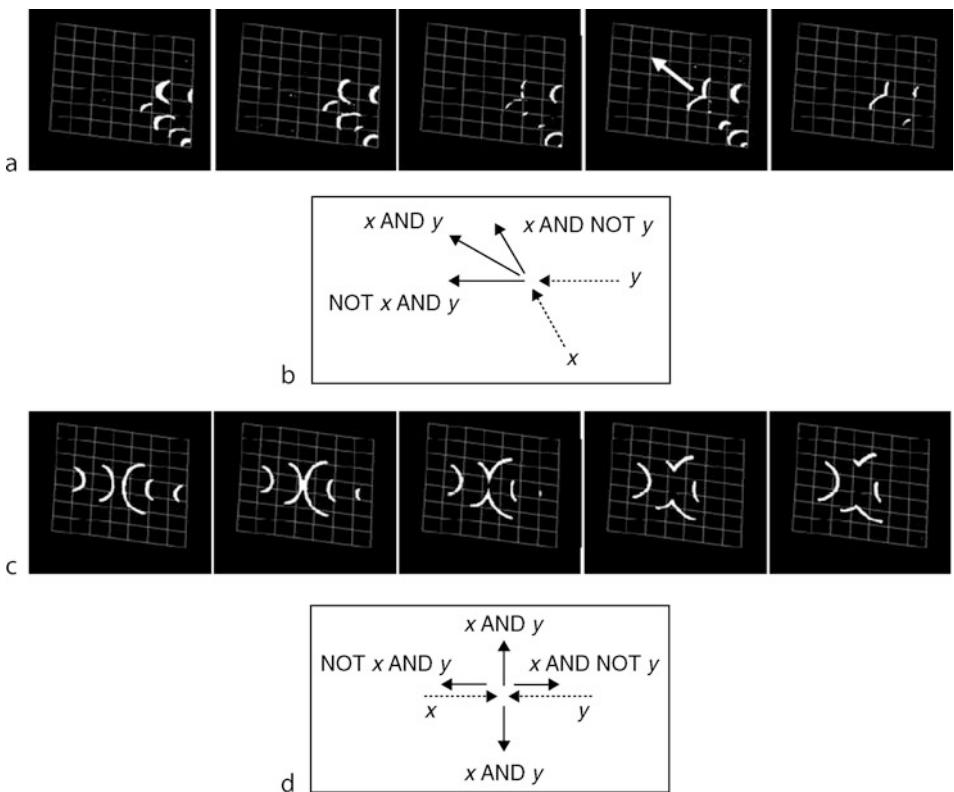

Most collisions between wave-fragments in a sub-excitatory BZ medium follow the basic rules of the Fredkin–Toffoli billiard ball model but not always conservatively. In most cases, particularly when chemical laboratory experiments are concerned, the wave-fragments do not simply scatter as a result of collisions but rather fuse, split or generate additional new mobile localizations. Two examples of logical gates realized in the BZ medium are shown in [Fig. 12](#).

In the first example ([Fig. 12a, b](#)) the wave-fragment traveling north-west collides with the wave-fragment traveling west, a new wave-fragment traveling north-west-west is produced as a result of the collision ([Fig. 12a](#)). This new wave-fragment represents the conjunction of the Boolean variables represented by the colliding wave-fragments ([Fig. 12b](#)).

In the second example of experimental implementation ([Fig. 12c, d](#)), one can see two wave-fragments, traveling east and west, colliding “head-on.” Two new wave-fragments are produced as a result of the collision. One wave-fragment travels north, another wave-fragment travels south. The corresponding logical gate is shown in [Fig. 12d](#).

Fig. 12

Two logical gates implemented in experimental laboratory conditions (Toth et al. 2007). Time lapsed snapshots of propagating wave-fragments are shown in (a) and (c), schemes of the logical gates are shown in (b) and (d).

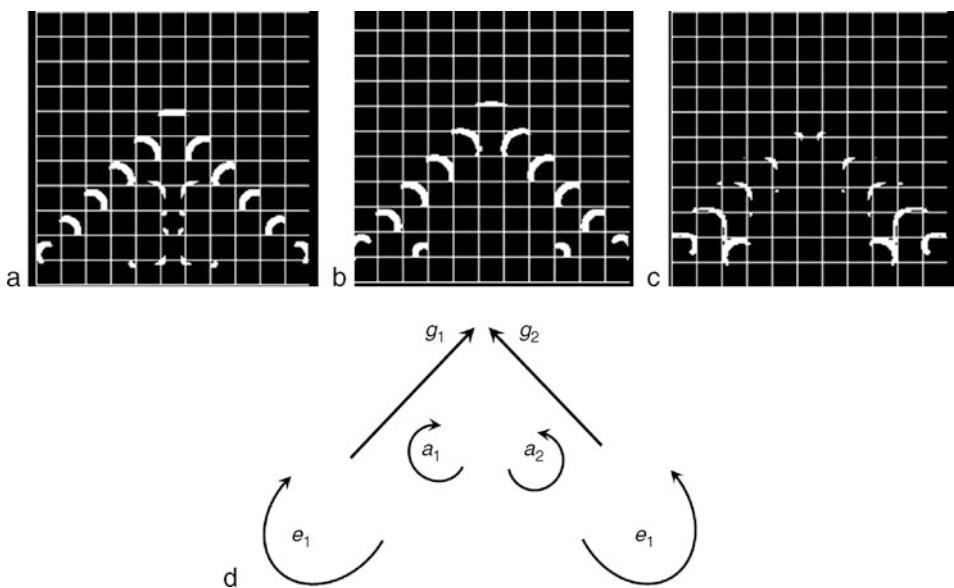

6.2 Constant Truth Generators

In the previous section, the design of logical gates in theoretical and experimental implementations of a sub-exitable BZ medium was demonstrated. The negation operator was the only thing missing in the construction, without negation and just one AND or OR gate a functional completeness could not be achieved. In cellular automata models of collision-based computers, see overview in Adamatzky (2002), negation is implemented with the help of glider guns – an autonomous generator of gliders. Streams of gliders emitted by the glider gun are collided with streams of data gliders to perform the negation operation. Until recently, there was no experimental proof that this missing component of current collision-based circuits could be obtained via experiments with the BZ medium. The gap was filled in Adamatzky et al. (2008), analogues of glider guns were realized in chemical laboratory conditions.

To produce the guns, a BZ light-sensitive sub-exitable processor was used with a slight modification, see Adamatzky et al. (2008) for details. A controllable regular configuration of excitable and non-exitable cells is created by projecting a 10×10 checkerboard pattern comprising low (0.394 mW cm^{-2}) and high (9.97 mW cm^{-2}) light intensity cells onto the gel surface using a data projector. In the checkboard pattern, the wave propagation depends on junctions between excitable and non-exitable cells. Junction permeability is affected by the excitability of the cell, the excitability of the neighboring cells, the size and symmetry of the network, the curvature of the wave fragments in the excitable cells, and the previous states of the junctions. When a junction fails, it acts as an impurity in the system, which leads to the

Fig. 13

Two glider guns where streams of fragments are in collision. (a–c) Snapshots of excitation dynamics in the BZ medium. (d) Scheme of the glider guns: e_1 and e_2 spiral wave fragments generating streams, g_1 and g_2 of localized excitations, a_1 and a_2 auxiliary wave fragments interacting with the wave streams (from De Lacy Costello et al. 2008).

formation of a spiral wave. In certain conditions a tail of the spiral wave becomes periodically severed. Thus, independently moving localized excitations are produced. The spiral generates trains of wave fragments. An example of two glider guns, generating trains of mobile self-localized excitations, is shown in Fig. 13.

7 Conclusion

Major achievements in the field of reaction-diffusion computing were listed, and using selected examples of chemical laboratory prototypes it was shown that chemical reaction-diffusion computers can solve a variety of tasks. They can perform image processing, calculate Voronoi diagrams of arbitrary-shaped planar objects and skeletons of planar shapes, approximate collision-free shortest paths, guide robots toward sources of stimulation, manipulate several small objects in parallel, and implement logical functions. Recipes for the preparation of precipitating and excitable chemical media capable of carrying out such computations were provided. It is hoped that this chapter is sufficient in order for the reader to obtain a basic understanding of reaction-diffusion computing; however, readers inspired to discover and design their own chemical reaction-diffusion computers are advised to consult a more specific and thus more detailed text (Adamatzky et al. 2005b).

Abstract

In recent years, a rapid growth of interest in rough set theory, fuzzy set theory, and their hybridization and applications has been witnessed worldwide. In this chapter, the basic concepts of rough/fuzzy computing are presented. The role of rough/fuzzy computing in the development of Wisdom Technology (Wistech) is also emphasized.

1 Introduction

Gottfried Wilhelm Leibniz, one of the greatest of mathematicians, discussed *calculi of thoughts*. In particular, he wrote

- ▶ *If controversies were to arise, there would be no more need of disputation between two philosophers than between two accountants. For it would suffice to take their pencils in their hands, and say to each other: "Let us calculate."*

(Dissertio de Arte Combinatoria (Leipzig, 1666)).

- ▶ *...Languages are the best mirror of the human mind, and that a precise analysis of the signification of words would tell us more than anything else about the operations of the understanding.*

(New Essays on Human Understanding (1705), translated and edited by Peter Remnant and Jonathan Bennett, Cambridge University Press, 1982).

Only much later was it possible to recognize that new tools are necessary for developing such calculi, e.g., due to the necessity of reasoning under uncertainty about objects and vague concepts. Fuzzy set theory (Zadeh 1965) and rough set theory (Pawlak 1982) represent two complementary approaches to vagueness and, in a more general sense, to imperfect knowledge. Both of these approaches aim to approximate vague concepts. Fuzzy set theory addresses the “gradualness” of knowledge and expresses this in terms of fuzzy membership, whereas rough set theory addresses the granularity of knowledge. This granularity is manifest in the classes (knowledge granules) contained in the partition of each set of sample data defined by the indiscernibility relation.

In the rough/fuzzy approach, computations aim to construct granules satisfying a given specification, often vague and expressed in a natural language, to a satisfactory degree (Polkowski and Skowron 1996; Zadeh 2006). Granular computing (GC), introduced by Zadeh (1973, 1998) (Zadeh 2007; Bargiela and Pedrycz 2003; Pedrycz et al. 2008), may now be regarded as a unified framework for theories, methodologies, and techniques for the modeling of calculi of thoughts based on objects called granules. In the generalized theory of uncertainty, introduced by Zadeh (2006), reasoning under uncertainty is treated as a generalized constraint propagation. The generalized constraint language is used to express propositions, commands, and questions expressed in natural language.

One of the issues discussed in connection with the basic notion of a set is *vagueness*. Mathematics requires that all mathematical notions (including that of a set) must be exact, otherwise precise reasoning would be impossible. However, philosophers (Keefe 2000; Read 1994; Russell 1923; Black 1937) and recently computer scientists (see references in Pawlak and Skowron 2007c) as well as other researchers have become interested in *vague* (imprecise) concepts.

In classical set theory, a set is uniquely determined by its elements. In other words, this means that every element must be uniquely classified as belonging to the set or not. That is

to say, the notion of a set is a *crisp* (precise) one. For example, the set of odd numbers is crisp because every number is either odd or even. In contrast to odd numbers, the notion of a beautiful painting is vague, because all paintings cannot be classified uniquely into two classes: beautiful and not beautiful. For some paintings, it cannot be decided whether they are beautiful or not, and these paintings thus remain in the “doubtful” area. Hence, *beauty* is not a precise concept, but a vague concept. Almost all concepts in natural language are vague. Therefore, commonsense reasoning based on natural language must be based on vague concepts and not on classical logic. An interesting discussion on this issue can be found in, for example, Read (1994).

The idea of vagueness can be traced back to the ancient Greek philosopher Eubulides of Megara (ca. 400 BC) who first formulated the so-called “sorites” (heap) and “falakros” (bald man) paradoxes (see, e.g., Keefe 2000). The bald man paradox goes as follows: suppose a man has 100,000 hairs on his head; removing one hair from his head surely cannot make him bald. Repeating this step, it can be concluded that a man without any hair is not bald. A similar reasoning can be applied to a heap of stones.

Vagueness is usually associated with the boundary region approach (i.e., the existence of objects that cannot be uniquely classified relative to a set or its complement), which was first formulated in 1893 by the father of modern logic, the German logician, Frege (1848–1925) (Frege 1903).

According to Frege, a concept must have a sharp boundary. To a concept without a sharp boundary there would correspond an area that would not have any sharp boundary – i.e., no line all around the concept that clearly distinguishes the objects to which that concept applies. This means that mathematics must use crisp concepts and not vague ones; otherwise it would be impossible to reason precisely.

However, it should be noted that the modern understanding of the notion of a vague (imprecise) concept has a quite firmly established meaning in context, involving the following issues (Keefe 2000):

1. The presence of borderline cases
2. Boundary regions of vague concepts are not crisp
3. Vague concepts are susceptible to sorites paradoxes

Let it be noted that it is usually assumed that the understanding (approximation) of vague concepts (their semantics is determined by the satisfiability relation) depends, e.g., on the agent’s knowledge, which is often changing dynamically. Hence, the approximation of vague concepts by an agent should also be considered changing in time (this is known as concept drift). In the twentieth century, it became obvious that new specialized logic tools needed to be developed to investigate and implement practical problems involving vague concepts. Such tools can be based on rough sets and fuzzy sets. For example, it was shown that the rough set approach makes it possible to deal with vague concepts (see, e.g., Pawlak and Skowron 2007c; Bazan et al. 2006; Skowron 2005).

Vague complex concepts are very often related to one another through a hierarchy induced by the abstraction levels of these concepts. Such hierarchies occur, for instance, when some concepts are components of other concepts. In such a context, there is a great interest in investigating the relation *being a part-of*. This is a different approach from the ontology of modern mathematics (also known as *Cantor ontology*), which is based on the relation *being an element-of*. Such an alternative ontology for mathematics was proposed by Leśniewski (1929) and became the inspiration for an important research area within *rough mereology* (see, e.g., Polkowski and Skowron 1996). Within this approach, the notion of a *rough inclusion relation*

plays a central role. The rough inclusion relation describes to what degree some concepts are parts of other concepts. A rough mereological approach is based on the relation “to be a part of to a degree.”

Certainly, the mereological approach is not the only attempt at establishing links between vague concepts and rough sets. Among others are links based on treating vague concepts by means of logical values. In this case, one can build an algebra of such vague concepts as an algebra of logical values. Usually, this kind of algebra is a pseudo-Boolean algebra and the relationships between vague concepts can be expressed as relationships of logical values of an intermediate logic (see, e.g., Jankowski and Skowron 2008a).

Summing up, vagueness is (1) not allowed in mathematics, (2) interesting for philosophy, and (3) necessary for natural language, cognitive science, artificial intelligence, machine learning, and computer science.

It is worth mentioning that a large amount of knowledge related to natural computing (Rozenberg 2008; Cooper et al. 2008) is expressed in terms of vague concepts. Hence, natural computing seems to be the domain for future potential applications of rough/fuzzy computing.

The remainder of this chapter is structured as follows. ➤ [Section 2](#) presents the basic concepts of rough computing. ➤ [Section 3](#) reports the basic issues of fuzzy computing. Then, the combination of rough computing and fuzzy computing is surveyed in ➤ [Sect. 4](#). Finally, conclusions together with some comments on future applications of rough/fuzzy computing in Wistech (Jankowski and Skowron 2007, 2008a) are presented.

2 Rough Sets

The first paper on rough sets was published by Professor Pawlak in 1982 (Pawlak 1982, 1991). During recent years, numerous publications on the advances of the foundations of fuzzy sets and applications in many different areas have been published (see, e.g., the survey papers, Pawlak and Skowron 2007a, b, c and the bibliography included in these papers, as well as information about recent publications on rough set theory and applications on Web pages, e.g., <http://www.roughsets.org>, <http://logic.mimuw.edu.pl>, <http://rsds.wsiz.rzeszow.pl>).

The rough set philosophy is founded on the assumption that some information (data, knowledge) is associated with every object in the universe of discourse. For example, if objects are patients suffering from a certain disease, symptoms of the disease form information about patients. Objects characterized by the same information are indiscernible (similar) in view of the available information about them. The indiscernibility relation generated in this way is the mathematical basis of rough set theory. This understanding of indiscernibility is based on the idea of Gottfried Wilhelm Leibniz that objects are indiscernible if and only if all available functionals take identical values on them (Leibnizian indiscernibility).

Any set of all indiscernible (similar) objects is called an elementary set and forms a basic granule (atom) of knowledge about the universe. Any union of some elementary sets is referred to as a crisp (precise) set – otherwise the set is rough (imprecise, vague).

Consequently, each rough set has boundary-line cases, i.e., objects that can neither be classified with certainty as members of the set nor of its complement. Obviously, crisp sets have no boundary-line elements at all. This means that boundary-line cases cannot be properly classified by employing the available knowledge.

Thus, the assumption that objects can be *seen* only through the information available about them leads to the view that knowledge has a granular structure. Due to the granularity

of knowledge some objects of interest cannot be discerned and appear as the same (or similar). As a consequence, vague concepts, in contrast to precise concepts, cannot be characterized in terms of information about their elements. Therefore, in the proposed approach, it can be assumed that any vague concept is replaced by a pair of precise concepts – these are called the lower and the upper approximations of the vague concept. The lower approximation consists of all objects that surely belong to the concept and the upper approximation contains all objects that possibly belong to the concept. The difference between the upper and the lower approximation constitutes the boundary region of the vague concept. These upper and lower approximations are two basic operations in rough set theory.

In the following, the basic concepts are presented more formally.

Suppose two finite, nonempty sets U and A are given, where U is the *universe of objects*, and A is a set of *attributes*. The pair (U, A) is called an *information table*. With every attribute $a \in A$, a set V_a of its *values* is associated, called the *domain* of a . Any subset B of A determines a binary relation $I(B)$ on U , called an *indiscernibility relation*, defined by

$$xI(B)y \text{ if and only if } a(x) = a(y) \text{ for every } a \in B \quad (1)$$

where $a(x)$ denotes the value of attribute a for object x .

Obviously, $I(B)$ is an equivalence relation. The family of all equivalence classes of $I(B)$, i.e., the partition determined by B , will be denoted by $U/I(B)$, or simply U/B ; an equivalence class of $I(B)$, i.e., the block of the partition U/B containing x , will be denoted by $B(x)$ (or $[x]_B$).

If $(x, y) \in I(B)$, it can be said that x and y are *B-indiscernible*. Equivalence classes of the relation $I(B)$ (or blocks of the partition U/B) are referred to as *B-elementary sets* or *B-elementary granules*. In the rough set approach, the elementary sets are the basic building blocks (concepts) of our knowledge about reality. The unions of *B-elementary sets* are called *B-definable sets*.

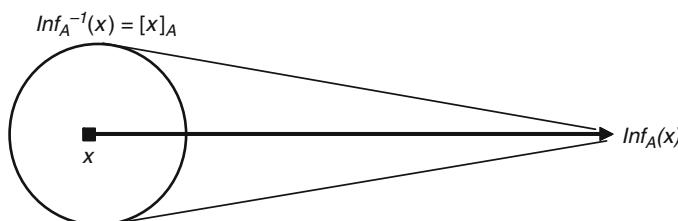

Let $\text{Inf}_B(x)$ denote the *B-signature* of $x \in U$, i.e., the set $\{(a, a(x)) : a \in B\}$. The signature of any object represents incomplete information about this object. The above definition of the indiscernibility relation can be rewritten in the following way:

$$xI(B)y \text{ if and only if } \text{Inf}_B(x) = \text{Inf}_B(y) \quad (2)$$

Hence, one can see that any *B-elementary granule* is defined by the signature of any of its objects, i.e., $B(x) = \text{Inf}_A^{-1}(x)$, where x is an arbitrary object from the granule (see [Fig. 1](#)). Any object from a given elementary granule is labeled by the same signature.

The equality on the right-hand side in the definition in (2) may be substituted by a similarity (tolerance) relation. This leads to the tolerance rough set approach (see, e.g., Skowron and Stepaniuk [1996](#)). It should be noted that the signatures of objects may be incomplete

Fig. 1
Elementary granule.

(e.g., when some values of attributes are missing) or can be influenced by noise. Many papers on rough sets are related to missing values (see the bibliography in Pawlak and Skowron 2007a, c). Recently, it was observed that the signature of objects can be extended to the relevant object contexts by hierarchical modeling (Skowron and Szczuka 2010).

The indiscernibility relation will be further used to define basic concepts of rough set theory. The two operations on sets can now be defined as

$$B_*(X) = \{x \in U : B(x) \subseteq X\} \quad (3)$$

$$B^*(X) = \{x \in U : B(x) \cap X \neq \emptyset\} \quad (4)$$

assigning to every subset X of the universe U two sets, $B_*(X)$ and $B^*(X)$, called the *B-lower* and the *B-upper approximation* of X , respectively. The set

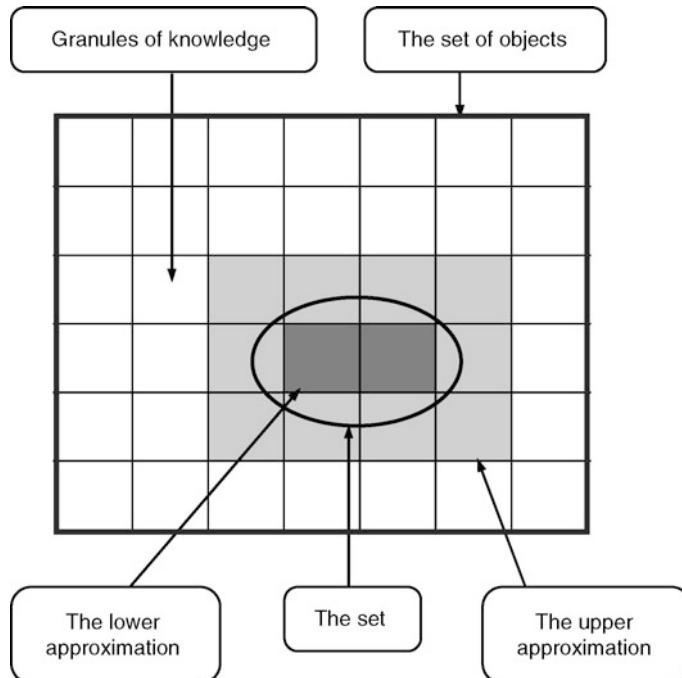

$$BN_B(X) = B^*(X) - B_*(X) \quad (5)$$

will be referred to as the *B-boundary region* of X .

If the boundary region of X is the empty set, i.e., $BN_B(X) = \emptyset$, then the set X is *crisp (exact)* with respect to B ; in the opposite case, i.e., if $BN_B(X) \neq \emptyset$, the set X is referred to as *rough (inexact)* with respect to B .

Approximations are illustrated in  Fig. 2.

 **Fig. 2**
A rough set.

The approximations have the following properties:

$$\begin{aligned}
 & B_*(X) \subseteq X \subseteq B^*(X) \\
 & B_*(\emptyset) = B^*(\emptyset) = \emptyset, B_*(U) = B^*(U) = U \\
 & B^*(X \cup Y) = B^*(X) \cup B^*(Y) \\
 & B_*(X \cap Y) = B_*(X) \cap B_*(Y) \\
 & X \subseteq Y \text{ implies } B_*(X) \subseteq B_*(Y) \text{ and } B^*(X) \subseteq B^*(Y) \\
 & B_*(X \cup Y) \supseteq B_*(X) \cup B_*(Y) \\
 & B^*(X \cap Y) \subseteq B^*(X) \cap B^*(Y) \\
 & B_*(-X) = -B^*(X) \\
 & B^*(-X) = -B_*(X) \\
 & B_*(B_*(X)) = B^*(B_*(X)) = B_*(X) \\
 & B^*(B^*(X)) = B_*(B^*(X)) = B^*(X)
 \end{aligned} \tag{6}$$

A rough set can also be characterized numerically by the following coefficient:

$$\alpha_B(X) = \frac{|B_*(X)|}{|B^*(X)|} \tag{7}$$

called the *accuracy of approximation*, where $|X|$ denotes the cardinality of $X \neq \emptyset$. Obviously, $0 \leq \alpha_B(X) \leq 1$. If $\alpha_B(X) = 1$, then X is *crisp* with respect to B (X is *precise* with respect to B); otherwise, if $\alpha_B(X) < 1$, then X is *rough* with respect to B (X is *vague* with respect to B).

Several generalizations of the classical rough set approach based on approximation spaces defined by (U, R) , where R is an equivalence relation (called indiscernibility relation) in U , have been reported in the literature. Two of the more prominent of these generalizations will now be presented.

A generalized approximation space can be defined by a tuple $AS = (U, I, v)$ where I is the *uncertainty function* defined on U with values in the powerset $P(U)$ of U ($I(x)$ is the *neighborhood* of x) and v is the *rough inclusion function* defined on the Cartesian product $P(U) \times P(U)$ with values in the interval $[0, 1]$ measuring the degree of inclusion of sets. The lower AS_* and upper AS^* approximation operations can be defined in AS by

$$AS_*(X) = \{x \in U : v(I(x), X) = 1\} \tag{8}$$

$$AS^*(X) = \{x \in U : v(I(x), X) = 0\} \tag{9}$$

In the standard case, $I(x)$ is equal to the equivalence class $B(x)$ of the indiscernibility relation $I(B)$; in case of tolerance (similarity) relation $\tau \subseteq U \times U$, $I(x) = \{y \in U : x \tau y\}$, i.e., $I(x)$ is equal to the tolerance class of τ defined by x . The standard rough inclusion relation is defined for $X, Y \subseteq U$ by

$$v(X, Y) = \begin{cases} \frac{|X \cap Y|}{|X|} & \text{if } X \neq \emptyset \\ 1 & \text{otherwise} \end{cases} \tag{10}$$

For applications, it is important to have some constructive definitions of I and v .

One can consider another way to define $I(x)$. Usually together with AS one can consider some set F of formulae describing sets of objects in the universe U of AS defined by semantics $\|\cdot\|_{AS}$, i.e., $\|\alpha\|_{AS} \subseteq U$ for any $\alpha \in F$. Now, one can take the set

$$N_F(x) = \{\alpha \in F : x \in \|\alpha\|_{AS}\} \quad (11)$$

and $I(x) = \{\|\alpha\|_{AS} : \alpha \in N_F(x)\}$. Hence, more general uncertainty functions having values in $P(P(U))$ can be defined. Usually there are considered families of approximation spaces which are labeled by some parameters. By tuning of such parameters one can search for the optimal, under chosen criteria (e.g., the minimal description length), approximation space for a given concept description.

The approach based on rough inclusion functions has been generalized to the *rough mereological approach* (Polkowski and Skowron, 1996). The inclusion relation $x\mu_r y$, with the intended meaning x is a part of y to a degree at least r , has been taken as the basic notion of rough mereology, being a generalization of the Leśniewski mereology (Leśniewski, 1929). Research on rough mereology has shown the importance of another notion, namely, the *closeness* of complex objects (e.g., concepts). This can be defined by $xcl_{r,r'}y$ if and only if $x\mu_r y$ and $y\mu_{r'}x$.

Rough mereology offers a methodology for the synthesis and analysis of objects in a distributed environment of intelligent agents, in particular, for the synthesis of objects satisfying a given specification to a satisfactory degree, or for control in such complex environments. Moreover, rough mereology has been used for developing the foundations of the *information granule calculi*, aimed at formalizing the “Computing with Words” paradigm, recently formulated by Zadeh (2001). More complex information granules are defined recursively using already defined information granules and their measures of inclusion and closeness. Information granules can have complex structures like classifiers or approximation spaces. Computations on information granules are performed to discover relevant information granules, e.g., patterns or approximation spaces for complex concept approximations.

It should be noted that rough sets can also be defined by employing the rough membership function instead of approximation. That is, consider

$$\mu_X^B : U \rightarrow \langle 0, 1 \rangle$$

defined by

$$\mu_X^B(x) = v(B(x), X) \quad (12)$$

where $x \in X \subseteq U$ and v is the standard rough inclusion (see Eq. 10).

The value $\mu_X^B(x)$ can be interpreted as the degree to which x belongs to X in view of knowledge about x expressed by B , or the degree to which the elementary granule $B(x)$ is included in the set X . This means that the definition reflects subjective knowledge about elements of the universe, in contrast to the classical definition of a set.

The rough membership function can also be interpreted as the conditional probability that x belongs to X given B . It is worth mentioning that set inclusion to a degree has been considered by Łukasiewicz (1970) in studies on assigning fractional truth values to logical formulae.

It can be shown that the rough membership function has the following properties:

1. $\mu_X^B(x) = 1$ iff $x \in B_*(X)$
2. $\mu_X^B(x) = 0$ iff $x \in U - B^*(X)$
3. $0 < \mu_X^B(x) < 1$ iff $x \in BN_B(X)$
4. $\mu_{U-X}^B(x) = 1 - \mu_X^B(x)$ for any $x \in U$
5. $\mu_X^B \cup Y(x) \geq \max(\mu_X^B(x), \mu_Y^B(x))$ for any $x \in U$
6. $\mu_X^B \cap Y(x) \leq \min(\mu_X^B(x), \mu_Y^B(x))$ for any $x \in U$

From these properties, it follows that the rough membership function differs in essential ways from the fuzzy membership function (Zadeh 1965), since properties (5) and (6) show that membership for the union and intersection of sets, in general, cannot be computed – as in the case of fuzzy sets – from their constituents' membership. Thus, formally, rough membership is more general than fuzzy membership. Moreover, the rough membership function depends on available knowledge (represented by attributes from B). Besides, the rough membership function, in contrast to the fuzzy membership function, has a probabilistic flavor.

Sometimes one can distinguish, in an information table (U, A) , a partition of A into two classes $C, D \subseteq A$ of attributes, called *condition* and *decision (action)* attributes, respectively. The tuple $\mathcal{A} = (U, C, D)$ is called a *decision table*.

Let $V = \bigcup\{V_a | a \in C\} \cup V_d$. Atomic formulae over $B \subseteq C \cup D$ and V are expressions $a = v$ called *descriptors (selectors)* over B and V , where $a \in B$ and $v \in V_a$. The set $\mathcal{F}(B, V)$ of formulae over B and V is the smallest set containing all atomic formulae over B and V and closed with respect to the propositional connectives \wedge (conjunction), \vee (disjunction), and \neg (negation).

By $\|\varphi\|_{\mathcal{A}}$ we denote the meaning of $\varphi \in \mathcal{F}(B, V)$ in the decision table \mathcal{A} , which is the set of all objects in U with the property φ . These sets are defined by $\|a = v\|_{\mathcal{A}} = \{x \in U | a(x) = v\}$, $\|\varphi \wedge \varphi'\|_{\mathcal{A}} = \|\varphi\|_{\mathcal{A}} \cap \|\varphi'\|_{\mathcal{A}}$; $\|\varphi \vee \varphi'\|_{\mathcal{A}} = \|\varphi\|_{\mathcal{A}} \cup \|\varphi'\|_{\mathcal{A}}$; $\|\neg\varphi\|_{\mathcal{A}} = U - \|\varphi\|_{\mathcal{A}}$. The formulae from $\mathcal{F}(C, V)$, $\mathcal{F}(D, V)$ are called *condition formulae of \mathcal{A}* and *decision formulae of \mathcal{A}* , respectively.

Any object $x \in U$ belongs to a *decision class* $\|\bigwedge_{a \in D} a = a(x)\|_{\mathcal{A}}$ of \mathcal{A} . All decision classes of \mathcal{A} create a partition of the universe U .

A *decision rule* for \mathcal{A} is any expression of the form $\varphi \Rightarrow \psi$, where $\varphi \in \mathcal{F}(C, V)$, $\psi \in \mathcal{F}(D, V)$, and $\|\varphi\|_{\mathcal{A}} \neq \emptyset$. Formulae φ and ψ are referred to as the *predecessor* and the *successor* of decision rule $\varphi \Rightarrow \psi$. Decision rules are often called “*IF … THEN …*” rules.

The decision rule $\varphi \Rightarrow \psi$ is *true* in \mathcal{A} if and only if $\|\varphi\|_{\mathcal{A}} \subseteq \|\psi\|_{\mathcal{A}}$. Otherwise, one can measure its *truth degree* by introducing some inclusion measure of $\|\varphi\|_{\mathcal{A}}$ in $\|\psi\|_{\mathcal{A}}$. It is important to note that an inclusion measure expressed in terms of the confidence measure, widely used in data mining, was considered by Łukasiewicz (1970) a long time ago in studies on assigning fractional truth values to logical formulae. Given two unary predicate formulae $\alpha(x)$, $\beta(x)$ where x runs over a finite set U , Łukasiewicz proposes to assign to $\alpha(x)$ the value $\|\alpha(x)\|/|U|$, where $\|\alpha(x)\| = \{x \in U : x \text{ satisfies } \alpha\}$. The fractional value assigned to the implication $\alpha(x) \Rightarrow \beta(x)$ is then $\|\alpha(x) \wedge \beta(x)\|/|\alpha(x)|$ under the assumption that $|\alpha(x)| \neq \emptyset$.

Each object x of a decision table determines a *decision rule* $\bigwedge_{a \in C} a = a(x) \Rightarrow \bigwedge_{a \in D} a = a(x)$.

Decision rules corresponding to some objects can have the same condition parts but different decision parts. Such rules are called *inconsistent (nondeterministic, conflicting, possible)*; otherwise the rules are referred to as *consistent (certain, sure, deterministic, nonconflicting)* rules. Decision tables containing inconsistent decision rules are called *inconsistent (nondeterministic, conflicting)*; otherwise the table is *consistent (deterministic, nonconflicting)*.

Numerous methods have been developed within the rough sets literature for generating decision rules. They typically involve searching for decision rules that are (semi) optimal with respect to some optimization criteria describing the quality of decision rules in concept approximations.

In the case of searching for concept approximations in an extension of a given universe of objects (sample), the following steps are typically used. When a set of rules has been induced from a decision table containing a set of training examples, they can be inspected to see if they reveal any novel relationships between attributes that are worth pursuing for further research.

Furthermore, the rules can be applied to a set of unseen cases in order to estimate their classification power. For a systematic overview of rule application methods the reader is referred to the literature (Bazan 1998; Grzymała-Busse 1998; Bazan et al. 2000; Nguyen 2002; Triantaphyllou and Felici 2006) (see also references in Pawlak and Skowron 2007a, b, c).

Another important issue in data analysis is that of discovering dependencies between attributes. Intuitively, a set of attributes D depends totally on a set of attributes C , denoted $C \Rightarrow D$, if the values of attributes from C uniquely determine the values of attributes from D . In other words, D depends totally on C , if there exists a functional dependency between values of C and D . Formally, dependency can be defined in the following way. Let D and C be subsets of A .

We say that D depends on C to a degree k ($0 \leq k \leq 1$), denoted $C \Rightarrow_k D$, if

$$k = \gamma(C, D) = \frac{|\text{POS}_C(D)|}{|U|} \quad (13)$$

where

$$\text{POS}_C(D) = \bigcup_{X \in U/D} C_*(X) \quad (14)$$

called a *positive region* of the partition U/D with respect to C , is the set of all elements of U that can be uniquely classified to blocks of the partition U/D , by means of C .

If $k = 1$, we say that D depends totally on C , and if $k < 1$, we say that D depends partially (to a degree k) on C .

The coefficient k expresses the ratio of all elements of the universe, which can be properly classified to blocks of the partition U/D , employing attributes C and will be called the *degree of the dependency*.

It can be easily seen that if D depends totally on C then $I(C) \subseteq I(D)$. This means that the partition generated by C is finer than the partition generated by D . Notice that the concept of dependency discussed above corresponds to that considered in relational databases.

Summing up: D is *totally (partially)* dependent on C , if *all (some)* elements of the universe U can be uniquely classified to blocks of the partition U/D , employing C .

The question as to whether or not some data from a data-table can be removed while preserving its basic properties, i.e., whether a table contains some superfluous data, is a common one. This idea can be expressed more precisely.

Let $C, D \subseteq A$, be sets of condition and decision attributes, respectively. We say that $C' \subseteq C$ is a *D-reduct* (reduct with respect to D) of C , if C' is a minimal subset of C such that

$$\gamma(C, D) = \gamma(C', D) \quad (15)$$

The intersection of all *D-reducts* is called a *D-core* (core with respect to D). Because the core is the intersection of all reducts, it is included in every reduct, i.e., each element of the core belongs to some reduct. Thus, in a sense, the core is the most important subset of attributes, since none of its elements can be removed without affecting of the classification power of attributes.

Many other kinds of reducts and their approximations are discussed in the literature. It turns out that they can all be efficiently computed using heuristics based on a Boolean reasoning approach.

Tasks collected under the labels of data mining, knowledge discovery, decision support, pattern classification, approximate reasoning, and so on, require tools aimed at discovering *templates (patterns)* within the data, and classifying them into certain *decision classes*. Templates are in many cases the most frequent sequences of events, the most probable events,

regular configurations of objects, the decision rules of highest quality, and so on. Tools for discovering and classifying templates are based on *reasoning schemes* rooted in various paradigms (Hastie et al. 2001). Such patterns can be extracted from data by means of methods based on Boolean reasoning and discernibility.

The discernibility relation is one of the most important relations considered in rough set theory.

The ability to discern between perceived objects is important for constructing many entities like reducts, decision rules, or decision algorithms. In the classical rough set approach, the discernibility relation $\text{DIS}(B) \subseteq U \times U$ is defined by $x \text{ DIS}(B)y$ if and only if $\text{non}(xI(B)y)$. However, this is in general not the case for the generalized approximation spaces (one can define indiscernibility by $x \in I(y)$ and discernibility by $I(x) \cap I(y) = \emptyset$ for any objects x, y).

The idea of Boolean reasoning is based on the construction of, for a given problem P , a corresponding Boolean function f_P with the following property: the solutions for the problem P can be decoded from the prime implicants of f_P . It should be noted that to solve real-life problems it is necessary to deal with Boolean functions having a large number of variables.

A successful methodology based on the discernibility of objects and Boolean reasoning has been developed for computing many application-critical entities such as reducts and their approximations, decision rules, association rules, discretization of real-value attributes, symbolic value grouping, searching for new features defined by oblique hyperplanes or higher-order surfaces, pattern extraction from data, as well as conflict resolution or negotiation (Nguyen and Skowron 1997; Nguyen and Nguyen 1998; Nguyen 1998, 2006; Skowron 2002; Pawlak and Skowron 2007a).

Most of the problems related to generating the above mentioned entities are NP-complete or NP-hard. However, it has been found possible to develop efficient heuristics yielding suboptimal solutions. The results of experiments on many data sets are very promising (Nguyen and Skowron 1997; Nguyen and Nguyen 1998; Nguyen 1998, 2006; Skowron 2002; Pawlak and Skowron 2007a). They show very good quality of solutions generated by the heuristics in comparison with other methods reported in the literature (e.g., with respect to the classification quality of unseen objects). Moreover, they are very efficient from the point of view of the time necessary for computing the solution.

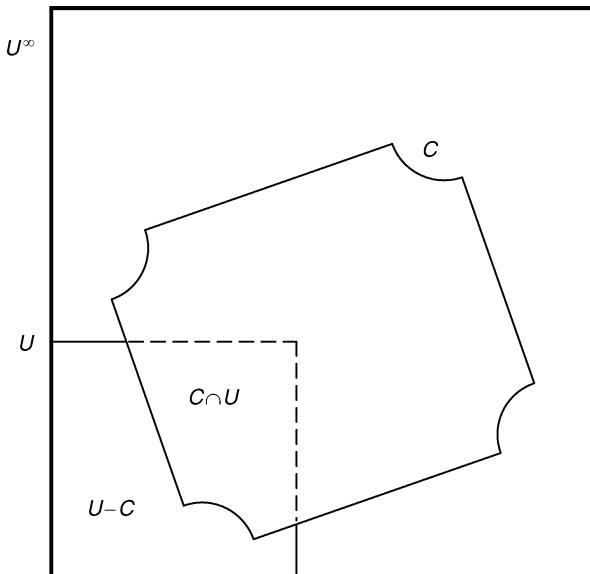

It is important to note that the methodology makes it possible to construct heuristics having a very important *approximation property*, which can be formulated as follows: expressions generated by heuristics (i.e., implicants) close to prime implicants define approximate solutions for the problem (Skowron 2002; Nguyen 2006).

The problem of approximation of concepts over a universe U^∞ (concepts that are subsets of U^∞) is now outlined. It is assumed that the concepts are perceived only through some subsets of U^∞ , called samples. This is a typical situation in the machine learning, pattern recognition, or data-mining approaches (Hastie et al. 2001). The rough set approach to induction of concept approximations is explained using the generalized approximation spaces of the form $AS = (U, I, v)$, defined earlier.

Let $U \subseteq U^\infty$ be a finite sample. By Π_U we denote a perception function from $P(U^\infty)$ into $P(U)$ defined by $\Pi_U(C) = C \cap U$ for any concept $C \subseteq U^\infty$. $\Pi_U(C)$ represents partial information relative to the given sample U about the concept C (see Fig. 3).

Let $AS = (U, I, v)$ be an approximation space over the sample U . The problem as to how to extend the approximations of $\Pi_U(C)$ defined by AS to the approximation of C over U^∞ is considered. It is shown that the problem can be described as searching for an extension $AS_C = (U^\infty, I_C, v_C)$ of the approximation space AS , relevant for the approximation of C .

Fig. 3
Concept sample.

This requires us to show how to extend the inclusion function v from subsets of U to subsets of U^∞ that are relevant for the approximation of C . Observe that for the approximation of C , it is enough to induce the necessary values of the inclusion function v_C without knowing the exact value of $I_C(x) \subseteq U^\infty$ for $x \in U^\infty$.

Let AS be a given approximation space for $\Pi_U(C)$ and let a language L be considered in which the neighborhood $I(x) \subseteq U$ is expressible by a formula $\text{pat}(x)$, for any $x \in U$. This means that $I(x) = \|\text{pat}(x)\|_U \subseteq U$, where $\|\text{pat}(x)\|_U$ denotes the meaning of $\text{pat}(x)$ restricted to the sample U . In the case of rule-based classifiers, patterns of the form $\text{pat}(x)$ are defined by feature value vectors.

It is assumed that for any new object $x \in U^\infty \setminus U$ (e.g., as a result of sensor measurement) a pattern $\text{pat}(x) \in L$ with semantics $\|\text{pat}(x)\|_{U^\infty} \subseteq U^\infty$ can be obtained. However, the relationships between information granules over U^∞ like sets: $\|\text{pat}(x)\|_{U^\infty}$ and $\|\text{pat}(y)\|_{U^\infty}$, for different $x, y \in U^\infty$, are, in general, known only if they can be expressed by relationships between the restrictions of these sets to the sample U , i.e., between sets $\Pi_U(\|\text{pat}(x)\|_{U^\infty})$ and $\Pi_U(\|\text{pat}(y)\|_{U^\infty})$.

The set of patterns $\{\text{pat}(x) : x \in U\}$ is usually not relevant for approximation of the concept $C \subseteq U^\infty$. Such patterns are too specific or not sufficiently general, and can directly be applied only to a very limited number of new objects. However, by using some generalization strategies, one can search, within a family of patterns definable from $\{\text{pat}(x) : x \in U\}$ in L , for such new patterns that are relevant for the approximation of concepts over U^∞ . Let a subset $\text{PATTERNS}(AS, L, C) \subseteq L$ chosen as a set of pattern candidates for the relevant approximation of a given concept C be considered. For example, in the case of rule-based classifiers, one can search for such candidate patterns among sets definable by subsequences of feature value vectors corresponding to objects from the sample U . The set $\text{PATTERNS}(AS, L, C)$

can be selected by using some quality measures checked on the meanings (semantics) of its elements restricted to the sample U (such as the number of examples from the concept $\Pi_U(C)$ and its complement that support a given pattern). Then, on the basis of properties of sets definable by these patterns over U , we induce approximate values of the inclusion function v_C on subsets of U^∞ definable by any such pattern and the concept C .

Next, the value of v_C on pairs (X, Y) is induced where $X \subseteq U^\infty$ is definable by a pattern from $\{\text{pat}(x) : x \in U^\infty\}$ and $Y \subseteq U^\infty$ is definable by a pattern from PATTERNS(AS, L, C).

Finally, for any object $x \in U^\infty \setminus U$, the approximation of the degree $v_C(\|\text{pat}(x)\|_{U^\infty}, C)$ is induced applying a conflict resolution strategy *Conflict_res* (a voting strategy, in the case of rule-based classifiers) to two families of degrees:

$$\{v_C(\|\text{pat}(x)\|_{U^\infty}, \|\text{pat}\|_{U^\infty}) : \text{pat} \in \text{PATTERNS(AS, L, C)}\} \quad (16)$$

$$\{v_C(\|\text{pat}\|_{U^\infty}, C) : \text{pat} \in \text{PATTERNS(AS, L, C)}\} \quad (17)$$

Values of the inclusion function for the remaining subsets of U^∞ can be chosen in any way – they do not have any impact on the approximations of C . Moreover, observe that for the approximation of C , the exact values of the uncertainty function I_C need not be known – it is enough to induce the values of the inclusion function v_C . Observe that the defined extension v_C of v to some subsets of U^∞ makes it possible to define an approximation of the concept C in a new approximation space AS_C.

In this way, the rough set approach to induction of concept approximations can be explained as a process of inducing a relevant approximation space.

It is worthwhile mentioning that for any formula α over descriptors one can consider its semantics $\|\alpha\|_U$ over U and semantics $\|\alpha\|_{U^\infty}$ over U^∞ , respectively: (1) $\|\alpha\|_U \subseteq U$ and (2) $\|\alpha\|_{U^\infty} \subseteq U^\infty$. In approximate reasoning, hypotheses on relationships of semantics of formulae over U^∞ are induced (estimated) from information on relationships between semantics of formulae over U .

Many tasks in rough computing are based on searching for (semi)optimal approximation spaces (Jankowski et al. 2008). There are numerous significant results and active current research directions on rough set theory and applications (Pawlak and Skowron 2007a, b, c).

3 Fuzzy Sets

Fuzzy set theory has entered its fifth decade of research and development efforts since the first paper on fuzzy sets was published by Zadeh (1965). During these decades, numerous publications on the advances of the foundations of fuzzy sets and applications in many different areas have been published (see, e.g., Dubois and Prade 2000; Hohle and Rodabaugh 1999; Bezdek et al. 1999a, b; Słowiński 1998; Nguyen and Sugeno 1998; Zimmermann 1999; Klir and Yuan 1995; Klir 2006; Pedrycz and Gomide 2007; Nikravesh et al. 2007, 2008).

In this section, some basic issues that are important for fuzzy computing are discussed.

Fuzzy sets differ from classical sets by rejecting the requirement that for any object it must be possible to determine whether the object is, or is not, a member of the set. More formally, in classical set theory, it can be assumed that for any set $X \subseteq U$, where U is the universe of objects, the following condition holds:

$$\forall x \in U(x \in X \vee x \notin X). \quad (18)$$

Contrary to classical sets, fuzzy sets are not required to have sharp boundaries distinguishing their members from other objects. The membership in a fuzzy set is a matter of degree. Due to their sharp boundaries, classical sets are usually referred to in the fuzzy literature as *crisp* sets.

Any fuzzy set over a given (crisp) universe of objects is defined by a function analogous to the characteristic function of crisp sets. This function is called a (fuzzy) membership function.

Let U be the universe of objects. A *fuzzy set* is defined uniquely by a *fuzzy membership function* of the form $\mu : U \rightarrow [0, 1]$. For any $x \in U$, the value $\mu(x)$ defines the degree of membership of the object x from U in the fuzzy set identified with the function μ .

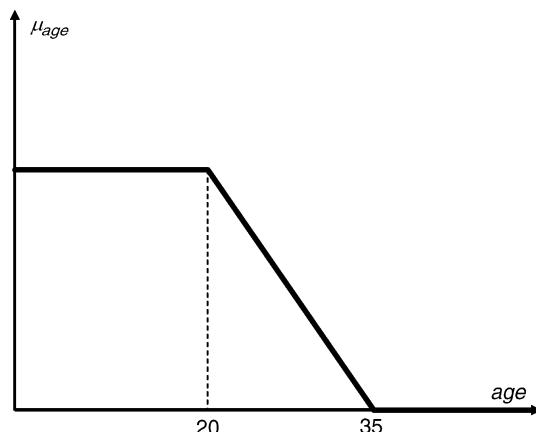

The membership of any object from the universe of objects in any fuzzy set is a matter of degree. By using degrees of membership, fuzzy sets make it possible to express gradual transitions from membership to nonmembership. This expressive capability is important for expressing, e.g., the meanings of vague expressions in natural language. Membership degrees in the fuzzy sets define compatibilities of relevant objects with the linguistic expression that the fuzzy sets attempt to approximate. Crisp sets are inadequate for this purpose.

Let an illustrative example of a fuzzy set corresponding to a linguistic hedge *young* be considered. The membership function corresponding to this hedge is presented in [Fig. 4](#).

In the example, the universe U consists of age values. One can see that if the age of a person is not greater than 20, then the membership degree is equal to 1, i.e., this person is classified with certainty as *young*. If the age of a person is greater than 35, then the membership degree is equal to 0, i.e., this person is classified with certainty as *not young*. If the age is between 20 and 35 years the certainty degree is greater than 0 but less than 1, and the higher the age the smaller the degree of membership. Definitely, this membership function is subjective. One can ask how such a function may be acquired from data or from experts, or computed from some other fuzzy sets. One can assume that in the discussed example, the membership function was drawn by an expert. Another solution may be to select the membership function from a parameterized family of functions that are candidates for the membership function so that

Fig. 4

A fuzzy set corresponding to the linguistic expression: *young*.

the selected function could match the expert opinions in the best way. One can consider, e.g., the following simple parameterized family of functions:

$$\mu_{a,b}(x) = \begin{cases} 1 & \text{if } x \leq a \\ \frac{x-a}{b-a} & \text{if } a < x < b \\ 0 & \text{otherwise} \end{cases} \quad (19)$$

where a, b are parameters to be tuned to match the expert opinions. In the example, the selected parameters are $a = 20$ and $b = 35$. Certainly, in many applications, the process of construction of the relevant fuzzy membership function may not be so easy. The construction of fuzzy membership functions the most suited for the application under consideration is one of the main tasks in fuzzy computing.

In the above definition of fuzzy sets, membership degrees are expressed by real numbers from the interval $[0, 1]$. In generalizations of the concept of fuzzy sets, which are often referred to as nonstandard fuzzy sets, degrees of membership may be expressed by more complex objects such as intervals of reals or elements of lattices (Goguen 1967). For the sake of simplicity, our considerations are restricted mainly to the case of degrees of membership from the interval $[0, 1]$.

The set of all fuzzy sets over the universe U is denoted by $\mathcal{F}(U)$.

If $\mu, v \in \mathcal{F}(U)$, then the fuzzy set μ is a fuzzy subset of the fuzzy set v , in symbols $\mu \subseteq v$ iff $\mu(x) \leq v(x)$ for any $x \in U$.

When U is a finite set, then one can consider a fuzzy subsethood relation, Sub defined for any fuzzy subset μ, v over U by

$$\text{Sub}(\mu, v) = \frac{\sum_{x \in U} \mu(x) - \sum_{x \in U} \max\{0, \mu(x) - v(x)\}}{\sum_{x \in U} \mu(x)} \quad (20)$$

Many characteristics are defined for any fuzzy set $\mu \in \mathcal{F}(U)$. Some of them are considered here. When U is a finite set, then $|\mu|$ denotes the fuzzy cardinality of μ defined by $|\mu| = \sum_{x \in U} \mu(x)$. Among the most important concepts of fuzzy sets are the concepts of α -cut and strong α -cut, which are defined for any fuzzy set $\mu \in \mathcal{F}(U)$ and any $\alpha \in [0, 1]$ by ${}^{\alpha}\mu = \{x \in U : \mu(x) \geq \alpha\}$ and ${}^{>\alpha}\mu = \{x \in U : \mu(x) > \alpha\}$. The set ${}^{0+}\mu$ is called the *support* and the set ${}^{1+}\mu$ is called the *core* of the fuzzy set μ .

Another task in fuzzy computing is the task of searching for the construction of membership functions (e.g., this is highly relevant for applications) from given fuzzy sets. Some examples of operations that can be used in this process are presented here.

The counterparts of set theoretical operations (i.e., complement, union, and intersection of sets) are not unique for fuzzy sets. These operations for fuzzy sets are defined relative to some functions.

The complement operation for fuzzy sets is defined by *complementation operations*, i.e., functions $n : [0, 1] \rightarrow [0, 1]$ that satisfy the following conditions: (1) n is order reversing, (2) $n(0) = 1$, (3) $n(1) = 0$, and (4) $n(n(s))$ for all $s \in [0, 1]$ (n is an involution). An example of a complementation function is $n_{\lambda}(s) = (1 - s^{\lambda})^{1/\lambda}$, where $\lambda > 0$. For a given complementation operation and a fuzzy set $\mu \in \mathcal{F}(U)$ the n -complement of μ is defined by $\mu'(x) = n(\mu(x))$ for $x \in U$.

The operations of union and intersection on fuzzy sets are defined relative to functions referred to in the research literature as *triangular norms* (or *t-norms*) and *triangular conorms* (or *t-conorms*), defined in terms of functions from the product $[0, 1] \times [0, 1]$ into $[0, 1]$,

which are (1) commutative, (2) associative, (3) monotone nondecreasing, and (4) consistent with the characteristic functions of set theoretical intersections and unions, respectively. The standard example of a t -norm is *min*, and the standard example of a t -conorm is *max*. There are many other examples of t -norms and t -conorms such as

$$g(s, w) = 1 - \min\{1, [(1-s)^\lambda + (1-w)^\lambda]^{1/\lambda}\} \quad (21)$$

$$h(s, w) = \min\{1, (s^\lambda + w^\lambda)^{1/\lambda}\} \quad (22)$$

where $\lambda > 0$ is a parameter tuned for each application by knowledge acquisition techniques.

For given fuzzy sets $\mu, v \in \mathcal{F}(U)$, t -norm g , and t -conorm h , the g -union and h -intersection of μ and v are defined by

$$(\mu \cup v)(x) = g(\mu(x), v(x)) \quad (23)$$

$$(\mu \cap v)(x) = h(\mu(x), v(x)) \quad (24)$$

respectively, where $x \in U$.

There are other operations used for constructing fuzzy sets without counterparts in classical set theory. Among them are modifiers and averaging operations. For example, modifiers are unary operations preserving the order used for modifying fuzzy sets representing linguistic terms. They make it possible to account for linguistic hedges such as *very*, *fairly*, *extreme*, and *more or less*.

Relations are defined in classical set theory as subsets of Cartesian products of some universes of objects. One can also consider fuzzy relations as elements of $\mathcal{F}(U_1 \times \dots \times U_k)$, where U_1, \dots, U_k are universes of objects. Fuzzy relations involve additional concepts and operations due to their multidimensionality. Among these operations are projections, cylindric extensions, compositions, joins, and inverses or fuzzy relations.

Let two examples of operations on fuzzy relations, namely, projection and composition be considered. For simplicity, it can be assumed that $\mu \in \mathcal{F}(U_1 \times U_2)$. Then the projection of μ on U_2 is defined by $\mu_{U_2}(x) = \max_{y \in Y} \mu(x, y)$, where $x \in U_1$. In the example of composition of fuzzy relations, let it be assumed that two fuzzy relations $\mu_1 \in \mathcal{F}(U_1 \times U_2)$ and $\mu_2 \in \mathcal{F}(U_2 \times U_3)$ are given. Then the fuzzy composition μ of μ_1 and μ_2 is defined by

$$\mu(x, y) = \max_{z \in U_2} \min\{\mu_1(x, z), \mu_2(z, y)\} \quad (25)$$

where $x \in U_1$ and $y \in U_3$.

An illustrative operation transforming fuzzy sets into fuzzy sets can be defined by a crisp function $f: U_1 \rightarrow U_2$. Any such function defines an operation $F: \mathcal{F}(U_1) \rightarrow \mathcal{F}(U_1)$ by the *extension principle*, i.e., by

$$\mu'(y) = \begin{cases} \sup\{\mu(x) : x \in U_1 \text{ and } f(x) = y\} & \text{if } f^{-1}(y) \neq \emptyset \\ 0 & \text{otherwise} \end{cases} \quad (26)$$

Some properties of fuzzy sets can be derived from properties of standard sets. Such properties are called *cutworthy properties*. For example, a fuzzy set over reals is said to be a *fuzzy interval* if and only if all of its α -cuts are closed intervals of reals. The equivalence property of fuzzy binary relations can be considered as another example. A fuzzy relation $\mu \in \mathcal{F}(U \times U)$ is a fuzzy equivalence relation if and only if this relation is reflexive, symmetric, and max-min-transitive, i.e., $\mu(x, y) \geq \max_{z \in U} \min\{\mu(x, z), \mu(z, y)\}$ for all $x \in U \times U$.

The equivalence property of binary relation over U is also a cutworthy property. However, many operations on fuzzy sets are not cutworthy (e.g., when t -norms or t -conorms, different from \min and \max , are applied in definitions of fuzzy union or intersection).

Several measures of fuzziness of fuzzy sets have been introduced. The basic idea in defining such measures is based on the observation that the less the fuzzy set differs from its fuzzy complement, the fuzzier it is. This idea can be expressed by the following functional $f : \mathcal{F}(U) \rightarrow \mathcal{R}_+$ defined by

$$f(\mu) = \sum_{x \in U} (1 - |\mu(x) - n(\mu(x))|) \quad (27)$$

where $x \in U$, U is a finite universe of objects, and n is a fuzzy negation.

The degree of fuzzy membership $\mu(x)$, for a given fuzzy set $\mu \in \mathcal{F}(U)$ and $x \in U$ can be interpreted as the degree of truth of the proposition x is a member of μ .

The simplest fuzzy canonical propositional form is defined by

$$f_\mu(\mathbf{x}) : \mathbf{x} \text{ is } \mu \quad (28)$$

where \mathbf{x} is a variable with values in U and $\mu \in \mathcal{F}(U)$, which is called a fuzzy predicate. By substituting into the propositional form instead of the variable \mathbf{x} a particular object $x \in U$, a fuzzy proposition is obtained

$$f_\mu(x) : x \text{ is } \mu \quad (29)$$

where $f_\mu(x)$ also denotes the degree of truth of the proposition x is μ , which is equal to $\mu(x)$ for $x \in U$.

This simple correspondence is used to define the truth of more complex propositions constructed by using negations, conjunctions, disjunctions, or implications of fuzzy propositions. Let the case of implication be considered. The propositions constructed using fuzzy implication are called conditional fuzzy propositions. They are essential for knowledge-based systems (Nguyen and Sugeno 1998). Conditional fuzzy propositions are based on the propositional form

$$f_{\mu'|\mu} : \text{if } \mathbf{x} \text{ is } \mu \text{ then } \mathbf{y} \text{ is } \mu' \quad (30)$$

where \mathbf{x} and \mathbf{y} are variables with values in the universes U_1 and U_2 , respectively. This form may also be presented as

$$f_{\mu'|\mu} : (\mathbf{x}, \mathbf{y}) \text{ is } \xi \quad (31)$$

where $\xi \in \mathcal{F}(U_\infty \times U_\infty)$ is defined by

$$\xi(x, y) = \iota(\mu(x), \mu'(y)) \quad (32)$$

where $\iota : [0, 1] \times [0, 1] \rightarrow [0, 1]$ defines a relevant fuzzy implication in the given application context. The class of such functions defining fuzzy implications is large and the selection of the relevant implication is a challenging task in the given application. One can consider some natural conditions that should satisfy any function $\iota : [0, 1] \times [0, 1] \rightarrow [0, 1]$ defining fuzzy implications (Klir and Yuan 1995; Pedrycz and Gomide 2007). The basic conditions are the following: (1) (monotonicity) if $b \leq b'$ then $\iota(a, b) \leq \iota(a, b')$, (2) (dominance of falsity) $\iota(0, b) = 1$, and (3) (neutrality of truth) $\iota(1, b) = b$. In addition, also often some other conditions are added (4) if $a \leq a'$ then $\iota(a, b) \geq \iota(a', b)$, (5) $\iota(a, \iota(a', b)) = \iota(a', \iota(a, b))$,

(6) $\iota(a, a) = 1$, (7) $\iota(a, b) = 1$ iff $a \leq b$, (8) $\iota(a, b) = \iota(n(b), n(a))$, where n is a fuzzy negation, and (9) ι is a continuous function. In all conditions (1)–(9) $a, b, a', b' \in [0, 1]$.

In general, one class of implications is defined in terms of negation and disjunction. Another class of fuzzy implications may be defined by the residuation of continuous t -norms. Any t -norm g defines its residuation by

$$\iota(a, b) = \sup_{c \in [0, 1]} \{g(a, c) \leq b\} \quad (33)$$

where $a, b \in [0, 1]$.

An important subclass of fuzzy implications known as Łukasiewicz implications is defined by

$$\iota(a, b) = \min [1, 1 - a^\lambda + b^\lambda]^{1/\lambda} \quad (34)$$

where $\lambda > 0$ is a parameter to be tuned to obtain a relevant implication for the given application and $a, b \in [0, 1]$. There are many other fuzzy implications used in fuzzy set theory and its applications. Among them are the Gödel implication and the Kleene implication defined by

$$\iota(a, b) = \begin{cases} 1 & \text{if } a \leq b \\ b & \text{otherwise} \end{cases} \quad (35)$$

and

$$\iota(a, b) = \max\{1 - a, b\} \quad (36)$$

respectively, where $a, b \in [0, 1]$.

Fuzzy propositions constructed by means of fuzzy connectives may also be quantified by means of fuzzy quantifiers. Fuzzy quantifiers are usually fuzzy intervals.

Reasoning based on fuzzy propositions is related to approximate reasoning. The most fundamental components of approximate reasoning are conditional fuzzy propositions that can be quantified in different ways. Various methods have been developed to deal with different kinds of fuzzy propositions attempting to emulate commonsense reasoning based on natural language. Let one simple example be considered that is related to the *generalized modus ponens* rule, defined by the following scheme:

Fuzzy rule: if x is μ then y is μ'

Fuzzy fact: x is v

Fuzzy conclusion: y is v'

where $\mu, v \in \mathcal{F}(U_1)$, $\mu', v' \in \mathcal{F}(U_2)$.

Assuming that the fuzzy rule has been presented in the relational form

$$(x, y) \text{ is } \xi \quad (37)$$

where ξ is represented by a fuzzy implication. The fuzzy conclusion v' is obtained by composition v and ξ , i.e., $v' = v \circ \xi$, where \circ denotes the fuzzy composition, i.e.,

$$v'(y) = \max_{x \in U_1} \{\min\{v(x), \xi(x, y)\}\} \quad (38)$$

where $y \in U_2$.

Observe that in any application, it is necessary to choose a relevant fuzzy implication and use it to describe the relation ξ . This requires searching, in particular, for relevant fuzzy implication making it possible to derive conclusions matching the empirical observations or expectations by human experts. There are several methods for the selection of the necessary parameters (Dubois and Prade 2000; Hoehle and Rodabaugh 1999; Bezdek et al. 1999a; Pedrycz and Gomide 2007).

Fuzzy systems are represented by a set of variables and dependencies among values (states) of the variables, which are fuzzy sets. Very often, the values are fuzzy intervals representing linguistic terms such as *small*, *medium*, *large*, *very large*, with the interpretation of these variables depending on the application under consideration. Each linguistic variable is defined by (1) a name of this variable; (2) a base variable with a given set of values, which is often the set of reals; (3) a set of linguistic terms referring to the base variable such as *small*, *medium*, *large*, *very large* and (4) a set of fuzzy intervals defining the semantics of each linguistic term. Fuzzy sets defining semantics of linguistic terms create a *fuzzy partition*, i.e., for any object x from the domain of the base variable the sum of membership degrees in these fuzzy sets is equal to 1.

In knowledge-based systems, relationships between variables are given by a set of *fuzzy inference rules*. These rules are conditional fuzzy propositional forms representing the relevant human expert knowledge, often expressed in natural language. Another class of fuzzy systems involves creating model-based fuzzy systems based on traditional modeling combined with the application of fuzzy sets. By combining knowledge-based systems and model-based systems, such hybrid systems are obtained.

The input–output relationship of such a knowledge-based system can be described by the following scheme of inference:

Rule 1: if x_1 is μ_{11} and x_2 is μ_{21} ...
then y_1 is μ'_{11} and y_2 is μ'_{21} and ...

Rule 2: if x_1 is μ_{12} and x_2 is μ_{22} ...
then y_1 is μ'_{12} and y_2 is μ'_{22} and ...

.....
Rule k: if x_1 is μ_{1k} and x_2 is μ_{2k} ...
then y_1 is μ'_{1k} and y_2 is μ'_{2k} and ...

Fact: x_1 is v_1 and x_2 is v_2 and ...

Conclusion: y_1 is v_1 and y_2 is v_2 and ...

Different inference methods based on the fuzzy inference rules presented above have been developed. A thorough consideration of all the details of those methods is beyond the scope of this overview. However, it is appropriate to make some general comments. Let it be assumed that (1) each fuzzy inference rule is based on input and output linguistic variables and (2) the values of variables on the left-hand side of rules are given, and the fuzzy intervals (over reals) corresponding to these variables are defined. Then, for each rule r , the inference is performed using the following steps:

1. Selection of aggregation methods of membership degrees given for fuzzy sets on the left-hand side of the rule r . This requires, e.g., the selection of some t -norms corresponding to conjunctions occurring on the left-hand side of the rule r . It is worth mentioning that interpretation of all conjunctions by the t -norm *min* may not be satisfactory for a given application and it may then be necessary to search for different t -norms for different conjunctions.

2. *Modification of fuzzy sets on the right-hand side of the rule r using the aggregated membership degree from the previous step.* As a consequence, the result of application of each fuzzy inference rule is a fuzzy interval for each output variable. Next, for each output variable, the fuzzy intervals obtained from different inference rules are aggregated and a new fuzzy interval is obtained. Finally, a defuzzification process is launched, i.e., for each variable, the obtained fuzzy interval is transformed into a single real number representing, in the context of the given application and in the best way, the fuzzy set. One of the basic defuzzification methods, which is called a *centroid method*, can be described for a finite universe U of objects by

$$d(\mu) = \frac{\sum_{x \in U} x \cdot \mu(x)}{\sum x \in U \mu(x)} \quad (39)$$

where $x \in U$.

Methods based on fuzzy logic have been applied to many real-life problems including control problems (Nguyen and Sugeno 1998). Fuzzy logic was inspired by a number of remarkable human capabilities. Among them Zadeh distinguishes (1) the ability to reason and make decisions in cases of imprecision, uncertainty, incompleteness of information and partial truth and (2) the capability to perform many tasks based on perceptions, without any measurements and any computations. In the case of fuzzy logic, we move away from numerical variables and toward linguistic variables or words in natural languages; we sacrifice precision in order to achieve important advantages down the line. This is what is called *the fuzzy gambit*. Let it be noted that in this case, the values of the variables are known precisely. Fuzzy logic is also applied when the values of variables are not known precisely (Zadeh 2007). There are three principal rationales that dictate when words should be used in preference to numbers: (1) when available information is not precise enough to use numbers; (2) when there is a tolerance for imprecision that can be exploited to achieve tractability, robustness, and low solution costs; and (3) when the expressive power of words is higher than the expressive power of numbers.

The problem of construction of fuzzy sets (fuzzy membership functions) is very important for applications. This problem is also related to knowledge acquisition. Methods for constructing fuzzy membership functions can be classified into direct and indirect. In direct methods, experts are expected to define the fuzzy membership function. In indirect methods, experts are asked to compare elements in pairs from the universe of objects relative to the order of the membership degrees. Methods for constructing fuzzy membership functions and relevant operations on fuzzy sets for a given application are crucial for successful applications of fuzzy sets.

There are numerous significant results and active current research directions on fuzzy set theory and applications (Dubois and Prade 2000; Hoehle and Rodabaugh 1999; Bezdek et al. 1999a, b; Słowiński 1998; Nguyen and Sugeno 1998; Zimmermann 1999; Klir and Yuan 1995; Klir 2006; Pedrycz and Gomide 2007; Nikravesh et al. 2007, 2008).

4 Rough/Fuzzy Hybridization

There are numerous theoretical results and real-life applications based on the combination of rough set theory and fuzzy set theory (see, e.g., Dubois and Prade 1987, 1988, 1990; Nanda

1992; Pal and Banerjee 1996; Greco et al. 1998; Pal and Skowron 1999; Greco et al. 1999, 2000, 2006; Pal 2003; Polkowski 2002; Wu et al. 2003; Inuiguchi et al. 2004; Lingras and Jensen 2007; Maji and Pal 2007, 2005; Pawlak and Skowron 2007a, c and references in these papers). These results show the fruitful complementarity of fuzzy set theory and rough set theory, which were both created to deal with imperfect knowledge, in particular, with vague concepts. In fuzzy set theory, any object is characterized by a grade of membership relative to a given concept (*gradualness of membership*), while rough set theory started from the assumption about the possible indiscernibility of perceived objects (*granularity of knowledge*).

Let some examples be considered illustrating the results of the hybridization of fuzzy sets and rough sets in the definition of concept approximation.

Let it be assumed that $\mu \in \mathcal{F}(U)$. The fuzzy set μ can be characterized by a set of α -cuts $\{\mu_\alpha\}_{\alpha \in [0, 1]}$. Let it also be assumed that $R \subseteq U \times U$ is an equivalence relation over the universe of objects U . Then, the rough/fuzzy set corresponding to μ is defined by two families of sets, the lower approximation family of cuts and the upper approximation family of cuts defined by

$$R(\mu) = \bigcup_{x \in U} \{[x]_R : [x]_R \subseteq^\alpha \mu\} \quad (40)$$

and

$$\overline{R}(\mu) = \bigcup_{x \in U} \{[x]_R : [x]_R \cap^\alpha \mu \neq \emptyset\} \quad (41)$$

respectively, where $x \in U$, and $[x]_R$ denotes the equivalence class of R defined by x .

Another approach can be used to define the so-called fuzzy/rough sets. In this case, it is assumed that $\mu \in \mathcal{F}(U)$ and $v = \{v_i\}_{i \in I}$ is a fuzzy partition of U . Then two fuzzy sets (over the universe of elements v_i of fuzzy partition v) are defined: the fuzzy/rough lower approximation of μ relative to v and the fuzzy/rough upper approximation of μ relative to v by

$$v\mu(v_i) = \inf_{x \in U} \max\{1 - v_i(x), \mu(x)\} \quad (42)$$

and

$$\overline{v}\mu(v_i) = \sup_{x \in U} \min\{v_i(x), \mu(x)\} \quad (43)$$

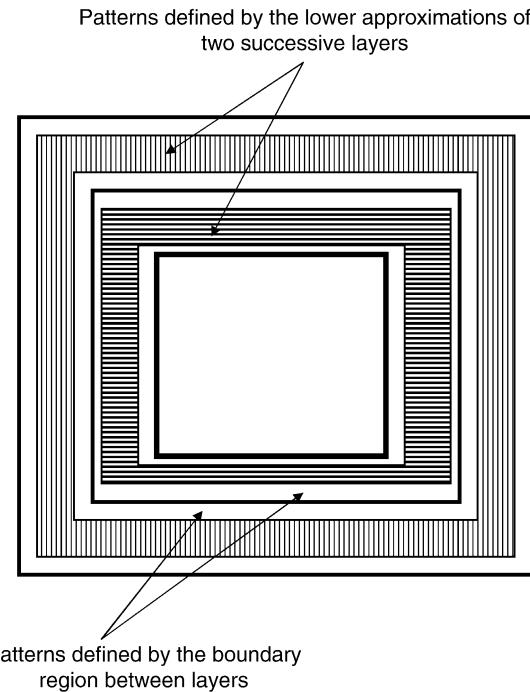

where $i \in I$.

There are many results on fuzzy/rough sets and rough/fuzzy sets including the generalizations of the above definitions (see, e.g., the references in Lingras and Jensen 2007).

Many methods have also been developed that are based on the combination of rough sets and fuzzy sets for real-life applications. In particular, these methods have been applied in supervised learning, information retrieval, feature selection, clustering, neurocomputing, and evolutionary computing (Lingras and Jensen 2007). There are different strategies for the combination of these two approaches. Let one possible application be illustrated, in which rough sets are used in the approximation of fuzzy sets by searching for *subconcepts* of a given fuzzy set that can be approximated by rough set methods with high quality. The layers defined by the differences of successive cuts are selected as subconcepts. The problem that should be solved is the selection of relevant cuts so that the patterns defined by approximations of layers are relevant for the application under consideration (Skowron and Stepaniuk 2003; Bazan 2008a, b).  **Figure 5** illustrates patterns corresponding to the lower approximations of layers and boundary regions. In applications, it is necessary to select the relevant number of

Fig. 5

Learning layers and their approximations.

layers and regions representing layers before the approximations can be constructed. Optimization strategies supported by domain knowledge are used in searching for layers to obtain the relevant patterns for the given application.

One of the very active research areas in which rough/fuzzy computing plays a very important role is GC (see, e.g., Bargiela and Pedrycz 2003; Pedrycz et al. 2008). In fuzzy logic, everything may be graduated and granulated. The concepts of graduation, granulation, and graduated granulation play a key role in GC. In GC, computations are performed on granules that are clumps of objects drawn together by indistinguishability, similarity, proximity, or functionality. Graduated granulation is inspired by the way in which humans deal with complexity and imprecision (Zadeh 2007). In searching for different relevant granules, rough set methods can be used making it possible to construct, e.g., complex classifiers of high quality. The goal of computations is to construct granules satisfying a given specification (generalized constraints), often expressed in natural language, to a satisfactory degree (Polkowski and Skowron 1996; Zadeh 2006).

5 Wisdom Technology

One of the potential areas for many further applications of rough/fuzzy computing is Wistech discussed in Jankowski and Skowron (2007, 2008a, b) as one of the main paradigms for the development of modern intelligent systems. It will be useful to present some basic ideas of

Wistech because in our opinion Wistech is also very important for developing new methods in natural computing (Rozenberg 2008; Cooper et al. 2008).

There are many indications that we are currently witnessing the onset of an era of radical technological changes. These radical changes depend on the further advancement of technology to acquire, represent, store, process, discover, communicate, and learn “wisdom.” We call this technology *wisdom technology* (or Wistech, for short). The term *wisdom* commonly means *rightly judging*. This common notion can be refined. By *wisdom*, we understand an adaptive ability to make judgments correctly to a satisfactory degree (in particular, correct decisions) having in mind real-life constraints. The intuitive nature of wisdom understood in this way can be expressed by the so-called *wisdom equation* (Jankowski and Skowron 2007), as shown metaphorically in (44):

$$\text{Wisdom} = \text{knowledge} + \text{adaptive judgment} + \text{interactions} \quad (44)$$

Wisdom can be treated as a special type of knowledge processing. To explain the specificity of this type of knowledge processing, let it be assumed that a control system of a given agent Ag consists of a society of agent control components interacting with the other agent Ag 's components and with the agent Ag 's environments. Moreover, there are special agent components called the agent coordination control components that are responsible for the coordination of control components. Any agent coordination control component mainly searches for answers to the following question: What to do next? Or, more precisely: Which of the agent Ag control components should be activated now? Of course, any agent control component has to process some kind of knowledge representation. In the context of agent perception, the agent Ag itself (by using, e.g., interactions, memory, and coordination among control components) is processing a very special type of knowledge reflecting the agent perception of the hierarchy of needs (objectives, plans, etc.) and the current agent or the environment constraints. This kind of knowledge processing mainly deals with complex vague concepts (such as risk or safety) from the point of view of the selfish agent needs. Usually, this kind of knowledge processing is not necessarily logical reasoning in terms of proving statements (i.e., labeling statements by truth values such as TRUE or FALSE). This knowledge processing is rather analogous to the judgment process in a court aiming at recognition of evidence that could be used as an argument for or against. Arguments for or against are used in order to make the final decision as to which one of the solutions is the best for the agent in the current situation (i.e., arguments are labeling statements by judgment values expressing the action priorities). The evaluation of current needs by agent Ag is realized by using a hierarchy of agent Ag life values/needs). Wisdom style knowledge processing by the agent Ag is characterized by the ability to improve the quality of the judgment process based on the agent Ag 's experiences. In order to emphasize the importance of this ability, we use the concept of adaptive judgment in the wisdom equation instead of just judgment. An agent who is able to perform adaptive judgment in the above sense is simply called a judge.

The adaptivity aspects are also crucial from the point of view of interactions (Goldin et al. 2006; Nguyen and Skowron 2008; Skowron 2008; Skowron and Szczyka 2010). The need for adaptation follows, e.g., from the fact that complex vague concepts on the basis of which the judgment is performed by the agent Ag are approximated by classification algorithms (classifiers), which should drift in time following changes in data and represented knowledge.

An important aspect of Wistech is that the complexity and uncertainty of real-life constraints mean that in practice we must reconcile ourselves to the fact that our judgment is based on non-crisp concepts (i.e., concepts with borderline cases) and also does not take into

account all the accumulated and available knowledge. This is why our judgments are usually imperfect. But, as a consolation, we also learn to improve the quality of our judgments via observation and analysis of our experience during interaction with the environment. Satisfactory decision-making levels can be achieved as a result of improved judgments.

Thus, wisdom is directly responsible for the focusing of an agent's attention on problems and techniques for their solution that are important in terms of the agent's judgment mechanism. This mechanism is based on the Maslow hierarchy of needs (Jankowski and Skowron 2008a) and agent perception of ongoing interactions with other agents and environments. In particular, the agent's wisdom can be seen as the control at the highest level of hierarchy of the agent's actions and reactions, and is based on concept processing in the metaphoric Aristotle tetrahedron. One can use the following conceptual simplification of agent wisdom: Agent wisdom is an efficient and an online agent judgment mechanism making it possible for agents to answer the following questions: (1) How to construct the most important priority list of problems to be solved? (2) How to solve the top priority problems under real-life constraints? (3) What to do next?

One of the main barriers hindering an acceleration in the development of Wistech applications lies in developing satisfactory computational models implementing the function of *adaptive judgment*. This difficulty primarily consists in overcoming the complexity of integrating the local assimilation and processing of dynamically changing, non-crisp, and incompletely specified concepts necessary to make correct judgments. In other words, we are only able to model tested phenomena using local (subjective) models and interactions between them. In practical applications, usually, we are not able to give perfect global models of analyzed phenomena. However, global models can only be approximated by integrating the various incomplete perspectives of problem perception.

Wistech is based on techniques of reasoning about knowledge, information, and data, which helps apply the current knowledge to problem solving in real-life highly unpredictable environments and autonomous multiagent systems. This includes such methods as identification of the current situation on the basis of interactions or dialogs, extraction of relevant fragments of knowledge from knowledge networks, judgment for prediction for relevant actions or plans in the current situation, or judgment of the current plan reconfiguration.

The concepts surrounding Wistech can be summarized as follows.

Wisdom technology (*Wistech*) is a collection of techniques aimed at the further advancement of technology to acquire, represent, store, process, discover, communicate, and learn *wisdom* in the design and implementation of intelligent systems. These techniques include approximate reasoning by agents or teams of agents about vague concepts concerning real-life dynamically changing, usually distributed, systems in which these agents are operating. Such systems consist of other autonomous agents operating in highly unpredictable environments and interacting with each other. Wistech can be treated as the successor of database technology, information technology, and knowledge management technologies. Wistech is the combination of the technologies represented in (44) and offers an intuitive starting point for a variety of approaches to designing and implementing computational models of Wistech in intelligent systems.

Knowledge technology in Wistech is based on techniques for reasoning about knowledge, information, and data, which helps apply the current knowledge in problem solving. This includes, e.g., extracting relevant fragments of knowledge from knowledge networks for making decisions or reasoning by analogy.

Judgment technology in Wistech covers the representation of agent perception and adaptive judgment strategies based on results of the perception of real-life scenes in environments and their representations in the agent's mind. The role of judgment is crucial, e.g., in adaptive planning relative to the Maslow hierarchy of the agent's needs or goals. Judgment also includes techniques used for perception, analysis of perceived facts, learning, and adaptive improving of approximations of vague complex concepts (from different levels of concept hierarchies in real-life problem solving) applied to modeling interactions in dynamically changing environments (in which cooperating, communicating, and competing agents exist) by using uncertain and insufficient knowledge or resources.

Interaction technology includes techniques for performing and monitoring actions by agents and environments. Techniques for planning and controlling actions are the result of the combination of judgment and interaction technologies.

Clearly, one of the promising possible ways to build Wistech computational models is by using methods of rough/fuzzy computing and other soft computing approaches.

6 Conclusions

Some basic concepts related to rough/fuzzy computing have been outlined. There are numerous research directions based on the foundations and applications of rough sets, fuzzy sets, and their combinations. The interested reader is referred, e.g., to Pawlak and Skowron (2007a, b, c), Dubois and Prade (2000), Hoehle and Rodabaugh (1999), Bezdek et al. (1999a, b), Słowiński (1998), Nguyen and Sugeno (1998), Zimmermann (1999), Klir and Yuan (1995), Klir (2006), Pedrycz and Gomide (2007), and Nikravesh et al. (2007, 2008), and the bibliographies in these papers and books.

A large part of knowledge related to natural computing is expressed by vague concepts. Hence, natural computing seems to be the domain for future potential applications of rough/fuzzy computing, especially in the framework of Wistech.

Acknowledgments

The author would like to express his gratitude to Professor Dave Corne for suggestions and corrections helping to improve this chapter.

This research has been supported by the grant N N516 368334 from the Ministry of Science and Higher Education of the Republic of Poland.

Abstract

Collision-based computing is an implementation of logical circuits, mathematical machines, or other computing and information processing devices in homogeneous, uniform and unstructured media with traveling mobile localizations. A quanta of information is represented by a compact propagating pattern (gliders in cellular automata, solitons in optical systems, wave fragments in excitable chemical systems). Logical truth corresponds to presence of the localization, logical false to absence of the localization; logical values can also be represented by a particular state of the localization. When two or more traveling localizations collide, they change their velocity vectors and/or states. Post-collision trajectories and/or states of the localizations represent results of logical operations implemented by the collision. One of the principal advantages of the collision-based computing medium – hidden in 1D systems but obvious in 2D and 3D media – is that the medium is architecture-less: nothing is hardwired, there are no stationary wires or gates, a trajectory of a propagating information quanta can be seen as a momentary wire. The basics of collision-based computing are introduced, and the collision-based computing schemes in 1D and 2D cellular automata and continuous excitable media are overviewed. Also a survey of collision-based schemes, where particles/collisions are dimensionless, is provided.

1 Introduction

Edward Fredkin, Tommaso Toffoli, Norman Margolus, Elwyn Berlekamp and John Conway are fully recognized founders of the field of collision-based computing. The term “collision-based computing” was first used in Adamatzky (2002a). There are, however, several equivalent but lesser-used terms such as “signal computing,” “ballistic computing,” “free space computing,” and “billiard ball computing.” The idea of collision-based computing is based on studies dealing with collisions of signals traveling along discrete chains, on a one-dimensional cellular automata. The interaction of signals traveling along one-dimensional conductors was among the famous problems in physics, biology, and physiology for centuries, and the problem of interaction was interpreted in terms of finite state machines in the 1960s. The earliest computer science-related results on signal interaction can be attributed to:

- Atrubin (Atrubin 1965), who designed the first-ever multiplier based on a one-dimensional cellular automaton in 1965;
- Fischer (Fischer 1965), who developed a cellular automaton generator of prime numbers in 1965; and
- Waksman (Waksman 1966), who initiated the very popular firing squad synchronization problem and provided an eight-state solution, in 1966.

Banks (1971) showed how to build wires and simple gates in configurations of a two-dimensional binary-state cellular automaton. This was not architecture-free computing, because a wire was represented by a particular stationary configuration of cell states (this was rather a simulation of a “conventional” electrical, or logical, circuit). However, Banks’s design was a huge influence on the theory of computing in cellular automata and beyond.

In 1982, Elwyn Berlekamp, John Conway, and Richard Gay proved that Game of Life “can imitate computers” (Berlekamp et al. 1982).

They mimicked electric wires by lines “along which gliders travel” and demonstrated how to do a logical gate by crashing gliders into one another. Chapter 25 of their “Winning Ways” (Berlekamp et al. 1982) demonstrates computing designs that do not simply look fresh 20 years later but are still rediscovered again and again by Game of Life enthusiasts all over the Net.

Berlekamp, Conway, and Guy employed a vanishing reaction of gliders – two crashing gliders annihilate themselves – to build a NOT gate. They adopted Gosper’s eater to collect garbage and to destroy glider streams. They used combinations of glider guns and eaters to implement AND and OR gates, and the shifting of a stationary pattern or block, by a mobile pattern, or glider, when designing auxiliary storage of information.

There is even the possibility that space–time itself is granular, composed of discrete units, and that the universe, as Edward Fredkin of M.I.T. and others have suggested, is a cellular automaton run by an enormous computer. If so, what we call motion may be only simulated motion. A moving particle in the ultimate microlevel may be essentially the same as one of our gliders, appearing to move on the macro-level, whereas actually there is only an alteration of states of basic space–time cells in obedience to transition rules that have yet to be discovered. – Berlekamp et al. (1982).

Meanwhile, in 1978, Edward Fredkin and Tommaso Toffoli submitted a 1-year project proposal to DARPA, which got funding and thus started a chain of remarkable events.

Originally, Fredkin and Toffoli aimed to “drastically reduce the fraction of” energy “that is dissipated at each computing step” (Fredkin and Toffoli 2002). To design a non-dissipative computer they constructed a new type of digital logic – conservative logic – that conserves both “the physical quantities in which the digital signals are encoded” and “the information present at any moment in a digital system” (Fredkin and Toffoli 2002).

Fredkin and Toffoli (1982) further developed these ideas in the seminal paper “Conservative Logic,” from which a concept of ballistic computers emerged. The Fredkin–Toffoli model of conservative computation – the billiard ball model – explores “elastic collisions involving balls and fixed reflectors.” Generally, they proved that “given a container with balls one can do any kind of computation.”

The billiard ball model became a masterpiece of cellular automaton theory, thanks to Norman Margolus who invented a cellular automaton (block cellular automata or partitioned cellular automata) implementation of the model. Norman published this result in 1984 (Margolus 1984). “Margolus neighborhood” and “billiard ball model cellular automata” are exploited widely nowadays.

A detailed account of collision-based computing is not provided. There are no excuses to avoid reading original sources (Berlekamp et al. 1982; Fredkin and Toffoli 1982; Margolus 1984). A comprehensive, self-contained report of the modern state of collision-based computing is provided in the book by Adamatzky (2002a). The present chapter rather discusses personal experience designing collision-based computing schemes in one- and two-dimensional cellular automata, and spatially extended nonlinear media. It also provides some hands-on examples of recently discovered collision-based computing devices, with the hope that the examples will help readers to experiment with their own designs.

The chapter is structured as follows. Principles of collision-based computing are outlined in [Sect. 2](#). [Section 3](#) shows how basic logical gates can be implemented by colliding localizations in natural systems – simulated reaction–diffusion medium ([Sect. 3.1](#)) and light-sensitive Belousov–Zhabotinsky medium ([Sect. 3.2](#)). The theoretical foundations of computing with signals in 1D cellular automata are presented in [Sect. 4](#), including

collision-based implementation of 1D Turing machine (☞ Sect. 4.2.1) and cyclic tag systems (CTS) (☞ Sect. 4.2.2). The excursion to architectureless computing is complete with abstract geometrical computation in ☞ Sect. 5, where time and space are continuous and particles/localizations are dimensionless.

2 Principles of Collision-Based Computing

This section attempts to summarize all types of collision-based computers. A collision-based computer is an empty space populated with mobile and stationary localizations. The mobile localizations used for computing so far are:

- Billiard balls (Fredkin and Toffoli 1982)
- Gliders in cellular automata models (Berlekamp et al. 1982; Adamatzky and Wuensche 2007; Delorme and Mazoyer 2002; Rennard 2002; Rendell 2002)
- Solitons in nonlinear media (Jakubowski et al. 1996, 2001; Steiglitz 2001; Anastassiou et al. 2001; Rand et al. 2005; Rand and Steiglitz 2009), and
- Localized wave fragments in excitable chemical media (Adamatzky 2004; Adamatzky and De Lacy Costello 2007)

Examples of stationary localizations are:

- “Still lives,” blocks, and eaters in Conway’s Game of Life (Berlekamp et al. 1982; Rendell 2002)
- Standing waves in automaton models of reaction–diffusion systems (Adamatzky and Wuensche 2007) and
- Breathers in computing devices based on polymer chains and oscillons in vibrating granular materials (Adamatzky 2002b)

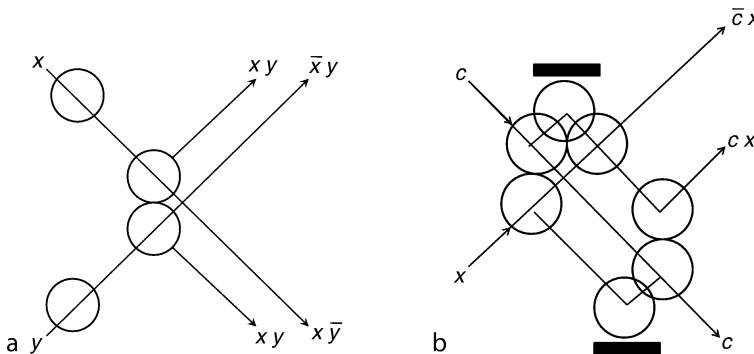

Usually mobile localizations represent signals and stationary localizations are used to route the signals in the space; however, by allowing balls and mirrors to change their states, in addition to velocity vectors, one can, in principle, build multivalued logic circuits.

Classical examples of collision-based gates are shown in ☞ Fig. 1. The interaction gate involves two balls to represent values of variables x and y (☞ Fig. 1a). If two balls are present at the input trajectories, this corresponds to both variables having TRUTH values that collide and deflect as a result of collisions. The deflected trajectories of the balls represent conjunctions of the input variables, xy . If only one ball—say the ball corresponding to the variable x —is present initially, then this ball travels along its original trajectories and does not change its velocity vector. The undisturbed trajectories of the balls represent logical functions $\bar{x}y$ and $x\bar{y}$ (☞ Fig. 1a).

The switch gate (☞ Fig. 1b) is another famous example, which also demonstrates the role of mirrors (stationary localizations). In the switch gate, the signal x is conditionally routed by a control signal c . If the signal is not present, the ball x continues along its original trajectory traveling southeast. The ball x is delayed and its trajectory shifts eastward if the signal c is present in the system. After collision, balls x and c are reflected but their further propagation is restricted by mirrors: the ball c collides with the Northern mirror and the ball x with the Southern mirror (☞ Fig. 1b).

Basics of billiard ball model: Fredkin–Toffoli interaction gate (a) and switch gate (b). (From Fredkin and Toffoli 1982.)

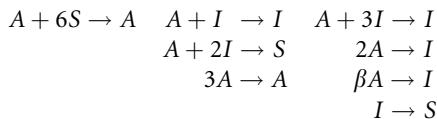

3 Collision-Based Computing in Natural Systems

Those focused on implementation issues may wonder how a scheme of collision-based computing can be implemented in natural, chemical, physical, or biological materials. This section provides two examples of computing with localizations in spatially extended quasi-chemical (reaction–diffusion cellular automata) and excitable chemical (Belousov–Zhabotinsky reaction) systems.

3.1 Computing Schemes in Reaction–Diffusion Cellular Automata: Spiral Rule

The reaction–diffusion cellular automaton Spiral Rule (Adamatzky and Wuensche 2007) exhibits a wide range of mobile and stationary localizations, thus offering unique opportunities to employ both traveling and still patterns in a computation process.

An automaton is designed that emulates nonlinearity of activator (A) and inhibitor (I) interaction for subthreshold concentrations of activator. The following quasi-chemical reaction was used to construct cell-state transition rules (Adamatzky and Wuensche 2007):

For subthreshold concentration of the inhibitor and threshold concentrations of activator, the activator is suppressed by the inhibitor. For critical concentrations of the inhibitor, both inhibitor and activator dissociate, producing the substrate.

The quasi-chemical reactions are mapped to cellular automaton rules as follows. Take a totalistic hexagonal cellular automaton (CA), where a cell takes three states – substrate S ,

activator A , and inhibitor I – and the cell updates its state depending on just the numbers of different cell-states in its neighborhoods. The update rule can be written as follows:

$$x^{t+1} = f(\sigma_I(x)^t, \sigma_A(x)^t, \sigma_S(x)^t)$$

where $\sigma_p(x)^t$ is the number of cell x 's neighbors (in seven cells neighborhood) with cell-state $p \in \{I, A, S\}$ at time step t . The rule is compactly represented as a matrix $M = (M_{ij})$, where $0 \leq i, j \leq 7$, $0 \leq i + j \leq 7$, and $M_{ij} \in \{I, A, S\}$ (Adamatzky et al. 2006). The output state of each neighborhood is given by the row-index i (the number of neighbors in cell-state I) and column-index j (the number of neighbors in cell-state A). One does not have to count the number of neighbors in cell-state S , because it is given by $7 - (i + j)$. A cell with a neighborhood represented by indices i and j will update to cell-state M_{ij} , which can be read off the matrix. In terms of the cell-state transition function, this can be presented as follows: $x^{t+1} = M_{\sigma_2(x)^t \sigma_1(x)^t}$. The exact structure of the transition matrix is as follows (Adamatzky and Wuensche 2007):

$$M = \left(\begin{array}{ccccccc} S & A & I & A & I & I & I \\ S & I & I & A & I & I & I \\ S & S & I & A & I & I & I \\ S & I & I & A & I & & \\ S & S & I & A & & & \\ S & S & I & & & & \\ S & S & & & & & \\ S & & & & & & \end{array} \right)$$

The entry $M_{01} = A$ symbolizes the diffusion of activator A , $M_{11} = I$ represents the suppression of activator A by the inhibitor I , and $M_{z2} = I$ ($z = 0, \dots, 5$) is the self-inhibition of the activator in particular concentrations. $M_{z0} = S$ ($z = 1, \dots, 7$) means that the inhibitor is dissociated in the absence of the activator, and that the activator does not diffuse in subthreshold concentrations; $M_{zp} = I$, $p \geq 4$ is an upper-threshold self-inhibition.

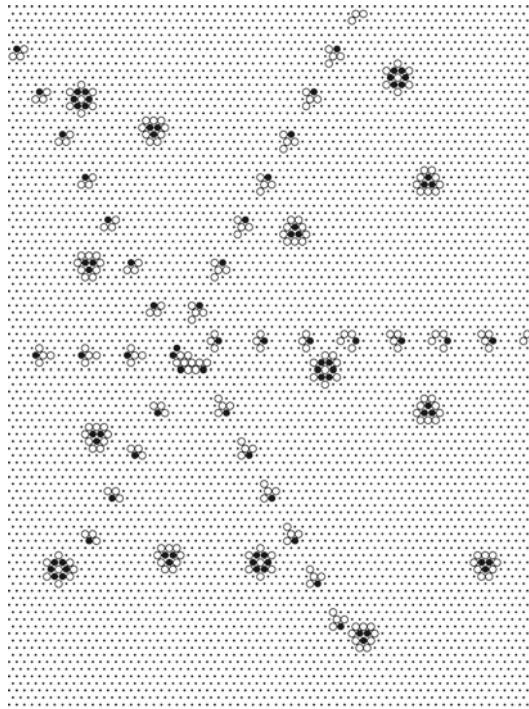

Starting in a random initial configuration, the automaton will evolve towards a quasi-stationary configuration, with typically two types of stationary localizations, and a spiral generator of mobile localizations, or gliders (Fig. 2). The core of a glider-gun is a discrete analog of a “classical” spiral wave. However, at some distance from the spiral wave tip, the wave front becomes unstable and splits into localized wave fragments. The wave fragments continue traveling along their originally determined trajectories and keep their shape and velocity vector unchanged unless disturbed by other localizations. So, the wave fragments behave as in sub-excitable Belousov–Zhabotinsky systems.

Basic gliders, those with one (activator) head, are found in five types (Fig. 3), which vary by the number of trailing inhibitors. Three types (G_{34}, G_{24}, G_{43}) alternate between two forms. Two types (G_4, G_5) have just one form. The spiral glider-gun in Fig. 2 emits G_{34} gliders. An alternative, low frequency, spiral glider-gun (Wuensche and Adamatzky 2006) (not shown) releases G_4 gliders. These basic gliders, and also a variety of more complicated gliders including mobile glider-guns, are also generated by many other interactions. Stationary localizations, or eaters (Fig. 3i, j), are another important feature of the CA.

The principal components of any computing device are the input interface, memory, routers, and logical gates. Readers are referred to the paper Adamatzky and Wuensche (2007) to study possible input functions.

Fig. 2

A typical quasi-stable configuration of the CA, which started its development in a random initial configuration (with 1/3 probability of each cell-state). Cell-state I (inhibitor) is shown by a black disk, cell-state A (activator) by a circle, and cell-state S (substrate) by a dot. One can see there are two types of stationary localizations (glider eaters) and a spiral glider-gun, which emits six streams of gliders, with a frequency of a glider per six time steps in each glider stream. (From Adamatzky and Wuensche 2007.)

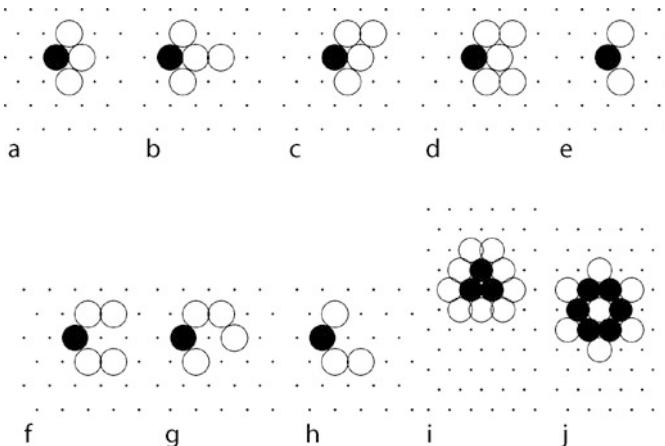

How does one implement a memory in the Spiral Rule CA? The eater E_6 can play the role of a 6-bit flip-flop memory device. The substrate-sites (bit-down) between inhibitor-sites ([Fig. 3i, j](#)) can be switched to an inhibitor-state (bit-up) by a colliding glider.

An example of writing one bit of information in E_6 is shown in [Fig. 4](#). Initially E_6 stores no information. The aim is to write one bit in the substrate-site between the northern and northwestern inhibitor-sites ([Fig. 4a](#)). A glider G_{34} is generated ([Fig. 4b, c](#)) that travels west. G_{34} collides with (or brushes past) the north edge of E_6 resulting in G_{34} being transformed to a different type of glider, G_4 ([Fig. 4g, h](#)). There is now a record of the collision – evidence that writing was successful. The structure of E_6 now has one site (between the northern and northwestern inhibitor-sites) changed to an inhibitor-state ([Fig. 4j](#)) – a bit was saved.

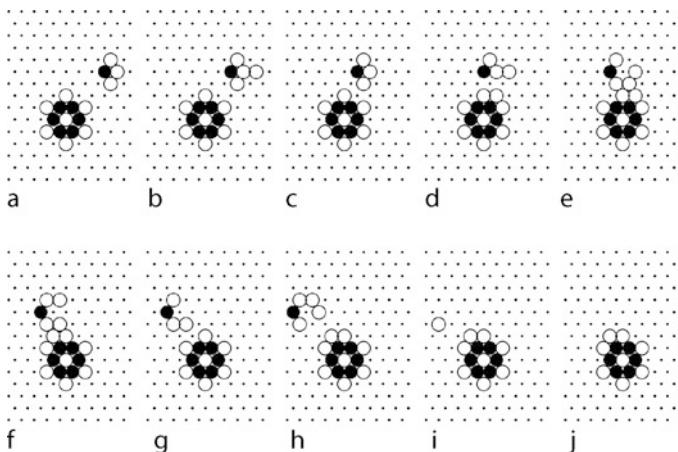

To read a bit from the E_6 memory device with one bit-up ([Fig. 5a](#)), one collides (or brushes past) with glider G_{34} ([Fig. 5b](#)). Following the collision, the glider G_{34} is transformed into a different type of basic glider, G_3 ([Fig. 5g](#)), and the bit is erased ([Fig. 5j](#)).

Fig. 3

The basic localizations in a Spiral Rule automaton: gliders (a–g) and eaters (h–i). (a–g) Five types of gliders, shown here traveling west, in the direction of their activator head (cell-state A), with a tail of trailing inhibitors made up of several cell-states I. The glider designator G_{ab} refers to the numbers of trailing inhibitors. (a) and (b) Two forms of glider G_{34} . (c) Glider G_4 . (d) Glider G_5 . (e) and (f) Two forms of glider G_{24} . (g) and (h) Two forms of glider G_{43} . (i) Eater E_3 . (j) Eater E_6 . (From Adamatzky and Wuensche 2007.)

**Fig. 4**

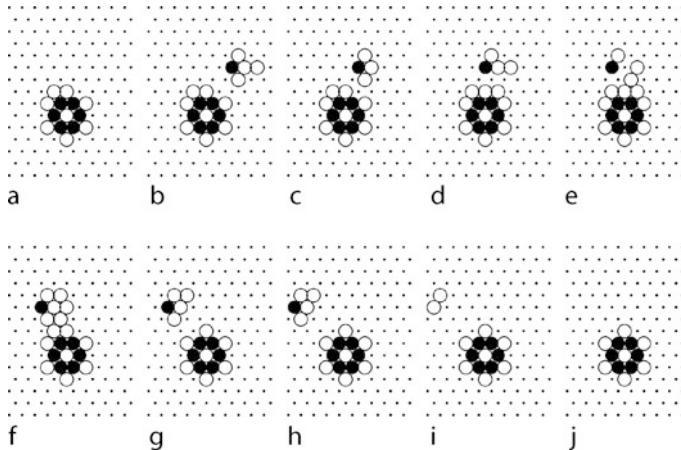

Write bit. (a) t. (b) $t + 1$. (c) $t + 2$. (d) $t + 3$. (e) $t + 4$. (f) $t + 5$. (g) $t + 6$. (h) $t + 7$. (i) $t + 8$. (j) $t + 9$. (From Adamatzky and Wuensche 2007.)

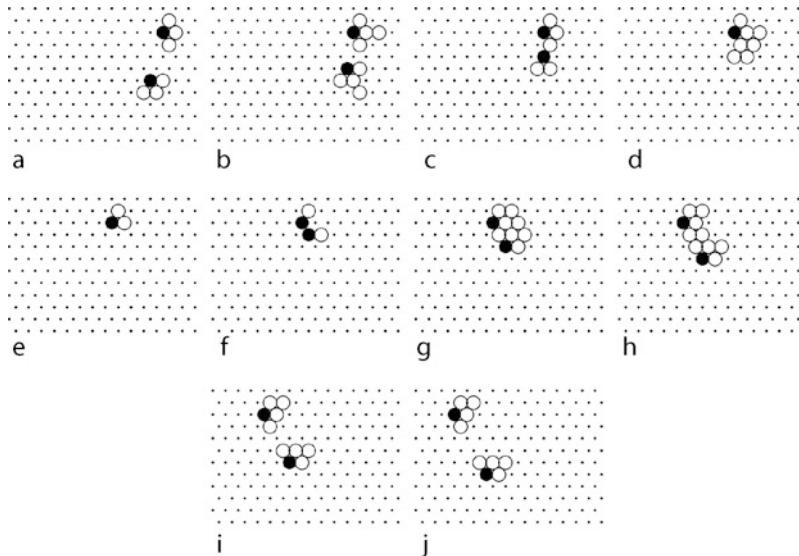

To route signals, one can potentially employ other gliders to act as mobile reflectors. **Figure 6** shows how a glider traveling northwest collides with a glider traveling west, and is reflected southwest as a result of the collision. However, both gliders are transformed to different types of gliders. This is acceptable on condition that both types of gliders represent the same signal, or signal modality.

**Fig. 6**

Glider reflection. (a) t . (b) $t + 1$. (c) $t + 2$. (d) $t + 3$. (e) $t + 4$. (f) $t + 5$. (g) $t + 6$. (h) $t + 7$. (i) $t + 8$. (j) $t + 9$. (From Adamatzky and Wuensche 2007.)

There are two more gates that are useful in designing practical collision-based computational schemes. They are the FANOUT gate and the ERASE gate. The FANOUT gate is based on glider multiplication. There are a few scenarios where one glider can be multiplied by another glider (for details see the original beehive rule [Wuensche 2005]); for example, one can make a FANOUT gate by colliding glider G_{34} with glider G_{24} . The gliders almost annihilate as a result of the collision, but recover into a complicated one, which splits into three G_5 gliders. To annihilate

a glider, one can collide it with the central body of an eater, or with another glider; for example, head-on collisions usually lead to annihilation.

The *asynchronous* XOR gate can be constructed from the memory device in [Fig. 4](#) and [Fig. 5](#), employing the eater E_6 and the glider G_{34} . The incoming trajectory of the gliders is an input $x = \langle x, y \rangle$ of the gate, and the state of the cell that is switched to the inhibitor state by the gliders is an output z of the gate (this cell is shown by \otimes in [Fig. 7a](#)). As seen in [Fig. 4](#), when glider G_{34} brushes by the eater E_6 it “adds” one inhibitor state to the eater configuration ([Fig. 4, t + 7](#)), and transforms itself into glider G_{43} . If glider G_{34} brushes by E_6 with an additional inhibitor state ([Fig. 5, t](#)), it “removes” this additional state and transforms itself into glider G_4 ([Fig. 5, t + 11](#)).

Assume that the presence of glider G_{34} symbolizes input logical TRUE and its absence – input FALSE, inhibitor state I in cell \otimes – output TRUE and substrate state S – output FALSE. The result of this logical operation can be read directly from the configuration of E_6 or by sending a control glider to brush by E_6 to detect how the glider is transformed. Then the structure implements exclusive disjunction ([Fig. 7b](#)). The gate constructed is asynchronous, because the output of the operation does not depend on the time interval between the signals but only on the value of signals: when the inhibitor state is added or removed from E_6 the configuration of E_6 remains stable and does not change till another glider collides into it.

The eater E_6 can take four different configurations resulting from the interactions of gliders brushing past, and there are seven types of gliders produced in collisions with the eater (including some basic types flipped). One therefore can envisage (Adamatzky and Wuensche 2007) that a finite state machine can be implemented in the eater-glider system. The internal state of such a machine is represented by the configuration of the eater, the type of the incoming glider symbolizes the input symbol of the machine, and the type of the outgoing glider represents the output state of the machine.

To construct the full state transition table of the eater-glider machine, seven types of gliders are collided into four configurations of the eater and the results of the collisions are recorded. For the sake of compact representation, the configurations of the eater are encoded as shown in [Fig. 8](#). The gliders are denoted as follows: G_{34} as a , G_{43} as b , G_5 as c , G_4 as d , G_{24} as e , G^4 (glider G_4 flipped horizontally) is f , and G^{43} (glider G_{43} flipped horizontally) is g . The state transition table is shown in [Fig. 9](#).

Consider the internal states of the eater-glider machine as unary operators on the set $\{a, b, c, d, e, f, g\}$, that is, the machine’s state is reset to its initial state after the collision with the glider. For example, the unary operator α implements the following transformation: $a \rightarrow b$, $b \rightarrow c$,

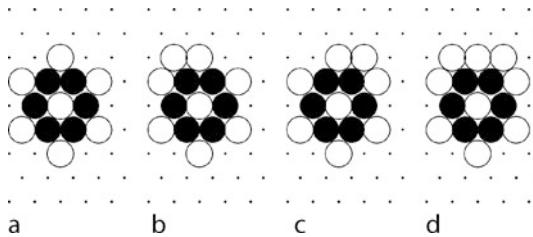

Fig. 7

Asynchronous XOR gate. (a) Position of output cell is shown by \otimes . (b) Operation implemented by the gate, input state G_{34} is logical TRUE, output state S is FALSE, output state I is TRUE. (From Adamatzky and Wuensche 2007.)

	x_1	x_2	y
G_{34}	0	0	S
G_{34}	0	G_{34}	I
G_{34}	G_{34}	I	
G_{34}	G_{34}	G_{34}	S

**Fig. 9**

The state transition table of the eater-glider machine. Tuple xy , a pair made up of an eater state x and glider state y , at the intersection of the i th row and j th column, signifies that being in state i while receiving input j the machine takes state x and generates output y .

	a	b	c	d	e	f	g
α	βb	δc	αb	αe	δd	αe	δc
β	αd	δe	βc	βc	χg	αa	χe
χ	χd	βe	δf	χa	βb	χa	βe
δ	δb	βc	χg	χe	αf	δe	αa

Fig. 10

Limit sets of unary operators a, \dots, g .

Operator	Limit set
a	$\{\alpha, \beta\}, \{\delta\}$
b	$\{\beta, \delta\}$
c	$\{\alpha\}, \{\beta\}, \{\delta, \chi\}$
d	$\{\alpha\}, \{\beta\}, \{\chi\}$
e	$\{\alpha, \delta\}, \{\beta, \chi\}$
f	$\{\alpha\}, \{\chi\}, \{\delta\}$
g	$\{\alpha, \delta\}, \{\beta, \chi\}$

$c \rightarrow a, d \rightarrow a, e \rightarrow d, f \rightarrow e, g \rightarrow e$. The operators have the following limit sets: operator α has the limit set $\{a, b, c\}$, β – set $\{c\}$, χ has two limit sets $\{a, d\}$ and $\{b, c\}$, and operator δ – two limit sets $\{a, b, c, d\}$ and $\{e, f\}$. Considering unary operators a, \dots, g operating on set $\{\alpha, \beta, \chi, \delta\}$, one obtains the limit sets shown in Fig. 10. Many of the operators have more than two limit sets, which may indicate a significant computational potential of the eater-glider machine.

To characterize the eater-glider machine in more detail, a study was conducted to find out what output strings are generated by the machine when the machine receives the uniform infinite string s^* , $s \in \{a, \dots, g\}$ on its input. These input string to output string transformations are shown in Fig. 11.

Input string $abcdefg$ evokes the following output strings when fed into the machine. The machine starting in state α generates string $begabac$, in state β string $dgcabac$, in state χ string $deccgac$, and in state δ string $bcccgae$.

Fig. 11

Input string to output string transformations implemented by the eater-glider machine. String s , at the intersection of the i th row and j th column, tells one that being initially in state i and receiving a uniform string j , the machine generates string s .

	a^*	b^*	c^*	d^*	e^*	f^*	g^*

β	$(db)^*$	$(ec)^*$	c^*	c^*	$(gb)^*$	ae^*	e^*
χ	d^*	$e(ec)^*$	$(fg)^*$	a^*	$b(gb)^*$	a^*	e^*
δ	b^*	$(ce)^*$	$(gf)^*$	ea^*	$(ed)^*$	e^*	$(ac)^*$

3.2 Collision-Based Computing in Excitable Chemical Media

This section gives a brief introduction to implementation of collision-based circuits in excitable chemical media, the Belousov–Zhabotinsky (BZ) system. Examples discussed here are based on numerical experiments; see the chapter [Reaction–Diffusion Computing](#) of this book for implementation of collision-based circuits in a BZ medium in chemical laboratory conditions. Now, computing is discussed with localized wave fragments in the Oregonator (Field and Noyes 1974; Tyson and Fife 1980) model adapted to a light-sensitive BZ reaction with applied illumination (Beato and Engel 2003; Krug et al. 1990):

$$\frac{\partial u}{\partial t} = \frac{1}{\varepsilon} \left(u - u^2 - (fv + \phi) \frac{u - q}{u + q} \right) + D_u \nabla^2 u, \text{ and}$$

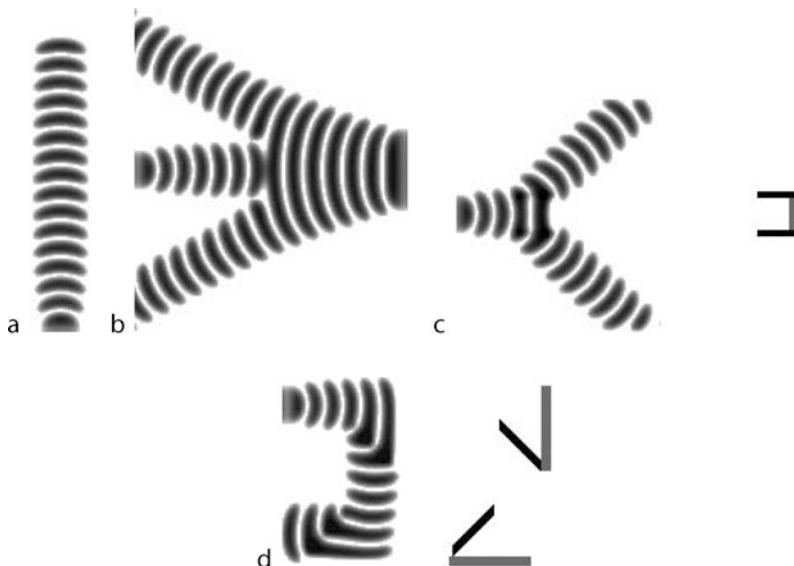

$$\frac{\partial v}{\partial t} = u - v$$

where variables u and v represent local concentrations of bromous acid HBrO_2 and the oxidized form of the catalyst ruthenium Ru(III), ε sets up a ratio of time scale of variables u and v , q is a scaling parameter depending on reaction rates, f is a stoichiometric coefficient, ϕ is a light-induced bromide production rate proportional to the intensity of illumination (an excitability parameter – moderate intensity of light will facilitate excitation process, higher intensity will produce excessive quantities of bromide which suppresses the reaction). It is assumed that the catalyst is immobilized in a thin layer of gel; therefore, there is no diffusion term for v . To integrate the system, one uses the Euler method with five-node Laplacian operator, time step $\Delta t = 10^{-3}$ and grid point spacing $\Delta x = 0.15$, with the following parameters: $\phi = \phi_0 + A/2$, $A = 0.0011109$, $\phi_0 = 0.0766$, $\varepsilon = 0.03$, $f = 1.4$, $q = 0.002$.

The chosen parameters correspond to a region of “higher excitability of the sub-excitability regime” outlined in Sendiña-Nadal et al. (2001), which supports propagation of sustained wave fragments ([Fig. 12a](#)). These wave fragments are used as quanta of information in the design of CB logical circuits. The waves were initiated by locally disturbing initial concentrations of species; for example, ten grid sites in a chain are given value $u = 1.0$ each. This generates two or more localized wave fragments, similar to counter-propagating waves induced by temporary illumination in experiments. The traveling wave fragments keep their shape for around $4 \cdot 10^3$ – 10^4 steps of simulation (4–10 time units), then decrease in size and vanish. The wave’s life-time is sufficient, however, to implement logical gates; this also allows one not to worry about “garbage collection” in the computational medium.

Fig. 12

Basic operations with signals. Overlay of images taken every 0.5 time units. Exciting domains of impurities are shown in black, inhibiting domains of impurities are shown in gray. (a) Wave fragment traveling north. (b) Signal branching without impurities: a wave fragment traveling east splits into two wave fragments (traveling southeast and northeast) when it collides into a smaller wave fragment traveling west. (c) Signal branching with impurity: wave fragment traveling west is split by impurity (shown on the right) into two waves traveling northwest and southwest. (d) Signal routing (U-turn) with impurities: wave fragment traveling east is routed north and then west by two impurities (shown on the right). An impurity-reflector consists of inhibitory (gray) and excitatory (black) chains of grid sites. (From Adamatzky 2004.)

Signals are modeled by traveling wave fragments (Sendiña-Nadal et al. 2001; Beato and Engel 2003): a sustainably propagating wave fragment (● Fig. 12a) represents the TRUE value of a logical variable corresponding to the wave's trajectory (momentarily wire). To demonstrate that a physical system is logically universal, it is enough to implement negation and conjunction or disjunction in the spatio-temporal dynamics of the system. To realize a fully functional logical circuit, one must also know how to operate input and output signals in the system's dynamics, namely to implement signal branching and routing; delays can be realized via appropriate routing.

One can branch a signal using two techniques. Firstly, one can collide a smaller auxiliary wave to a wave fragment representing the signal, the signal-wave will then split into two signals (these daughter waves shrink slightly down to stable size and then travel with constant shape a further $4 \cdot 10^3$ time steps of the simulation) and the auxiliary wave will annihilate (● Fig. 12b). Secondly, one can temporarily and locally apply illumination impurities on a signal's way to change properties of the medium and thus cause the signal to split (● Fig. 12c).

A control impurity, or reflector, consists of a few segments of sites for which the illumination level is slightly above or below the overall illumination level of the medium. Combining excitatory and inhibitory segments, one can precisely control the wave's trajectory, for example, determining a U-turn of a signal (● Fig. 12d).

A typical billiard ball model interaction gate (Fredkin and Toffoli 1982; Margolus 1984) has two inputs – x and y , and four outputs – $x\bar{y}$ (ball x moves undisturbed in the absence of ball y), $\bar{x}y$ (ball y moves undisturbed in the absence of ball x), and twice xy (balls x and y change their trajectories when they collide into each other). It was not possible to make wave fragments implement exact billiard-ball gates, because the interacting waves either fused or one of the waves was annihilated as a result of the collision with another wave.

However, a BZ (nonconservative) version of a billiard-ball gate with two inputs and three outputs is implemented, which is just one xy output instead of two. This BZ collision gate is shown in [Fig. 13](#).

The rich dynamic of the BZ medium allows one to also implement complicated logical operations just in a single interaction event. An example of a composite gate with three inputs and six outputs is shown in [Fig. 14](#). As one sees in [Fig. 14](#), some outputs, for example $\bar{x}yz$, are represented by gradually vanishing wave fragments. The situation can be dealt with by either using a very compact architecture of the logical gates or by installing temporary amplifiers made from excitatory fragments of illumination impurities.

As known from results of computer simulations and experimental studies, classical excitation waves merge or annihilate when they collide with one another. This may complicate the implementation of nontrivial logical circuits in classical excitable media. Wave fragments, however, behave a bit differently, more like quasi-particles.

In computational experiments with exhaustive analysis of all possible collisions between localized wave fragments (Adamatzky and De Lacy Costello 2007), all the collisions are classified as ([Fig. 15](#)): quasi-elastic reflection of wave fragments ([Fig. 15a](#)), pulling and pushing of a wave fragment by another wave fragment ([Fig. 15b, c](#)), sliding of one wave fragment along the refractory trail of another fragment ([Fig. 15d](#)), and translation of a wave fragment along one axis by another wave fragment ([Fig. 15e](#)). Examples of two types of collision are shown in [Fig. 16](#).

4 One-Dimensional Cellular Automata

This section deals with cellular automata in general and discrete signals in particular. It is shown both how they compute in the classical understanding and how they can be used to

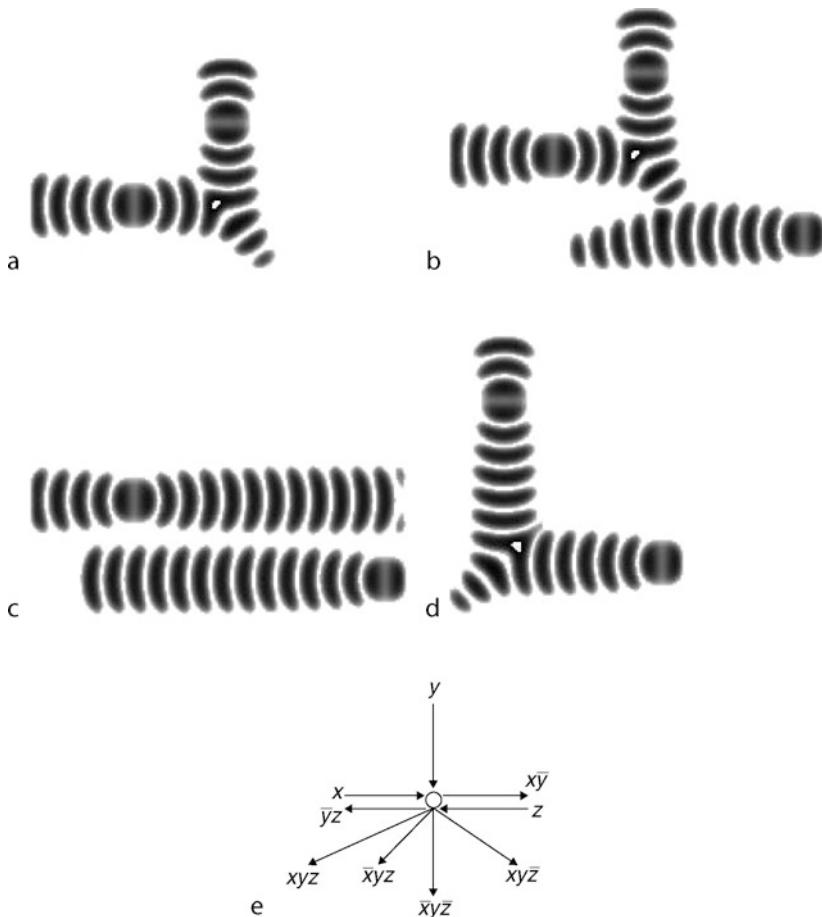

Fig. 13

Two wave fragments undergo angle collision and implement interaction gate $\langle x, y \rangle \rightarrow \langle x\bar{y}, xy, \bar{x}y \rangle$. (a) In this example $x = 1$ and $y = 1$, both wave fragments are present initially. Overlay of images taken every 0.5 time units. (b) Scheme of the gate. In upper left and bottom left corners of (a) one sees domains of wave generation, two echo wave fragments are also generated, they travel outward from the gate area and thus do not interfere with computation. (From Adamatzky 2004.)

Fig. 14

Implementation of $\langle x, y, z \rangle \rightarrow \langle x\bar{y}, \bar{y}z, xyz, \bar{x}yz, \bar{x}\bar{y}\bar{z}, xy\bar{z} \rangle$ interaction gate. Overlay of images of wave fragments taken every 0.5 time units. The following combinations of input configuration are shown: (a) $x = 1, y = 1, z = 0$, north-south wave collides with east-west wave. (b) $x = 1, y = 1, z = 1$, north-south wave collides with east-west wave, and with west-east wave. (c) $x = 1, y = 0, z = 1$, west-east and east-west wave fragments pass near each other without interaction. (d) $x = 0, y = 1, z = 1$, north-south wave collides with east-west wave. (e) Scheme of the gate. (From Adamatzky 2004.)

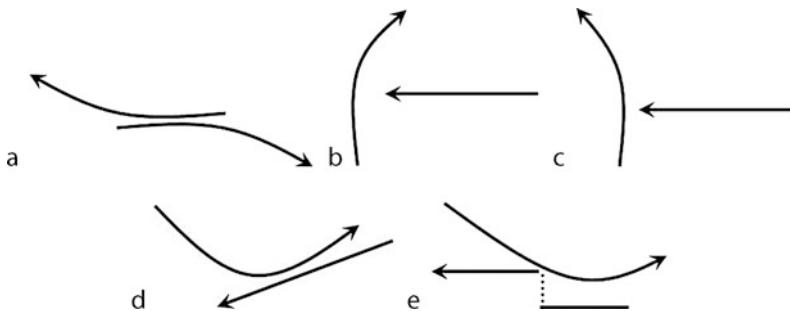

implement some phenomena relevant to massively distributed computing but without any sequential counterpart.

Cellular automata (CA) were introduced as a discrete model for parallel, local, and uniform phenomena, whether of engineering, physical, or biological nature. They often provide a medium where signals naturally appear and are thoroughly used to understand the global dynamics. On the other hand, a correct handling of such signals is the key to compute and to design special purpose CA.

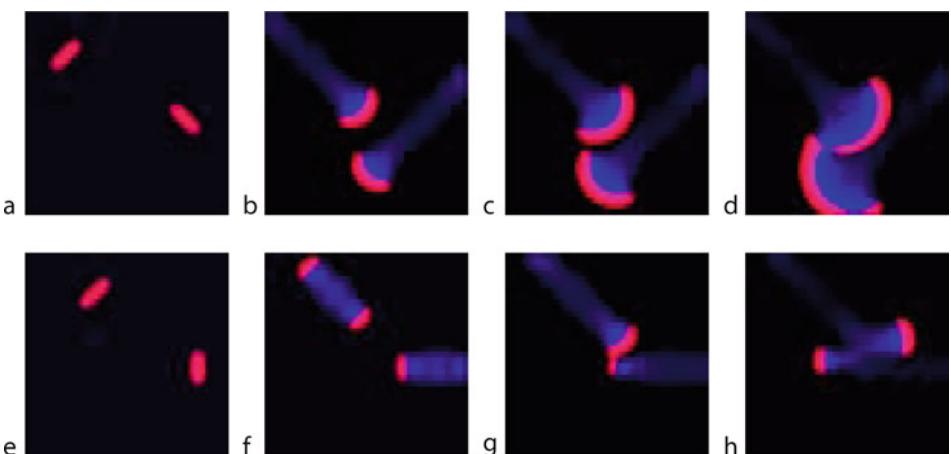

A cellular automaton works in the following way. The space is regularly partitioned in cells. All the cells are identical and are regularly displayed as an infinite array (having as many

Fig. 15

**Fig. 16**

(a–d) Sliding: snapshots of wave fragment moving southwest colliding with wave fragment traveling southeast. Center of the initial excitation of the southwest wave fragment is shifted southwards by 22 sites. (From Adamatzky and De Lacy Costello 2007.) (e–h) Slide-shift: snapshots of wave fragment moving southeast colliding with wave fragment traveling west.

dimensions as the modeled space). Each cell can be in finitely many states and evolves according to its state and the states of the surrounding cells – *locality*. All the cells are identical and behave similarly – *uniformity*. The cells are all updated *synchronously*, like a *massive parallel* process sharing a single clock. In essence, CA form a discrete model: discrete time, discrete space, and discrete values.

Generally, the array is considered to extend infinitely in all directions so that there are no boundaries to deal with. However, borders can be encoded using special states which are never changed and make the two sides independent. Another way to simulate a CA on a computer is to consider that outside of a finite range all cells are in the same stable state (called a *quiescent state*). Finite/periodic configuration can also be generated by displaying the cells to be on a ring (or torus): the last and first are then neighbors.

Previous collision-based systems are CA, or, more accurately, are simulated by CA, some of them work on hexagonal lattices. Computation in dimension 2 and above can be done straightforwardly as already presented by bit encoding and implementation of logic gates.

From now on only one-dimensional space is considered because, on the one hand, in higher dimensions it can – up to some point – be treated alike or correspond to what has been exemplified in previous sections, and, because, on the other hand, dimension 1 is particularly restrictive and needs special focus.

The reader interested in CA might consult Ilachinski (2001), Kari (2005), Sarkar (2000) for various topics not covered here.

4.1 Signals in CA

In space–time diagrams, or orbits, configurations are concatenated as iterations go. They are very important in order to comprehend the dynamics. Since the temporal coordinate is added, this leads to an array with one more dimension than the underlying space.

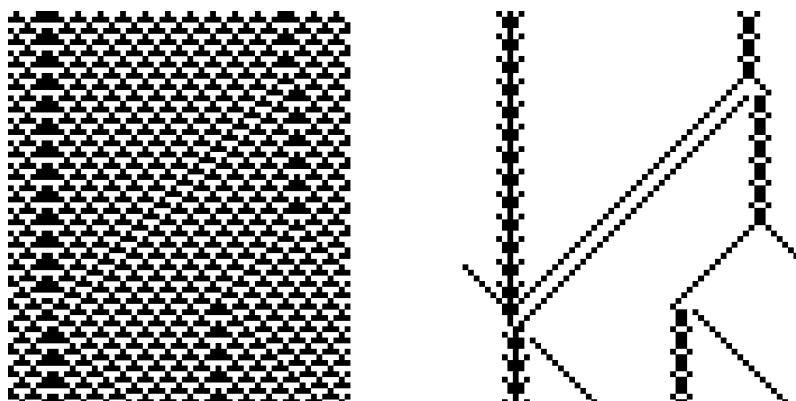

A signal is anything periodic in the space–time diagram. If the periodicity is in two directions, then it can fill the whole space–time and is referred as a *background*, the substrata upon which signals move. The frontier between two backgrounds is a signal as long as it is periodic. [Figure 17](#) provides an example with a complex background (alternatively 0111, 1000, 1101, and 0010 repeating) on the left. On the right, signals are revealed by an ad hoc filtering. This example illustrates the variety in width and pattern of signals. As can be seen, collisions between signals can be pretty complicated.

4.2 Computing in One-Dimensional Systems

In dimension two and above, as soon as it is possible to carry information around (with signal), to make information crossing and duplication, and to process it (with collision) in the proper way to yield a sufficiently large set of logical gates, computation is straightforwardly possible.

Fig. 17

Filtering to exhibit signals and backgrounds on rule 54 (inspired from Boccara et al. 1991, [Fig. 7](#)). Time is increasing upwards.

In dimension 1, this is not so easy, because there is no way for a signal to go around another one or some static artifact. This means that signal propagation is really an issue and, for example, handling garbage signals can be cumbersome. One way to cope with it is to have various kinds of signals not identically affected by artifacts (some would pass unaffected while others interact).

This means that to use the bits and gates scheme, one has to be very careful with available signals and have a very clever positioning of the logic circuitry, which is always thought of as two dimensional (time often provides the extra dimension for displaying it). For example, the construction of Ollinger (2002) provides a small CA that is able to compute with circuit implementation where displaying the circuit is not straightforward.

Another way to tackle computation is to use other formalisms. One classical way is to go back to Turing machines, another one is to implement minimal rewriting systems like cyclic tag systems.

4.2.1 Turing Machine

A Turing machine is a finite automaton acting on a potentially infinite array of symbols. The computation starts with the automaton in its initial state and the input written on the tape. The tape is accessed through a read/write head. At each iteration, the automaton reads the symbol under the head, rewrites a symbol, changes its state, and moves the head left or right. A Turing machine is basically as one dimensional as its tape, so that it naturally fits on a one-dimensional CA.

The simulation is rather simple: signals encoding the symbols are motionless and one signal amounting to the state of the automaton is moving round updating the symbols. Collisions are as follows: a moving state meets a stationary symbol, which leaves a new stationary symbol and a moving new state. (● [Figure 24](#) in the next section provides a clear illustration of this in a continuous setting.) This was implemented by, for example, Lindgren and Nordahl (1990).

4.2.2 Cyclic Tag Systems (CTS)

Another way to define computation is to rely on a word that is rewritten until the system halts. The input is given as the starting word and the output is the final word. Connexion with a Turing machine is straightforward when considering the tape as a finite word and the state of the automaton as an extra symbol at the head.

Cyclic tag systems (CTS) is a particular case of many Turing-universal rewriting systems. A CTS considers a binary word together with a circular list of binary words (*appendants*). At each iteration, the first bit is removed from the word; if it is 1, then the first appendant of the list is added at the end of the word, then the list is rotated. The computation stops when the word is empty or a special halting word (denoted *h* in the example) is activated. An example is provided in ● [Fig. 18](#).

Cyclic tag systems were proven to be able to perform any computation (Cook 2004) and even to do so in polynomial time (Woods and Neary 2006) and were used to build very small universal Turing machines (Neary and Woods 2009). They have been implemented in one-dimensional CA with collision/signal-based computing by Cook (2004) to produce

Fig. 18

computation universal CA with only two states (it is impossible to compute with less). The construction relies on signals moving and colliding that are sought and classified in order to work on a more abstract level.

As far as minimal CA are concerned, it is worth mentioning that four states are enough to get a one-dimensional CA, which is able to simulate any other one-dimensional CA (Richard and Ollinger 2008). This is not Turing universality since the simulation encompasses infinite configurations.

4.3 Signal-Specific Issues

Since CA form a model for physical phenomena and also for parallel computing architectures, other issues arise. One is to understand the underlying dynamics when used as a discrete model. The other is to design CA for special purposes.

4.3.1 Signals to Understand Dynamics

Once a simulation is running as a CA, one common way to understand the dynamics is to try to find regularities in the space–time diagram and observe them. They are often the key to the underlying dynamics and predictions. (Although it might happen that what is observed is nothing but an artifact of the model and has no counterpart in reality.) This is made clear by considering two examples.

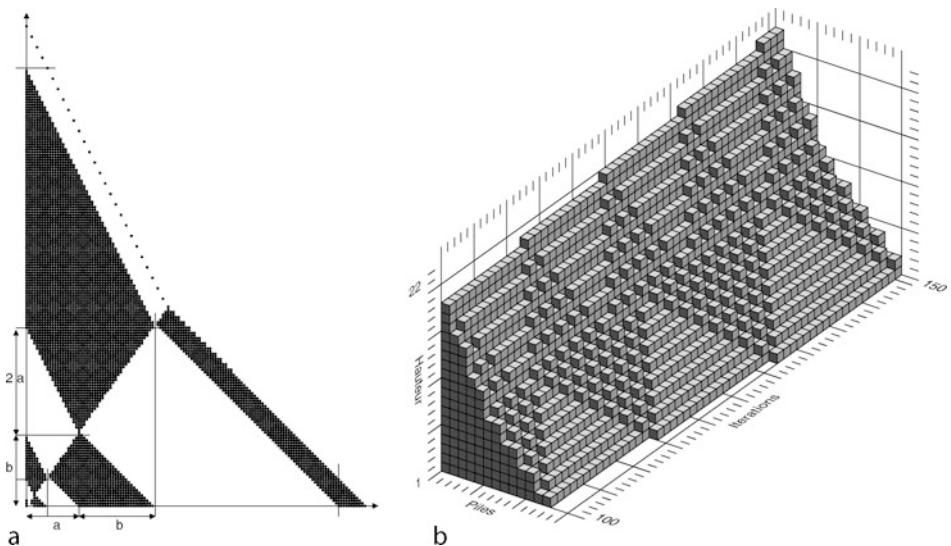

The first one models sand dripping in a one-dimensional space. The dynamics are quite simple: there is nothing in the initial configuration and at each iteration one grain is added to the first pile/cell. Each time a pile has at least two more grains than the next one, a grain falls.

If only grains dropping at odd time are colored in black, then their position is as in [Fig. 19a](#) after 10,000 iterations and only the top grains will ever move. This strange disposal, as well as the two different slopes and precise long-term behavior, are explained by signals (Durand-Lose 1996, 1998). These signals can be identified on [Fig. 19b](#) where the successive configurations (iteration 100–150) are set one after the other to form a volume. On this volume, triangles can be seen on the lower (as well as the upper parts), with their frontiers as signals (which can be revealed with an appropriate filtering).

Another example is provided by Das et al. (1995). The aim is to generate a CA with two states and a five-closest-cell neighborhood, such that, on a ring of any size, whatever configuration it is started on it always ends up blinking: all cells are 0 then all cells are 1, alternatively, forever. Instead of trying to build it straightaway, evolutionary programming is used: random

Fig. 19

One-dimensional sand dripping. (a) Dotting even grains (Durand-Lose 1996, Fig. 6) at iteration 10,000. (b) Successive configurations (Durand-Lose 1996, Fig. 3).

CA are generated; they are ranked according to their “blinking capability”; then the best are kept, recombined and mutated to form the next generation. It then cycles through ranking and the next generation until one “fully blinking” CA emerges.

The obtained CA is analyzed in terms of signal (again with some filtering), as illustrated in **Fig. 20**. (The apparent non-connectivity of some signals comes from the filtering and also because cells can influence one another up to distance 2.) The evolutionary process goes in steps where various intermediate levels of “blinking” appear. Analyzing typical members of each level reveals the progressive apparition of signals and collision rules.

It is very important to notice how, in a context where signals were not asked for by the evolutionary process, they indeed appear and are the key to both the desired dynamics and the evolutionary process.

The previous example does not compute in the classical understanding; nevertheless, it provides a relevant dynamical global property.

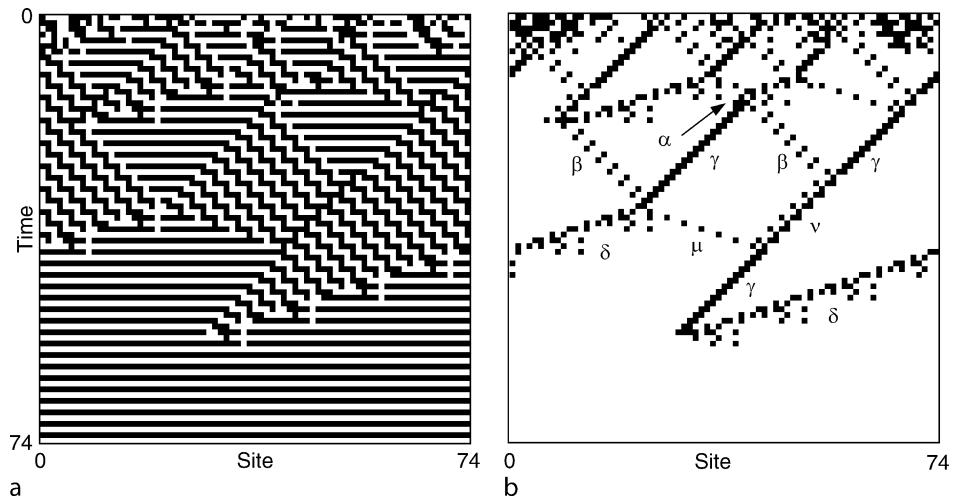

4.3.2 Signals to Generate a Particular Behavior

Computing, in the usual understanding, is a special behavior. But CA can also be thought of as a computing model on its own. Then primitives can be specially defined to take advantage of the huge parallelism. Signals are the key to managing it.

As already cited, the pioneering work of Fischer (1965) generates prime numbers using a parallel implementation of the Sieve of Eratosthenes where they are indicated as no signal on the first cell at the corresponding times. Prime numbers can then be read on the space–time diagram by observing the state of the first cell.

Fig. 20

Figure and filtering to highlight signals and analyze (from Das et al. 1995, Fig. 1). Time is increasing downward. (a) Space-time diagram. (b) Filtered space–time diagram.

Another complex behavior is the famous firing squad synchronization problem (FSS). Starting from all but one cell in a quiescent state, one wants all the cells to enter simultaneously the same state – which has not been used before. Like if they would all blink for the very first time synchronously.

Each example of [Fig. 21](#) shows the Euclidean conception and then the discrete implementation of a FSS solution. Both constructions rely on recursive cuts in half. In the discrete implementation, at some point, the granularity of space – a cell cannot be divided – is reached. Since CA are synchronous, this point is reached simultaneously everywhere, ensuring the global synchronization of the entire array of cells.

4.3.3 Signals as a Computational Model on Its Own

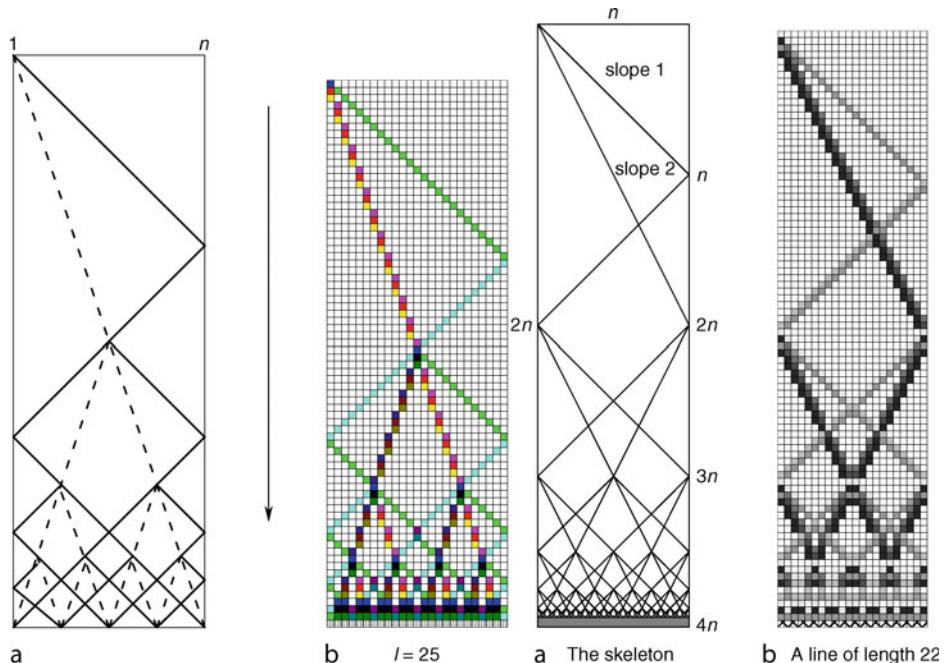

Mazoyer et al. developed a computing model where multiplication (as in [Fig. 22a](#)), composition (as in [Fig. 22b](#)), and even iteration are graphically achieved. The programming system is achieved by using a trellis of adaptable size that can be dynamically generated. The computation is carried out over the trellis. Composition is then achieved by having the next computation displayed on a new trellis. Recursion is provided by a scheme that dynamically starts another iteration providing each time an adapted trellis.

5 Abstract Geometrical Computation

Abstract geometrical computation (AGC) is an idealization of collision-based computing where particles/signals are dimensionless (time and space are continuous). Although the number of signals in a bounded space is expected to be finite, it is unbounded. Another way

Fig. 21

FSS implementations. (a) Divide and conquer in $3n$ -steps (Yunès 2007a, Fig. 2.3).
 (b) Eight-states and $4n$ -steps (Yunès 2007b, Fig. 1).

to consider AGC is as a continuous counterpart of CA as a limit when the size of the cells tends to zero. In CA, signals are almost always the key to understanding and designing, and, indeed, in the literature, the discreteness of CA and of their signals is often put aside to reason at a more abstract level and is left to technical details.

In abstract geometrical computation, dimensionless signals move at constant speed. When they meet, they are replaced by others according to some rewriting rules. A *signal machine* (SM) gathers the definition of the nature of available signals (called *meta-signals*), their speeds, and the collision rules. There are finitely many meta-signals and each one is assigned a constant speed (velocity and direction). The constant speed may seem surprising, but each discrete CA signal has indeed a constant speed.

The space–time diagrams generated are continuous in both space and time and the traces of signals form line segments. For a given meta-signal, all these segments are parallel. In this section, only one-dimensional AGC are considered, so that the space–time diagram is always two dimensional with time increasing upwards as illustrated by [Fig. 23](#).

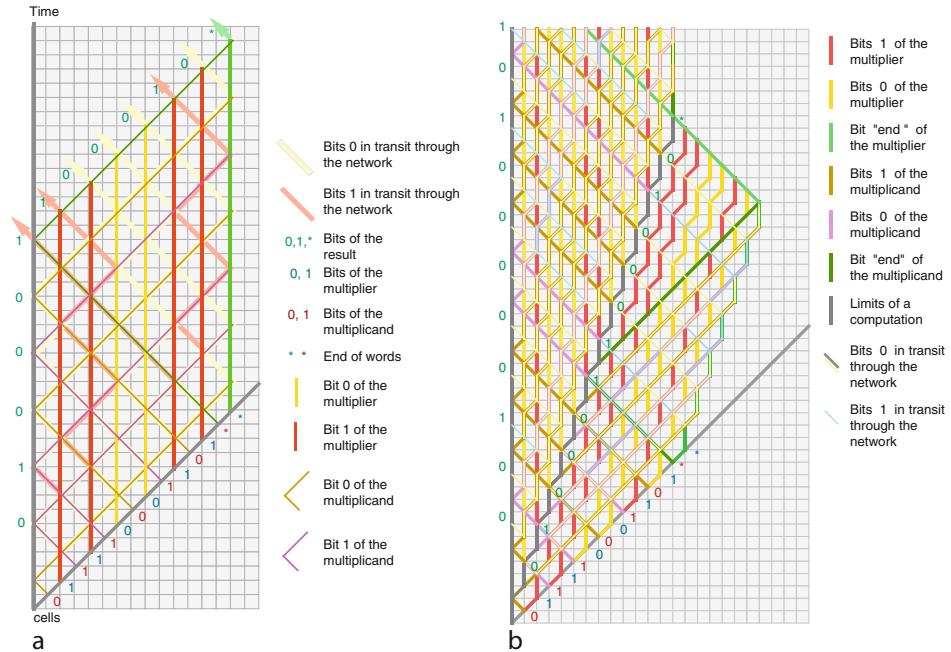

Space–time diagrams can be much more complicated and, as presented below, use continuity to implement the Zeno paradox and emulate the black hole model of computation.

5.1 Computing

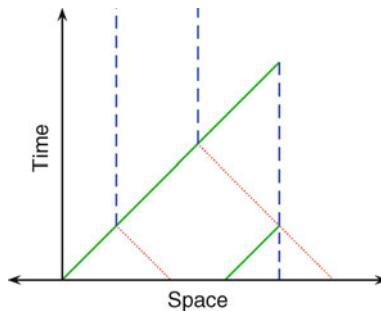

Computing, in the classical understanding, is pretty easy. In fact, many constructions for CA directly translate to ACG and are even easier, since discreteness does not have to be taken

Fig. 22

Mazoyer's system. Time is increasing upwards. (a) Multiplication (Mazoyer 1996, Fig. 4). (b) Composition of multiplications (Mazoyer 1996, Fig. 8).

**Fig. 23**

Example of a space–time diagram.

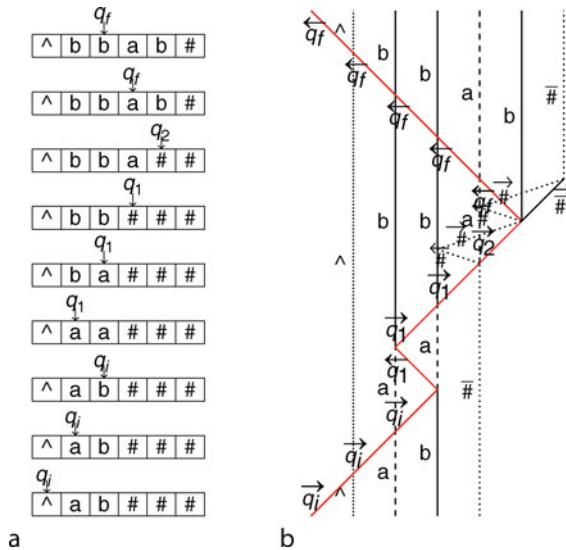

into account. Two ways to achieve computability are presented: Turing machines and cyclic tag systems.

For Turing machines (as presented in [Sect. 4.2.1](#)), the implementation is quite straightforward: static signals encode the tape – one signal per symbol – and one signal encodes the state of the automaton and the position of the head. The latter moves forth and back from symbol to symbol as the read/write head. This is depicted in [Fig. 24](#). The construction is detailed in Durand-Lose (2009).

Fig. 24

Simulating a Turing machine. (a) TM evolution. (b) TM simulation.

Cyclic tag systems are presented in [Sect. 4.2.2](#). The simulation is done by encoding, left to right, the word and then the circular list of appendants by parallel signals encoding the bits as shown in [Fig. 25a](#). At each iteration, the list is rotated to the right, but before that, if the erased bit of the word is 1, a copy is left. The copy is directly added at the right of the word as in [Fig. 25b](#), which presents one full iteration. The full simulation of the example of [Fig. 18](#) is given in [Fig. 25c](#). The rightward drifting corresponds to the erasure of the word from the left and to the rightward rotation of the list. Each group of oblique lines corresponds to one rotation of the list.

This simulation is detailed in Durand-Lose ([2008a](#)). The signal machine obtained is able to simulate any CTS, and is thus Turing universal. It is the smallest one known (it has only 13 meta-signals).

5.2 Geometric Primitives

As for CA, AGC can also be considered as a model on its own, with particular operators, which might not have any classical computation counterpart (like FSS) or discrete counterpart.

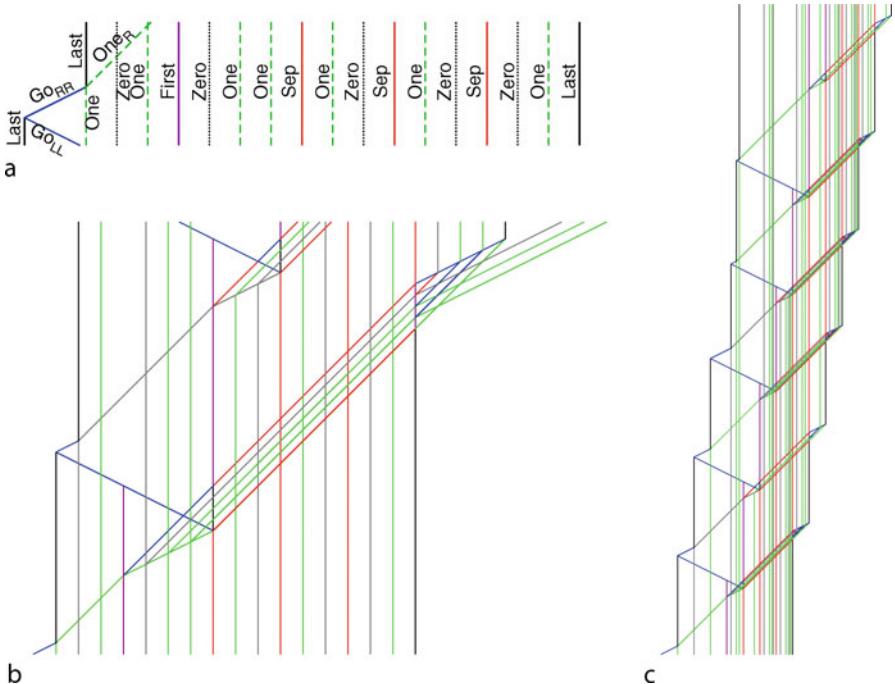

All the following constructions involve adding meta-signals and rules to a given SM, so that the desire capability exists. Signals have to be added to the initial configuration in order to fire the effect. Rules can also be modified in order to dynamically fire it.

Space and time are continuous and scaleless, and since signals have no dimension, there is no limit on the scalability. If all signals are scaled spatially by a given coefficient, the whole computation is also scaled temporally. So, the duration of a computation is meaningless and complexity measures, such as the maximal number of collisions, with a causal link, have to be used.

Spatial rescaling of the initial configuration is a static operation. It is also possible to do it during the computation. The construction relies on the ability to freeze a configuration.

Fig. 25

Simulating a cyclic tag system. (a) Initial configuration on 101 and 011 :: 10 :: 10 :: 01. (b) Initial configuration and first iteration on 101 and 011 :: 10 :: 10 :: 01. (c) Full simulation on 101 & 011 :: h :: 0110 :: 01011.

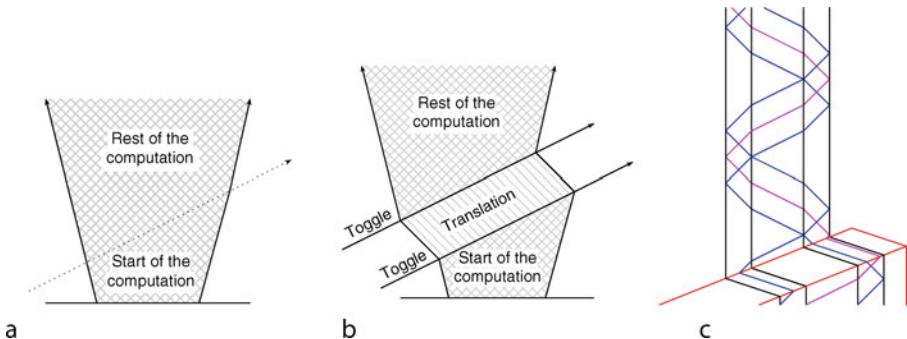

Freezing a computation is quite simple. One signal is added on one side and it crosses the entire configuration. Doing so, each time it meets a signal (or enters a previously existing collision), it replaces it with another signal encoding the meta-signal. All the encoding signals have the same speed: they are parallel and do not interact and, moreover, the distance between them is preserved. The configuration is frozen and shifts. To unfreeze it, a signal comes from the side, crosses the configuration, and replaces each encoding signal by the encoded one (or the result of the collision). Freezing and unfreezing signals must have the same speed so that the configuration is restored exactly as it was, up to a translation. (And indeed they correspond to the same meta-signal toggle.) This is depicted in [Fig. 26](#).

Meanwhile, when a configuration is frozen into parallel signals, it is possible to act on these signals. One simple trick is to change their direction. In [Fig. 27a](#), this is done twice so as to restore the original direction. (An extra signal is used on the right to delete the structure.) As a result, since different slopes are used to change direction, the distances between signals are scaled (here by one half). Adding freezing and unfreezing signals (automatically fired in due time), an artifact, to scale down a whole configuration, is generated as can be seen on the [Fig. 27c](#).

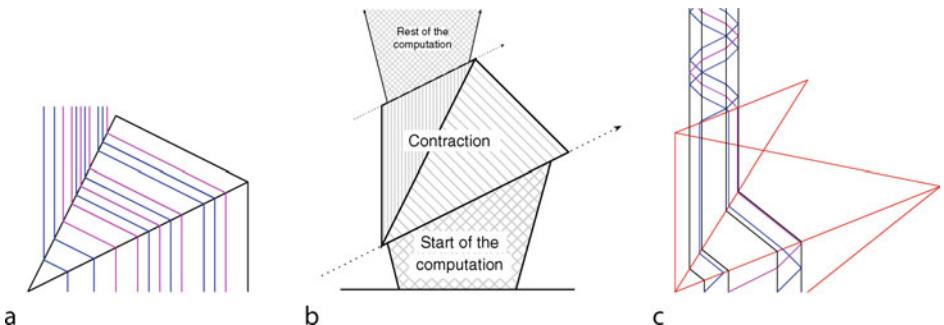

The initial configuration has been modified in order to start straightaway the effect. It is also possible to fire it dynamically during the computation when some special collision happens. This is used to iterate it.

Fig. 26

Freezing and unfreezing. (a) Normal computation. (b) Translated computation. (c) Example.

**Fig. 27**

Scaling. (a) Principle. (b) Scaled computation. (c) Example.

5.3 Infinite Acceleration and Non-recursive Function

Scaling can be automatically restarted ad infinitum; since both space and time are continuous, this is not a problem – at least before the singularity. In [Fig. 28](#), a computation producing an infinite trellis, extending indefinitely in both space and time, is folded into the structure. The right signal and the middle one are very important since the folded computations should be bounded in order to ensure that it is fully scaled.

A *singularity* refers to an accumulation of infinitely many collisions and signals to a given location. [Figure 28a](#) shows that the structure alone already creates a singularity. This illustrates the Zeno paradox. The leftmost signals of [Fig. 28a](#) form an infinite sequence with infinitely (yet countably) many collisions, although the time elapsed as well as the total distance crossed by signals is finite.

All the signals and collisions that would have existed if there would have been no folding indeed exist, but in a bounded portion of the space and time diagram. (The equivalence of the plane and a bounded part is somehow implemented.) So that up to the presence of the structure and of the frozen parts and the different scales, the computation is the same.

Any computation starting with finitely many signals can be folded. Inside the structure, the rescaling provides speedup (the closer they are, the faster they collide). This speedup is unbounded and goes to infinity. Inside the structure there is a space–time where time-lines are infinitely accelerated compared to the outside. This is the first step to emulate the black-hole model of computation (Hogarth 1994; Etesi and Németi 2002; Lloyd and Ng 2004).

The second step is to find a way for an atomic piece of information to leave the black hole, here the singularity. One meta-signal can be added and rules changed so that the new meta-signal is not affected by the structure but can be generated by the initial computation.

The final step is to add bounding signals on both sides of the folding (called here `horizonLe` and `horizonRi`). At their collision point, the folded computation is entirely in the causal past as displayed in Fig. 29. Any signal leaving the folding would have been collected.

This way the black-hole model is emulated: there are two time-lines, one for the machine and one for the observer. The machine one is infinite. On the observer one, after a finite duration, the whole machine one is entirely in the causal past. A single piece of information can be sent by the machine to the observer and it has to be sent after a finite (machine) duration. The ultimate date for the observer to receive anything from the machine is finite and known. To understand the power of this model, just imagine that the machine only sends a signal if its computation ends. The observer receives a signal only if it stops and after a duration the observer is aware that any signal sent would have been received. So, by just

Fig. 28

Folding or infinite rescaling. (a) Folding structure. (b) Example.

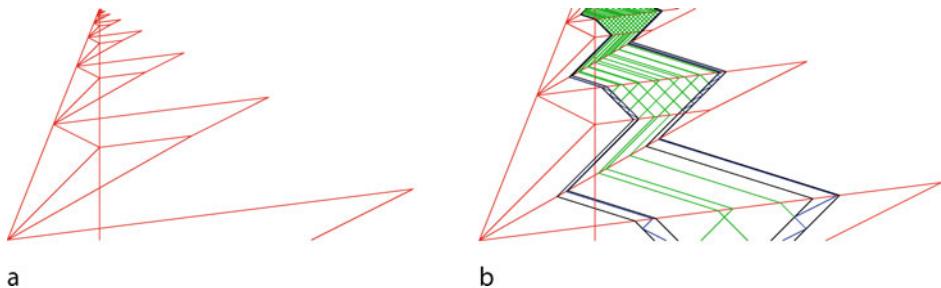

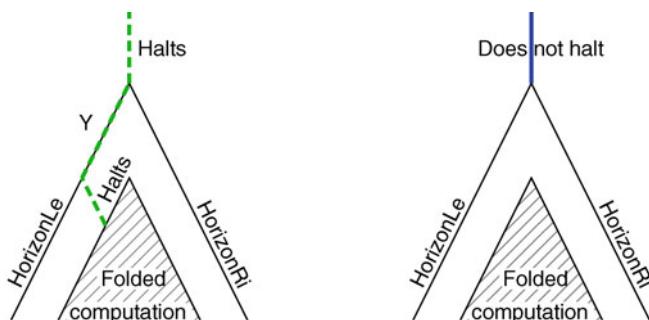

Fig. 29

Framing the folding to collect all signals exiting the folding.

checking its clock, the observer knows that the computation did not halt when it is the case. Altogether, the halting problem (whose undecidability is the cornerstone of Turing computability theory) is decidable!

This model, as well as AGC, clearly computes beyond Turing. In formal term, it can decide Σ_0^1 formulae in the arithmetical hierarchy, which is a recursive/computable predicate prefixed by an existential quantifier. This includes, for example, the consistency of Peano arithmetic and set theory, many conjectures such as the Collatz conjecture and Goldbach's conjecture.

Defining what happens at the singularity point is not easy, especially since the accumulating set can be a line segment, a fractal curve or even a Cantor! (To understand this, take a continuous look at the FSS: what would happen at the bottom of Fig. 21?) For singularity on a single point, a careful continuation has been proposed in Durand-Lose (2009) that allows us to climb the arithmetical hierarchy. There is also another use of isolated singularity as a way to provide limits for analog computation.

5.4 Analog Computation

Unlike collision-based computing and CA, with dimensionless signals in a continuous space, it is possible to encode real numbers as the distance between signals. In the AGC context, this distance is exact—that is, it is a real number in exact precision. As long as signals are parallel, this distance is preserved. This allows one to encode real numbers and to make some computations over them.

Since any real number can be encoded exactly, the model ipso facto falls out of classical computability (because of cardinalities, there is no way to encode all the reals with natural numbers or finite strings). Therefore, an analog model of computation has to be searched for.

With this encoding of real numbers, AGC is equivalent to the linear Blum–Shub–Smale model (BSS) (Blum et al. 1998). In the linear BSS model, variables hold (exact) real numbers and the operations available are addition, multiplication by a constant and branch, according to the sign of a variable. This equivalence is true as long as the BSS machine has an unbounded number of variables (accessed through a context shift like moving a window over an infinite array of variables), there are finite signals and there is no singularity (Durand-Lose 2007).

If singularities are used in a proper way, it becomes possible to multiply two variables. Then the classical BSS model can be implemented in AGC (Durand-Lose 2008b). The simulation is not possible in the other way anymore since, for example, the exact square rooting can also be computed by AGC.

Just as in the discrete case, a proper handling of isolated singularities of any order can be used to decide quantified (over natural but not real numbers) predicates in the BSS model and climb the BSS-arithmetical hierarchy (Durand-Lose 2009).

Abstract

In this chapter, computation is investigated from a dynamical systems perspective. A dynamical system is described in terms of its abstract *state space*, the system's current state within its state space, and a rule that determines its motion through its state space. In a classical computational system, that rule is given explicitly by the computer program; in a physical system, that rule is the underlying physical law governing the behavior of the system. Therefore, a dynamical systems approach to computation allows one to take a unified view of computation in classical discrete systems and in systems performing nonclassical computation. In particular, it gives a route to a computational interpretation of physical embodied systems exploiting the natural dynamics of their material substrates.

1 Introduction

In this chapter, we investigate computation from a dynamical systems perspective.

A dynamical system is described in terms of its abstract *state space*, the system's current state within its state space, and a rule that determines its motion through its state space. In a classical computational system, that rule is given explicitly by the computer program; in a physical system, that rule is the underlying physical law governing the behavior of the system. So a dynamical systems approach to computation allows us to take a unified view of computation in classical discrete systems and in systems performing nonclassical computation. In particular, it gives a route to a computational interpretation of physical embodied systems exploiting the natural dynamics of their material substrates.

We start with *autonomous* (closed) dynamical systems: those whose dynamics is not an explicit function of time, in particular, those with no inputs from an external environment. We begin with computationally conventional discrete systems examining their computational abilities from a dynamical systems perspective. The aim here is both to introduce the necessary dynamical systems concepts, and to demonstrate how classical computation can be viewed from this perspective. We then move on to continuous dynamical systems, such as those inherent in the complex dynamics of matter, and show how these too can be interpreted computationally, and see how the material embodiment can give such computation “for free,” without the need to explicitly implement the dynamics.

We next broaden the outlook to *open* (nonautonomous) dynamical systems, where the dynamics is a function of time, in the form of inputs from an external environment, and which may be in a closely coupled feedback loop with that environment.

We finally look at *constructive*, or developmental, dynamical systems, where the structure of the state space is changing during the computation. This includes various growth processes, again investigated from a computational dynamical systems perspective.

These later sections are less developed than for the autonomous cases, as the theory is less mature (or even nonexistent); however these are the more interesting computational domains, as they move us into the arena of considering biological and other natural systems as computational, open, developmental, dynamical systems.

2 Autonomous Dynamical Systems

Consider a dynamical system with N degrees of freedom; it has an abstract state space \mathcal{X}^N . Its state can be defined by N state variables $x_i \in \mathcal{X}$, or, equivalently, by an ND state vector $\mathbf{x} \in \mathcal{X}^N$ (e.g., \mathbf{x} may be a vector of binary bits, or a vector of continuous variables such as position and momentum). The state vector \mathbf{x}_t defines the value of the system state at a given time.

The deterministic dynamics is given by a function $f : \mathcal{X}^N \rightarrow \mathcal{X}^N$, which defines how a state vector \mathbf{x} changes with time, that is, it defines the *trajectory* that the system takes through its state space. So the dynamics associates a vector with each point in the state space, defining how that point evolves under the dynamics. (In conventional use, the meaning of this vector is unfortunately different in the discrete and continuous time cases. In the discrete time case (Sects. 2.1 and 2.2), $\mathbf{x}_{t+1} = f(\mathbf{x}_t)$, and so the vector is the next state; in the continuous time case (Sect. 2.3), $\dot{\mathbf{x}} = f(\mathbf{x})$, and so the vector is the derivative, pointing toward the next state an infinitesimal time later: $\mathbf{x}_{t+dt} = \mathbf{x}_t + f(\mathbf{x}_t) dt$. It would be possible to have a uniform meaning, by redefining the discrete case vector to be the difference in states, with $\mathbf{x}_{t+1} = \mathbf{x}_t + f(\mathbf{x}_t)$ (and an implicit $\Delta t = 1$). However, here we follow the conventional, and inconsistent, use.) If f is not itself an explicit function of time, then the system is *autonomous*.

In general, dynamical systems theory is not concerned with details of individual trajectories, but rather with the qualitative behaviors of sets of trajectories. For example, consider a set of states occupying some initial volume of the state space: As these states evolve under the dynamics, how does the volume change? We are mostly interested here in *dissipative systems*, where the volume contracts to *attractors* (regions of state space that attract trajectories), and we interpret such attractors from a computational perspective. This contracting behavior is a property of systems that dissipate energy or information. (Closed non-dissipative dynamical systems, on the other hand, have no attractor structure.)

2.1 Discrete Space, Discrete Time Dynamical Systems

We start by considering finite discrete spaces (finite number of finite dimensions), with discrete time dynamics $t \in \mathbb{N}$ (where \mathbb{N} is the set of natural numbers).

We take $\mathcal{X} = \mathcal{S}$, some set with finite cardinality $|\mathcal{S}| \in \mathbb{N}$ (typically \mathcal{S} will be the Boolean set \mathcal{B} , but it is not restricted to this). For an N -dimensional system, the state is defined by N state variables $s_i \in \mathcal{S}$, and the state space \mathcal{S}^N comprises $|\mathcal{S}|^N$ distinct discrete states. (When $\mathcal{S} = \mathcal{B}$, these states fall on the vertices of an N -dimensional hypercube.) Let the state vector be $\mathbf{s} \in \mathcal{S}^N$.

The dynamics of a particular system is determined by its particular transition function $f : \mathcal{S}^N \rightarrow \mathcal{S}^N$, with $\mathbf{s}_{t+1} = f(\mathbf{s}_t)$. There are $(|\mathcal{S}|^N)^{|\mathcal{S}|^N}$ such functions f .

Given a particular state $\mathbf{s}_0 \in \mathcal{S}^N$, its trajectory under f is a sequence of states $\mathbf{s}_0, \mathbf{s}_1, \dots, \mathbf{s}_t, \dots$. Eventually, because the state space is finite, a state that was met before will be met again: there exists a k such that $\mathbf{s}_k = \mathbf{s}_{k+p}$, for some p . Since the dynamics is deterministic, the trajectory will then recur: for all $i \geq k$, $\mathbf{s}_i = \mathbf{s}_{i+p}$. The system has entered an *attractor*, with cycle length or period p . States not on an attractor are called *transient*.

Given a trajectory $\dots, \mathbf{s}_t, \mathbf{s}_{t+1}, \dots$, then \mathbf{s}_t is the *pre-image* of \mathbf{s}_{t+1} in this trajectory, and \mathbf{s}_{t+1} is the *successor* of \mathbf{s}_t . Every state has precisely one successor (because the dynamics is deterministic). It may have zero, one, or more pre-images (trajectories may merge); if it has zero pre-images, it is a *Garden of Eden* state.

The set of all states \mathbf{s}_i whose trajectories lead to the same attractor forms the *basin of attraction* of that attractor. The total state space is partitioned into these basins: Every state is in precisely one basin. Note that there is no necessary correlation between the volume of the basin (the proportion of state space it occupies, and hence the probability that a state chosen at random will be in it) and the length of the attractor that it leads to.

The *microstate* of the system is which particular $\mathbf{s} \in \mathcal{S}$ it is in. The *macrostate* is which particular attractor (or basin of attraction if the microstate is currently a transient state) the system is in.

For a given dynamics f , there is a minimum of one attractor basin (all states are in the same attractor basin, for example, the zero function), and a maximum of $|\mathcal{S}|^N$ (the identity function where every state forms its own single-state attractor basin). There is a minimum transient length of 0 (all states on some attractor cycle, for example, the increment modulo 2^N function, interpreting the binary encoded state \mathcal{B}^N as a number), and a maximum transient length of $|\mathcal{S}|^N - 1$ (e.g., the decrement and halt on zero function). There is a minimum number of Garden of Eden states of 0 (all states on some attractor cycle), and a maximum number of Garden of Eden states of $|\mathcal{S}|^N - 1$ (e.g., the zero function). Nontrivial dissipative computational systems rarely lie at any of these extremes, however. (Note that reversible, non-dissipative systems have no Garden of Eden states, and no merging trajectories.)

2.1.1 Visualizing the Attractor Field

Visualizing the basins of attraction can help in understanding some aspects of their dynamics. For small systems, the most common approach is to lay out the state transition graph to highlight the separate basins, their attractors, and their symmetries (see [Fig. 1](#)). Wolfram (1986b, Fig 9.1) used this approach in early work on cellular automata; Wuensche (Wuensche 2002; Wuensche and Lesser 1992) has developed special purpose layout software, and uses this approach consistently, to highlight aspects of the dynamics.

2.1.2 Computation

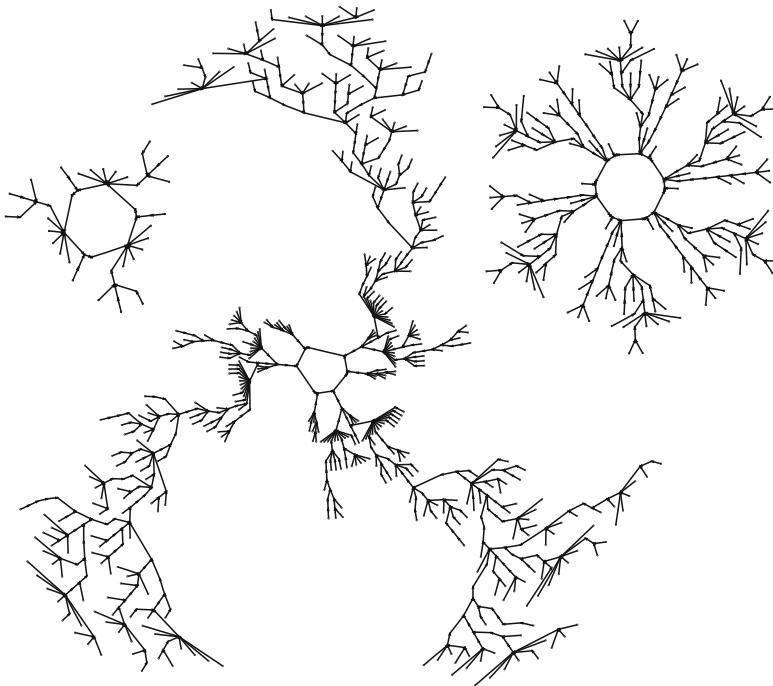

Given a finite system in initial microstate \mathbf{s}_0 (which may be considered to contain an encoding of any input data), the system follows its dynamics f until it reaches the relevant attractor. If this attractor has a cycle length of one, the system then stays in the single attractor state. For longer cycle lengths, the system perpetually repeats the cycle of states.

In Terms of Attractors

The *computation* performed by the system as it follows its dynamics f can be interpreted as the determination of which attractor basin it is in, by progressing to the attractor from its initial state \mathbf{s}_0 .

Fig. 1

Visualization of part of the state transition graph for ECA rule 110 (see [Sect. 2.1.5](#) on Elementary Cellular Automata), on the periodic lattice $N=12$, showing three of the basins of attraction. Each node corresponds to a state s_i ; each edge corresponds to a transition $s_i \rightarrow s_{i+1}$. The leaves of the graphs are Garden of Eden states; the attractor cycles can be seen at the centers of the basins.

The output of the computation may be the microstates, or some suitable projection thereof, of the discovered attractor cycle. (See, e.g., [Sect. 2.1.5](#), Example 1: the density classification task.)

In Terms of Trajectories

Alternatively, the *computation* performed by the system as it follows its dynamics f can be considered to be (some projection of) the microstates it passes through along its trajectory, including both transient and attractor cycle states. (See, e.g., [Sect. 2.1.5](#), Example 2: the Rule 30 PRNG.)

Programming Task

The programming task involves determining a dynamics f that leads to the required trajectories or attractor structure. (See, e.g., [Sect. 2.1.5](#), Example 1: the density classification task.)

For feasible programs, the discovery of an attractor should be performed in polynomial time (implying polynomial length transients and attractor cycles). At the other complexity

extreme, the dynamics should not be defined merely by a $|\mathcal{S}|^N$ -entry lookup table (which would allow all computations to find the attractor in a single step); it should admit a “compressed” description. (See, e.g., [Sect. 2.1.5](#) and [2.1.6](#) which define the global dynamics f in terms of the composition of local dynamics ϕ_i .)

Implementation

Natural physical systems do not tend to directly implement a discrete dynamics, particularly one that has been designed to perform a specific task. However, any such dynamics can be implemented (or simulated) on a classical digital computer. Hence, there are no implementation constraints imposed on the design of the dynamics f .

Inputs and Outputs

The input is encoded into the initial state; the output is decoded from (a projection of) the resulting attractor state(s). It is important when analyzing the complexity of the computation to take into account any “hidden” computation needed to encode the input, or to decode the output. This is particularly important if the computational interpretation is far removed from the dynamics, for example, if there is some kind of virtual machine present.

2.1.3 Virtual Machine Dynamics

In some cases, a dynamics needs to be accompanied by a very carefully chosen initial condition in order to implement the required computation. For example, when cellular automata are used to implement Turing machines (TMs; see [Sect. 2.1.5](#) on Universality), they are given a carefully chosen initial configuration that corresponds to the “program” of the TM, plus the “true” input corresponding to its initial tape. This requirement for an exquisitely tuned initial condition constrains the system to traverse only a very small part of its state space (certain basins of attraction are never explored; some transient trajectories are never taken). What is happening in these cases is that the underlying broader dynamics is being used to implement a “virtual machine” with its own dynamics confined to a small subspace of the underlying system; this subspace and its trajectories correspond to the computation of the virtual machine, and may possibly be implemented more directly. In the continuous case, this more direct implementation is what we want: The natural dynamics of the system, with no need for such highly tuned initial conditions, performs the desired computation.

2.1.4 Infinite-Dimensional State Spaces

When N is (countably) infinite, the dynamics of the system can change qualitatively.

In a finite dissipative system (which contains both transients and cycles), there must be Garden of Eden states, but this is no longer true in an infinite system: Transient behavior on the way to the attractor cycle need not have any starting Garden of Eden states (e.g., the decrement and halt on zero function).

An infinite system need not have an attractor cycle: There is no guarantee that the system will reach a previously seen state (e.g., the increment function). Even if there are attractor cycles, there may be states not in their basins (e.g., the function **if even then add 2 else halt**).

A Turing machine (TM) operates in a state space with a countably infinite (or, more precisely, finite but unbounded) number of dimensions. In dynamical systems terms, halting is reaching one of a number of particular attractor cycles of length 1, which describes the halting states. The output of the TM (the contents of its tape) is simply the microstate of the subspace representing the tape in this halting state. Hence there are potentially many attractors, one for each halting state with different tape contents, corresponding to different initial tape contents (different initial states s_0).

The halting problem means that it is in general undecidable whether a given initial state s_0 is in a halting basin, in some other (“looping”) basin, or not in a basin at all.

2.1.5 Cellular Automata

A finite cellular automaton (CA) comprises N cells laid out in a regular grid or lattice, usually arranged as an n -dimensional torus (n in common examples is typically 1 or 2). Each cell i at time t has a state value $c_{i,t} \in \mathcal{S}$.

Each cell has a *neighborhood* of k cells, comprising itself and certain nearby cells in the grid. This neighborhood is the same for all cells, in that v_i , the neighborhood of c_i , is v_0 , the neighborhood of the origin c_0 , translated by i (☞ Fig. 2a).

The state of cell c_i ’s neighborhood v_i at time t is $\chi_{i,t} \in \mathcal{S}^k$, a k -tuple of cell states that is the projection of the full state onto the neighborhood v_i (☞ Fig. 2b).

The local state transition rule, or update rule, is $\phi : \mathcal{S}^k \rightarrow \mathcal{S}$. (There are $|\mathcal{S}|^{|\mathcal{S}|^k}$ such rules, some of which are related by symmetries. So, since typically $k \ll N$, CA rules capture only a small fraction of all the possible dynamics over an ND space.) These cells form an array of state transition machines. At each timestep, the state of each cell is updated in parallel, $c_{i,t+1} = \phi(\chi_{i,t})$.

The global dynamics f is determined by the local rule ϕ and the shape of the neighborhood. This global behavior from a given initial state is conventionally visualized in the 1D case by drawing the global state at time t as a line of cells (with colors corresponding to the local state), then drawing the state at $t+1$ directly below, and so on (see ☞ Fig. 3). Higher dimensional CAs are conventionally visualized as animations.

☞ Figure 1 shows three basins of attraction of a small CA. There are many “repeated” basins (basins with identical topologies, over different specific states) due to the symmetries in

☞ Fig. 2

CA neighborhood. (a) A CA’s regular neighborhood, v , illustrated in a 2D lattice. The neighborhood of cell i is the image of the neighborhood of cell 0, translated by i . (b) The state of the neighborhood, illustrated in a 1D lattice. χ_i , the state of the neighborhood of cell i , is the projection of the full state s onto the neighborhood v_i .

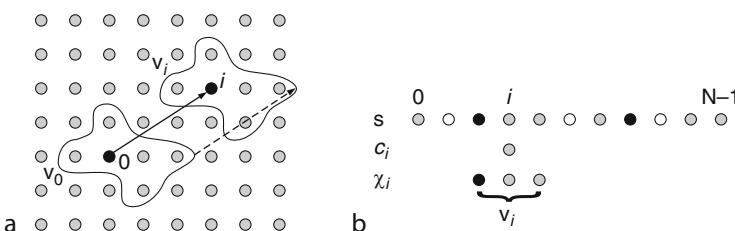

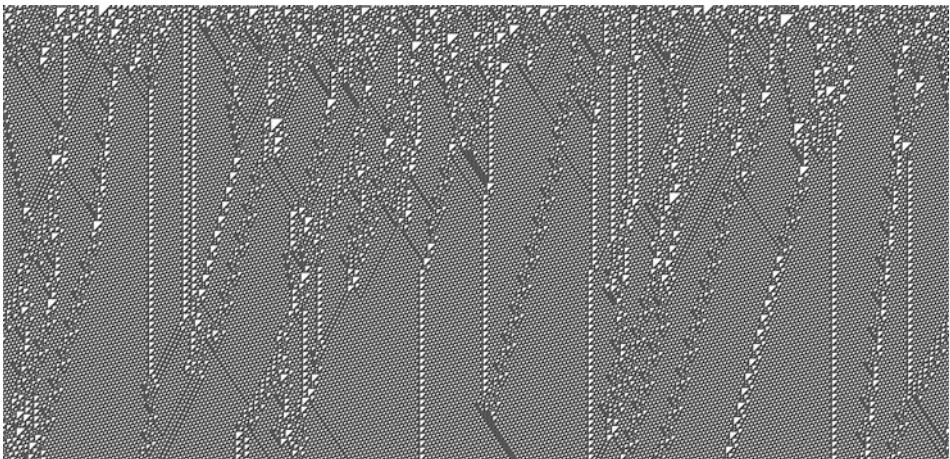

Fig. 3

Visualization of the time evolution of ECA rule 110 (see [Sect. 2.1.5](#) on Elementary Cellular Automata), with $N=971$, with random initial state s_0 , over 468 timesteps. Each horizontal line shows the N -bit representation of the state s_t ; subsequent lines correspond to subsequent timesteps s_t, s_{t+1}, \dots .

a CA rule (Powley and Stepney [2009a, b](#)). Every rule over a finite space with periodic boundary conditions has “shift” symmetries from shifting the arbitrary origin; additionally, some rules also have reflectional and other symmetries.

Elementary Cellular Automata (ECAs)

ECAs are 2-state ($\mathcal{S} = \mathcal{B}$) CAs, with the cells arranged in a 1D lattice, and with a neighborhood size of 3 (comprising the cell and its immediate left and right neighbors). There are $2^{2^3} = 256$ distinct ECA rules, conventionally referred to by a base 10 number $0\dots255$, representing the base 10 interpretation of the rule table bitstring. After reflection and inversion symmetries have been taken into account, there are 88 essentially distinct rules.

Wolfram’s Classification

Wolfram (1984b, a) provides a qualitative characterization of CAs, classifying their long-term evolution into four classes:

1. A unique homogeneous state, independent of the initial state (a single-state attractor cycle); patterns disappear with time
2. A simple periodic pattern of states (short attractor cycles, length $\ll |\mathcal{S}|^N$); patterns become fixed
3. Chaotic aperiodic pattern of states (long attractor cycles, length $O(|\mathcal{S}|^N)$, or no cycles in the infinite case); patterns grow indefinitely
4. Complex localized long-lived structures; patterns grow and contract

Wolfram’s classification scheme has been criticized for a variety of reasons, including the fact that even determination of quiescence (long-term fixed patterns) is undecidable (Culik and Yu [1988](#)). This is a recurring problem for any classification scheme: “CA behavior is so

complex that almost any question about their long-term behavior is undecidable” (Durand et al. 2003). See also Sutner (2005). Wolfram classes are nevertheless widely used in a qualitative manner to distinguish kinds of behaviors.

Class 3 and class 4 CAs demonstrate *sensitive dependence on initial conditions*: The effect of a minimal (one cell state) change to the initial condition propagates across the system, eventually resulting in a completely different dynamics (see ▶ Fig. 4). The 88 essentially distinct ECAs cover all 4 Wolfram classes of behavior.

Universality

Even though CA rules capture only a small fraction of all the possible dynamics over an ND space, there are computationally universal CAs that can emulate a TM. ECA rule 110 (▶ Fig. 3) is universal (Cook 2004), as is Conway’s Game of Life 2D CA (Berlekamp et al. 1982; Rendell 2002). The proof of universality in these cases involves constructing a virtual machine in the CAs, on which is implemented a TM (or equivalent). In other words, the computation is being performed by a carefully engineered initial condition, and a carefully engineered interpretation of the dynamical behavior. So these systems explore only a small fraction of their full state space: the fraction that corresponds to an interpretation of the state of a TM.

Wolfram (1984b, §8) speculates that “class 4 cellular automata are characterized by the capability for universal computation” (in the case of infinite-dimensional CAs).

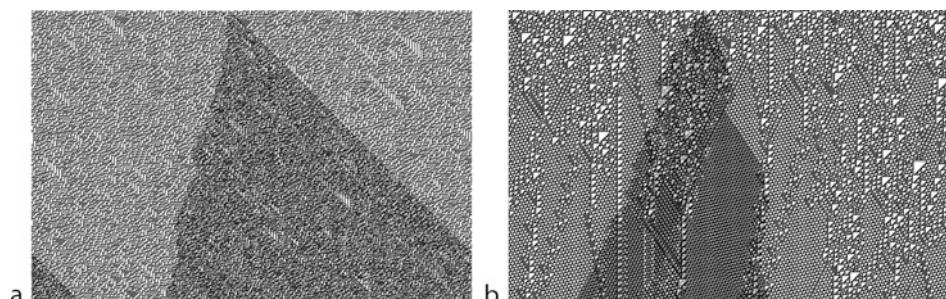

Example CA 1: The Density Classification Task

The requirement is to design a local two-state 1D CA rule ϕ , independent of lattice size N (assume N odd for simplicity), such that the global dynamics f has the following properties: (i) the system has two attractors, each of cycle length 1, one being the all zeros state, one being the all ones state; (ii) any initial state s_0 with more zeros than ones is in the basin of the all zeros state, and vice versa; (iii) the maximum transient length is at worst polynomial in n (i.e., the attractor is discovered in polynomial time). The computation determines which attractor basin the initial state is in, and hence, by inference, whether the initial state has more zeros than ones.

No two-state CA with a bounded neighborhood size can solve this problem exactly on arbitrary lattice size N (Land and Belew 1995). The best rules designed or evolved (e.g., Gács et al. 1978; Mitchell et al. 1996; Wolz and de Oliveira 2008) fail to correctly classify about 20%

◀ Fig. 4

Sensitive dependence on initial conditions. Each plot overlays the evolutions of two initial states differing in only one bit: the growing central dark region is different; the outer regions are the same. $N=971$, random initial state s_0 , over 646 timesteps (a) ECA rule 45; (b) ECA rule 110.

of states, that is, they define a dynamics where these states are in the “wrong” basin of attraction. Bossomaier et al. (2000) investigate the problem specifically in terms of the attractor basins.

Example CA 2: The Rule 30 Pseudorandom Number Generator

Wolfram (1986b) discusses ECA rule 30:

$$\phi_{30}(c_{i-1}, c_i, c_{i+1}) = c_{i-1} \text{ XOR } (c_i \text{ OR } c_{i+1}) \quad (1)$$

Starting from an initial state s_0 with a single cell j “on,” $c_{i,0} = (\text{if } i = j \text{ then } 1 \text{ else } 0)$, (Fig. 5), then the sequence of bits under this single on bit, $\tau = c_{j,0}, c_{j,1}, \dots, c_{j,t}, \dots$ forms a (pseudo) random sequence. Wolfram (1986b) presents evidence that the cycle length of the attractor starting from a state with a single nonzero cell grows exponentially with CA lattice size N .

This sequence τ is a projection (onto the single Boolean state variable c_j) of the trajectory from state s_0 under the dynamics defined by rule 30.

2.1.6 Random Boolean Networks

A random Boolean network (RBN) comprises N nodes. Each node i at time t has a binary valued state, $c_{i,t} \in \mathcal{B}$. Each node has k inputs assigned randomly from k of the N nodes (an input may be from the node itself); the wiring pattern is fixed throughout the lifetime of the network. This wiring defines the cell’s neighborhood, v_i . See Fig. 6.

The state of cell i ’s neighborhood at time t is $\chi_{i,t} \in \mathcal{B}^k$, a k -tuple of cell states that is the projection of the full state onto the neighborhood v_i .

Each node has its own randomly chosen local state transition rule, or update rule, $\phi_i : \mathcal{B}^k \rightarrow \mathcal{B}$. These cells form a network of state transition machines. At each timestep, the state of each cell is updated in parallel, $c_{i,t+1} = \phi_i(\chi_{i,t})$.

Fig. 5

ECA rule 30 (Eq. 1), initial state of a single nonzero cell.

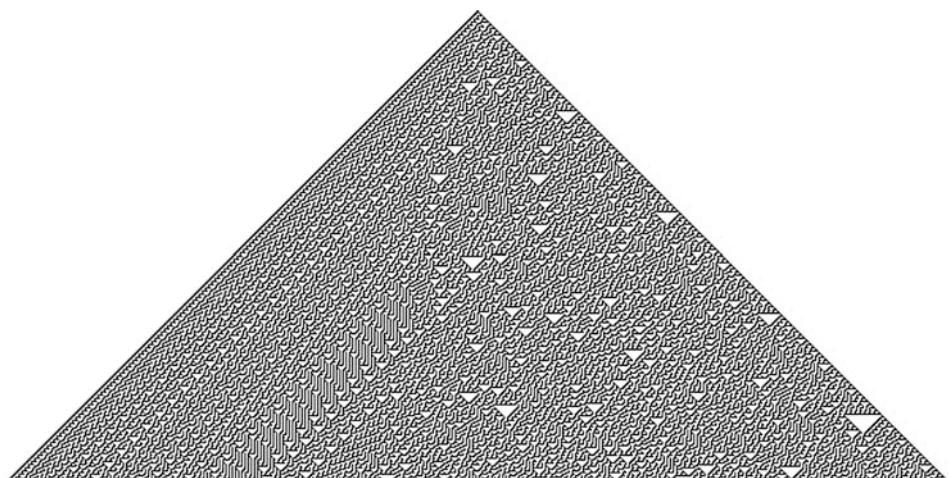

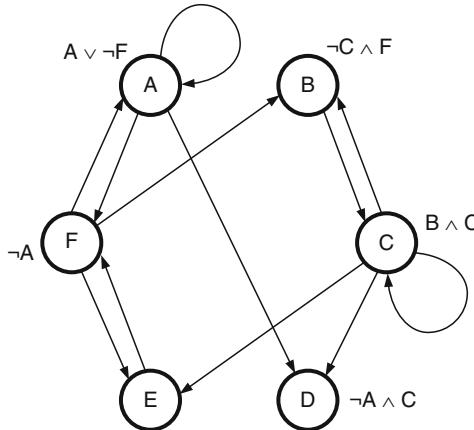

Fig. 6

An example random Boolean network (RBN) with $N=6, k=2$. Each node has $k=2$ inputs; it can have any number of outputs. So the neighborhood function is $v_A=(A,F)$, $v_B=(C,F)$, etc. Each node combines its inputs by a random Boolean function ϕ_i ; that function might ignore one (or both) of the inputs.

The global dynamics f is determined by the local rules ϕ_i and the connectivity pattern of the nodes v_i . In contrast to the regularity of a CA, in an RBN each node has its own random neighborhood connection pattern and its own random update rule. Like CAs, RBNs capture only a small fraction of all the possible dynamics over an ND space.

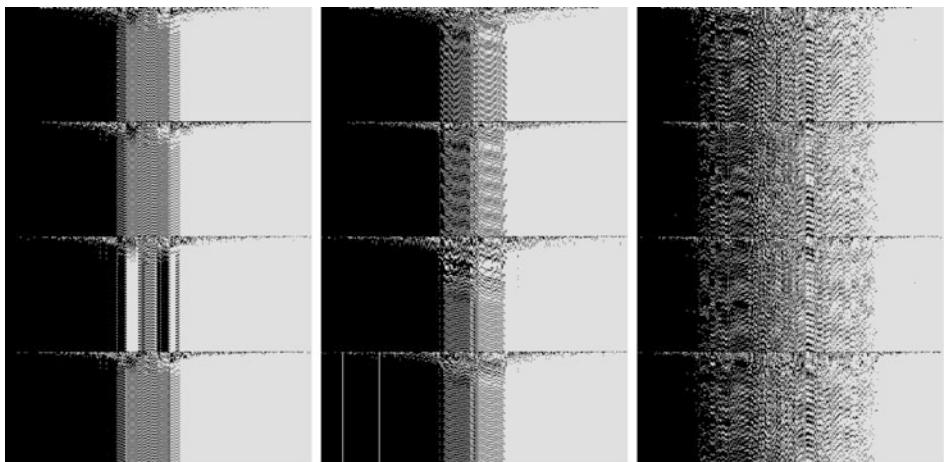

Kauffman (1990, 1993) investigates the properties of RBNs as a function of connectivity k . (The wiring conditions given above are not stated explicitly in these references. However, in the $k=N$ case, Kauffman (1993, p.192) states that “Since each element receives an input from all other elements, there is only one possible wiring diagram.” This implies that multiple connections from a single node are not allowed (otherwise more wiring diagrams would be possible) whereas self connections are allowed (otherwise k would be restricted to a maximum value of $N-1$). Subsequent definitions (e.g., Drossel 2008) explicitly use the same conditions as given here.) Unlike CAs, RBNs tend not to have repeated basins, because of the random nature of the connections, and hence the relative lack of symmetries. Despite all the randomness, however, “such networks can exhibit powerfully ordered dynamics” (Kauffman 1990), particularly when $k=2$ (Fig. 7; Table 1). Drossel (2008) notes that subsequent computer simulation of much larger networks shows that “for larger N the apparent square-root law does not hold any more, but that the increase with system size is faster.”

Kauffman identifies $k=1$ as the “ordered” regime, with a very large number of short period attractors. Large k is the chaotic regime, with very long period attractors (compare Wolfram’s class 3 behavior). $k=2$ occurs at a “phase transition” (Kauffman 1990), separating the ordered and chaotic regimes; it exhibits a moderate number of moderate period attractors.

Kauffman investigates RBNs as simplified models of gene regulatory networks (GRNs). He notes that “cell types are constrained and apparently stable recurrent patterns of gene expression,” and interprets his RBN results as demonstrating that a “cell type corresponds to a state cycle attractor” (Kauffman 1993, p. 467) (in a $k=2$ network).

Fig. 7

Visualization of the time evolution of three typical $k=2$ RBNs, with $N=400$, and initial condition all nodes “off”; after 150 timesteps all nodes are set to “on,” then all nodes are randomized (50% “on,” 50% “off”) every further 150 timesteps, to explore other attractors. They exhibit ordered behavior: short transients and low period attractors. The visualization scheme used here (Stepney 2009) orders the nodes to expose the frozen core (Kauffman 1993, p. 203) of nodes that do not change state on the attractor; this frozen core is well preserved on different attractors.

**Table 1**

Dynamics of random Boolean networks (RBNs) for different k (Adapted from Kauffman (1993, Table 5.1))

k	Attractor cycle length	# Attractors
1	$O(\sqrt{N})$	$O(2^N)$
2	$O(\sqrt{N})$	$O(\sqrt{N})$
>5	$O(2^N)$	$O(N)$

Emergent macrostates of the dynamics, in addition to the attractor cycle length, are the number of nodes whose states change during a cycle, compared to the number that form the static *frozen core*. In the GRN interpretation, the frozen core would correspond to genes whose regulatory state was constant in a particular cell type, and the changing nodes to those genes whose regulatory state was cycling.

2.2 Continuous Space, Discrete Time

We next consider continuous spaces, with $\mathcal{X} = \mathcal{R}$ (where \mathcal{R} is the set of real numbers), with discrete time dynamics $t \in \mathbb{N}$. Let the state vector be $\mathbf{r} \in \mathcal{R}^N$. The dynamics of a particular system is determined by its particular transition function $f : \mathcal{R}^N \rightarrow \mathcal{R}^N$, with $\mathbf{r}_{t+1} = f(\mathbf{r}_t)$.

These systems are called *difference equations* or *iterated maps*. A discrete-time trajectory $\mathbf{r}_t, \mathbf{r}_{t+1}, \mathbf{r}_{t+2}, \dots$ is also called an *orbit*.

The trajectories can display a range of behaviors, corresponding to a range of types of attractor, depending on the system. Trajectories may diverge ($|\mathbf{r}_t| \rightarrow \infty$); they may converge to a fixed point attractor ($\mathbf{r}_t \rightarrow \mathbf{r}^*$, where $f(\mathbf{r}^*) = \mathbf{r}^*$); they may converge to a periodic attractor; they may be chaotic, never repeating but still confined to a particular subregion of the state space. So, continuous space systems have chaotic behavior that differs qualitatively from the “chaotic” behavior of discrete space systems, since the finite discrete systems must eventually repeat and hence be periodic (although with exponentially long periods).

2.2.1 Parameterized Families of Systems

It is often convenient to consider a family of dynamics related by some parameter $p \in \mathcal{P}$, that is, $f(\mathbf{r}, p)$, and investigate how the dynamics of a system vary as a function of this parameter. The trajectories of such parameterized systems can display the whole range of behaviors corresponding to the range of types of attractor, depending on the value of the parameter. A small change to the parameter can make a fixed point move, or become unstable, or periodic, or disappear. It can move a system from period P to period $2P$ (*period doubling*), or from periodic to chaotic behavior. The parameter values where these qualitative changes in the dynamics occur are called *bifurcation points*. As the parameter crosses the bifurcation point, the change in the dynamics can be continuous (smooth), or discontinuous (*catastrophic*).

Many systems exhibit a sequence of period doublings as the parameter changes. Subsequent doublings happen ever more rapidly (requiring ever smaller changes to the parameter), then the system moves into a chaotic regime. This is known as the *period doubling route to chaos*. Appearance of a period doubling cascade in a parameterized system is indication that chaos will ensue if the parameter changes further.

Another typical behavior is the *intermittency route to chaos*. Here the parameter starts in a region with periodic dynamics; as it is changed, the periodic behavior is broken by intermittent bursts of irregular behavior. As the parameter changes further, there are more and more of these bursts, until the behavior becomes completely chaotic. Hence a fully deterministic system may be apparently periodic, interrupted by what look like bursts of noise, where these bursts are simply part of the same overall dynamics of the system, and in need of no external explanation.

2.2.2 Logistic Map

The logistic map, a parameterized family of 1D iterated maps,

$$r_{t+1} = \lambda r_t (1 - r_t) \quad (2)$$

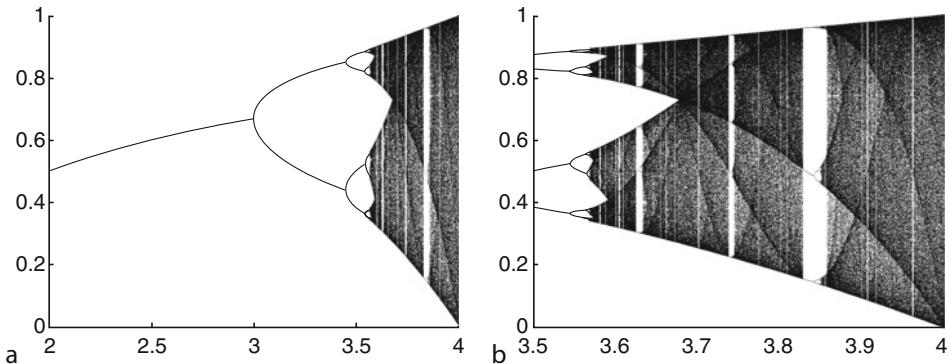

is a well-studied example of such a system (see ▶ Figs. 8 and ▶ 9). It is usually studied for $\lambda \in [0, 4]$, since in this region its dynamics is confined to the unit interval: $r \in [0, 1]$. It does have complex dynamics for other values of λ , but these are not constrained to the unit interval.

Its unintuitively rich, complex properties have been researched in detail, and May (1976) advised:

- ▶ Not only in research, but also in the everyday world of politics and economics, we would all be better off if more people realised that simple nonlinear systems do not necessarily possess simple dynamical properties.

Fig. 8

Orbit diagram of the logistic map, (a) $2 \leq \lambda \leq 4$, showing the period doubling route to chaos; (b) $3.5 \leq \lambda \leq 4$, zooming in on the window of period 3.

The attractor structure, visible in [Fig. 8](#), is summarized in [Table 2](#) as a function of parameter λ . It has period doubling cascades to chaos as λ is increased. The first cascade leads to the onset of chaos at $\lambda = 3.56994\ 56718\dots$. Within this chaotic region, there are windows of periodicity (such as the window of period 3), which then also period-double back to chaos. Given the existence of a period 3 cycle in a map, then every possible period can also be found in that map (Li and Yorke 1975). In the logistic map, there are windows of every period for some $3 < \lambda < 4$. Each of these periodic windows then period-doubles back to chaos as λ increases. The order in which these cascades occur itself has a complex structure, which can be calculated iteratively, in terms of symbolic sequences (Metropolis et al. 1973); the lowest order sequences are shown in [Table 2](#).

Cycles of the same period can nevertheless have different kinds of behaviors: see, for example, [Fig. 10](#).

The logistic map also exhibits the intermittency route to chaos. If the parameter λ falls in a window of periodic behavior, and is then slowly *reduced*, intermittent behavior is seen (e.g., [Fig. 9e](#)), until fully chaotic behavior is reached.

Binary Shift Map

Consider the fully chaotic case, $\lambda=4$. Changing variables, to $x = \frac{1}{\pi} \cos^{-1}(1 - 2r)$, yields the equation for the binary shift (Bernoulli) map:

$$x_{t+1} = 2x_t \bmod 1 \quad (3)$$

If x is expressed in base 2, each iteration of the map results in a left shift of the number (the multiplication by 2), and dropping any resulting leading 1 in front of the binary point (the mod 1). For example, if $x_t = 0.1110001\dots$, then $x_{t+1} = 0.110001\dots$, $x_{t+2} = 0.10001\dots$, etc. If x_0 is rational, its binary expansion is periodic, and hence the iteration will be periodic; if x_0 is irrational, its binary expansion is nonperiodic, and hence the iteration will be nonperiodic. Separate values of x_0 that are the same up to their n th bit will initially have similar iterations, but will eventually diverge, until they are completely different at the n th iteration: This is a manifestation of sensitive dependence on initial conditions.

Fig. 9

Timeseries of the logistic map, 100 iterations, with $r_0=0.1$, for various λ . Top row: (a) $\lambda=2.8$, period 1; (b) $\lambda=3.3$, period 2. Second row: (c) $\lambda=3.5$, period 4; (d) $\lambda=3.74$, period 5. Third row: (e) $\lambda=3.828$, chaos before period 3: period 3 behavior is interleaved with intermittent bursts of chaotic behavior; (f) $\lambda=3.829$, period 3. Bottom row: (g) $\lambda=4$, chaos; (h) $\lambda=4$, with $r_0=0.10001$, demonstrating sensitive dependence on initial conditions.

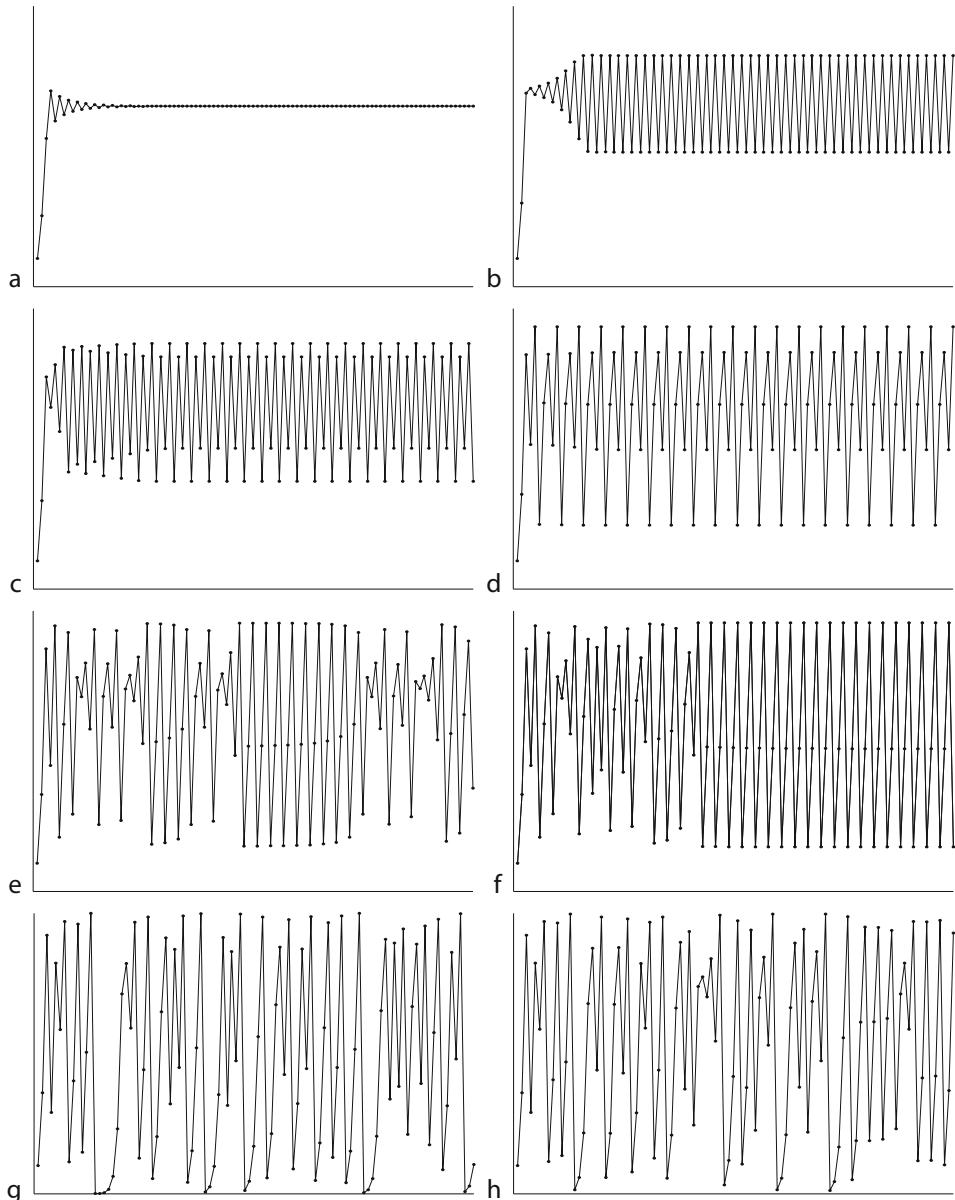

Table 2

Dynamical structure of the logistic map as a function of parameter λ (some λ values taken from Sloane (2008)); including order of occurrence of period doubling cascades, for all initial periods up to 7 (Adapted from Hao and Zheng (1998, Table 2.2)). Higher initial periods cascades are interleaved with these

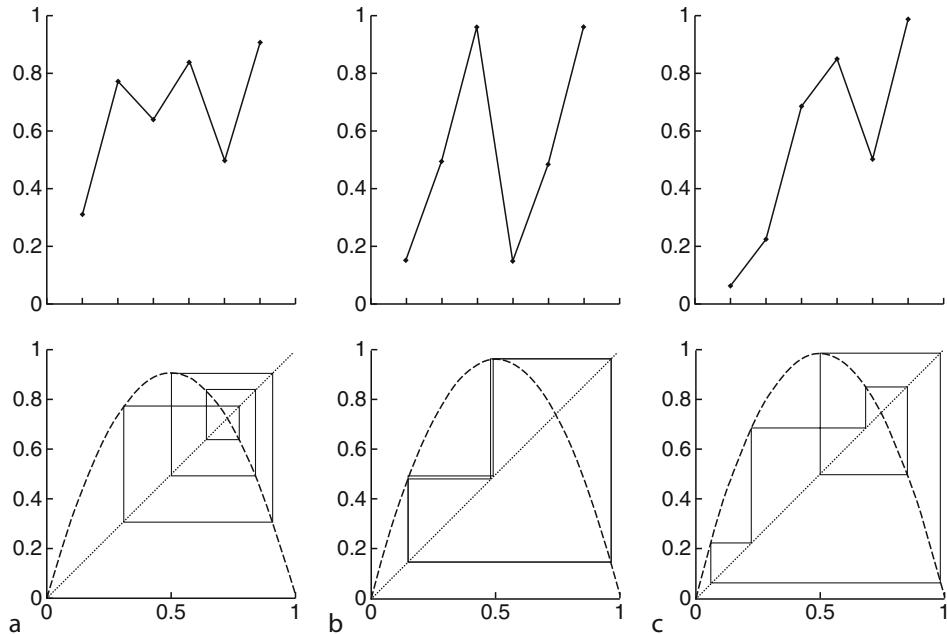

Lambda	Dynamics	Sloane number (Sloane 2008)

Computational Properties

Crutchfield (1994) investigates the *statistical complexity* of the logistic map as a function of λ . The statistical complexity is essentially a measure of the size of a stochastic finite state machine that can predict the statistical properties of a system. He finds that the map has *low* statistical complexity both when the map is periodic and when it is chaotic (essentially random), and has *highest* statistical complexity at the onset of chaos (via the period doubling route, or the intermittent route). At this point, there is a *phase transition* in the complexity of the

Fig. 10

Different classes of behavior of three different period 6 cycles. Top shows the time series of one period; bottom shows the geometry of the behavior in a cobweb diagram. (a) $\lambda = 3.6266$; (b) $\lambda = 3.8418$; (c) $\lambda = 3.93755$.

machine needed to predict the behavior, and these parameter values indicate the highest computational capacity.

Despite these observations, the majority of computational applications of the logistic map exploit its completely chaotic behavior, with λ at or near 4, and use this behavior to implement random number generators (Kanso and Smaoui 2009; Phatak and Rao 1995; Ulam and von Neumann 1947), encryption (Kocarev and Jakimoski 2001; Pareeka et al. 2006), etc.

2.2.3 Coupled Map Lattices

Kaneko (1983, 1984, 1985, 1986) introduces one-dimensional coupled map lattices (CMLs), where an array of N iterated maps are coupled together locally, with the following local dynamics ϕ :

$$r_{i,t+1} = \phi_0(r_{i,t}) + \frac{\varepsilon}{2} (\phi_c(r_{i-1,t}) - 2\phi_c(r_{i,t}) + \phi_c(r_{i+1,t})) \quad (4)$$

where ε is the coupling strength. Each element in the lattice evolves under the dynamics of the local process ϕ_0 , with an additional interaction contribution $\varepsilon\phi_c$ from its neighbors, while passing on a similar amount of its own to its neighbors (under periodic boundary conditions). The local state $r_i \in \mathcal{R}$ and the local dynamics $\phi : \mathcal{R}^3 \rightarrow \mathcal{R}$ define the global state $\mathbf{r} \in \mathcal{R}^N$ and global dynamics $f : \mathcal{R}^N \rightarrow \mathcal{R}^N$. The system is parameterized by the coupling strength ε , as well as by any parameters in ϕ .

An initial value of $r_{i,0} = \kappa$, where all the maps have the same initial value, is trivial, since all maps evolve in lock-step. Kaneko (1985) investigates several cases, one of which is where ϕ_0 is the logistic map with λ in the period 3 window with cycle (r_1^*, r_2^*, r_3^*) , with $r_{i \leq N/2,0} = r_1^*$, $r_{N/2 < i,0} = r_2^*$, or with random $r_{i,0}$, and with $\phi_c = \phi_0$. The dynamics exhibits the period doublings, intermittencies, and chaos of the logistic map, and in addition exhibits spatial patterns and structures similar to 1D CAs. Crutchfield and Kaneko (1987) examine the properties of this class of system in some detail.

Subsequent work generalizes the approach to topologies other than 1D nearest-neighbor (2D, tree-structured, irregular, larger neighborhoods), and allows the coupling to be asymmetric. In particular, Holden et al. (1992) provide a generic formalism, and investigate coupled map lattices in terms of their computational properties. A CML approach to the density classification problem has been evolved (Andersson and Nordahl 1998). Open CMLs are also being exploited computationally (see [Sect. 3.3.1](#)).

2.2.4 Note on Dimensionality and Topology

Papers on CMLs tend to describe them as having “discrete time, discrete space, and continuous state” (Kaneko 1986). Here we describe them as “continuous space,” because here we are talking purely about the *state space*.

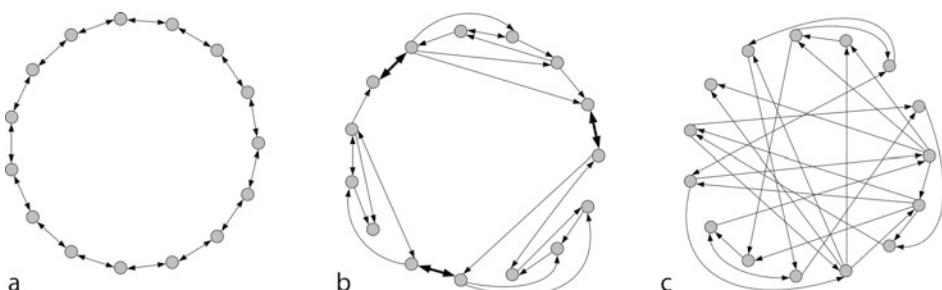

A CML of N maps laid out in 1D line in (physical) space has an (abstract) state space of \mathcal{R}^N . The “dimensionality” of the layout in physical space (a 1D line of maps) is unrelated to the dimensionality of the state space (of ND , because there are N maps); if the same N maps were instead laid out in a 2D grid, or even a 27D grid, say, it would not affect the dimensionality of the state space.

Instead, this “dimensionality” is related to the *topology* of the connections between the maps, and hence the potential information flow between the maps ([Fig. 11](#)).

Compare the information flow visible in a 1D (physical space) CA ([Fig. 4](#)) and that not visible in an RBN with a similar number of cells ([Fig. 7](#)). For this reason, it makes sense to talk of the (physical spatial) dimension of a CA (it has a regular local topology), but not of an RBN (it has an irregular graph topology).

Fig. 11

Dimensionality versus topology. Examples for three $N=5, k=2$ networks with different topologies. (a) Regular $N=15$ CA-like structure arranged in a 1D spatial lattice (periodic boundary conditions); (b) three $N=5, k=2$ RBNs linked in a 1D spatial lattice (that is, random connections with the groups of 5 nodes, lattice links between the groups); (c) general $N=15, k=2$ RBN.

When the physical spatial layout moves from discrete to continuous, the state space moves from being finite (discrete physical space, finite number of cells) or countably infinite (discrete physical space, countably infinite number of cells) to uncountably infinite (continuous physical space). See [Sect. 2.3.4](#).

2.2.5 Numerical Errors and the Shadowing Lemma

Chaotic systems, such as the logistic map with $\lambda=4$, display sensitive dependence on initial conditions: trajectories with nearby initial conditions diverge exponentially (compare [Fig. 9g](#) and [9h](#)).

Such systems are usually studied by numerical simulations, which generate *pseudo-orbits*, because of numerical noise. Additionally, the real physical systems that these maps (and below, differential equations) model are themselves subject to noise during their execution, and during measurement, and so potentially execute pseudo-orbits (or pseudo-trajectories) with respect to the model systems. The question naturally arises: What is the relation of these pseudo-orbits to the model orbits? Are they representative of the modeled dynamics?

Fortunately the answer is (a qualified) “yes.” The *Shadowing Lemma* states that, for certain classes of system, the pseudo-orbit *shadows* (stays close to) some true orbit of the (modeled) system for all time; this true orbit has a slightly different initial condition from the pseudo-orbit. This result has been extended to a wider class of systems, including those studied here, that the pseudo-orbit shadows some true orbit of the system for “a long time” (Hammel et al. 1988).

However, are the true orbits of the model that are shadowed by these pseudo-orbits themselves representative of the underlying dynamics; that is, are they typical true orbits? This is harder to answer, and is clearly false for some particular cases. For example, consider the binary shift map ([Eq. 3](#)). For any limited precision binary arithmetic implementation, *all* pseudo-orbits converge to 0 when the number of iterations (shifts) exceeds the binary numerical precision. But this case appears to be an exception, because most numerical trajectories do not behave like this, and Hayes and Jackson (2005) state:

- ▶ If otherwise reliable-looking pseudo-trajectories *are atypical*, they must be atypical in an extremely subtle way, because researchers have been making apparently reliable, self-consistent, peer-reviewed conclusions based on numerical simulations for decades.

So we continue here in assuming that the simulated pseudo-orbits, and the pseudo-trajectories of actual physical systems, are in general representative of the true dynamics defined by the equations.

2.3 Continuous Space, Continuous Time

We now consider continuous spaces, with $\mathcal{X} = \mathcal{R}$, with continuous time dynamics $t \in \mathcal{R}$. Let the state vector be $\mathbf{r} \in \mathcal{R}^N$. The dynamics of a particular system is determined by its particular transition function $f : \mathcal{R}^N \rightarrow \mathcal{R}^N$, with $\dot{\mathbf{r}} = f(\mathbf{r})$. Hence the system is defined by a set of N coupled first-order ordinary differential equations (ODEs).

We can recast higher order equations into this normal form by adding new variables. For example, consider the 1D equation for damped simple harmonic motion

$$\ddot{r} + \kappa \dot{r} + \omega^2 r = 0 \quad (5)$$

Let $r_1 = r, r_2 = \dot{r}$. Then, rearranging, we can get the 2D normal form version:

$$\dot{r}_1 = r_2 ; \quad \dot{r}_2 = \omega^2 r_1 - \kappa r_2 \quad (6)$$

Note how this normalization takes the single-state variable r , and results in two-state variables r_1 (r , position) and r_2 (\dot{r} , velocity). In a continuous system, and particularly when the state variables are position \mathbf{r} and momentum $m\dot{\mathbf{r}}$, the state space is also called the *phase space*.

Physical systems embody their own specific dynamics. If that dynamics can be controlled and exploited in a computational manner, it can be used to reduce the load on, or even replace, conventional classical digital control in embedded systems (Stepney 2007). Understanding the dynamical behavior of complex material systems from a computational perspective is also a necessary step along the way to understanding biological systems as information processing systems (Stepney 2008).

For a good overview of continuous dynamical systems from an embodied computational perspective, see Beer (1995). Abraham and Shaw (1987) provide an excellent visual description of various concepts such as attractors and bifurcations. For more background, see a textbook such as that by Strogatz (1994).

2.3.1 Kinds of Attractors

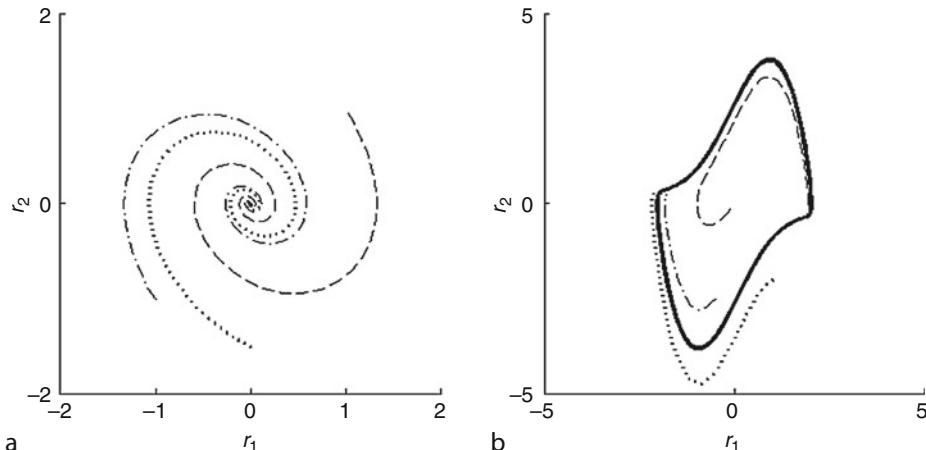

In these continuous time systems, trajectories are continuous paths through a continuous state space. There are four distinct kinds of attractor that can occur.

Point Attractors

A point attractor is a single point in state space that attracts the trajectories in its basin. An example is the equilibrium position and zero velocity that is the unique end state of damped simple harmonic motion (☞ Fig. 12a).

Fig. 12

Attractors and their transient trajectories: (a) point attractor: damped SHM, $\ddot{r} + \lambda \dot{r} + r = 0$, with $\lambda=0.5$; (b) limit cycle attractor: van der Pol oscillator, $\ddot{r} + \lambda(r^2 - r)\dot{r} + r = 0$, with $\lambda=2$.

Limit Cycle Attractors

A limit cycle is a closed loop trajectory that attracts nearby trajectories to it. See, for example, (●) Fig. 12b.

Toroidal Attractors

A toroidal attractor is a 2D surface in state space with periodic boundary conditions: shaped like a torus. Trajectories are confined to the surface of the torus. If the *winding number* (the number of times the trajectory loops around in one dimension while it performs one loop in the other dimension) is rational, the trajectory is periodic, otherwise it is *quasiperiodic*, and eventually covers essentially the entire surface of the torus.

Strange Attractors

A strange attractor attracts trajectories to its region of state space, but within this region, nearby trajectories diverge exponentially: it exhibits sensitive dependence on initial conditions, and thus chaotic behavior. This combination of attraction and divergence requires at least three dimensions in which to occur. The detailed structure of a strange attractor is usually fractal.

Example: Rössler Strange Attractor

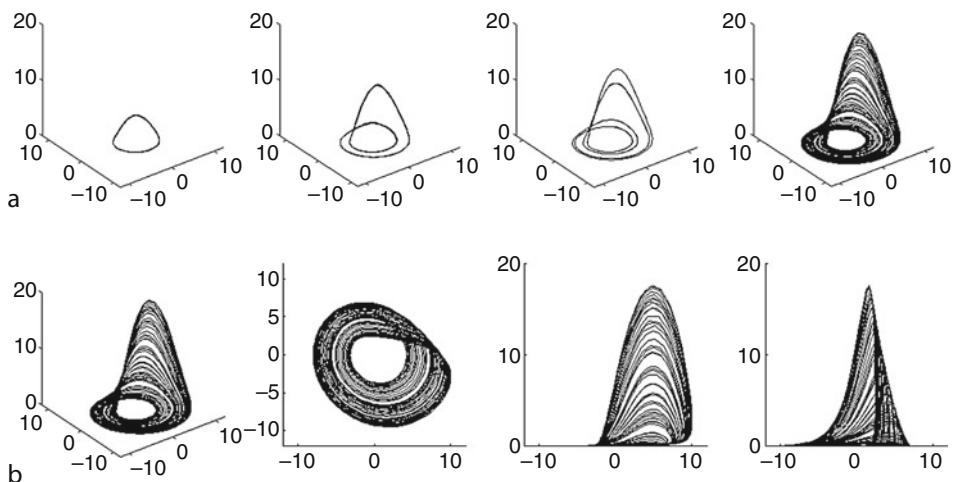

The Rössler system is defined by

$$\begin{aligned}\dot{r}_1 &= -r_2 - r_3 \\ \dot{r}_2 &= r_1 + ar_2 \\ \dot{r}_3 &= b + r_3(r_1 - c)\end{aligned}\tag{7}$$

It is a family of dynamical systems that displays a range of kinds of dynamics, some with strange attractor behavior, some without. It exhibits the period doubling cascade route to chaos (●) Fig. 13a).

■ Fig. 13

Rössler system: (a) period doubling cascade to chaos, with $a=b=0.2$, $c=2.5, 3.5, 4.0, 5.0$; (b) Rössler strange attractor.

The Rössler strange attractor occurs when $a=0.2, b=0.2, c=5$ (☞ Fig. 13b). It is the simplest strange attractor, with only one nonlinear term.

Example: Lorenz Strange Attractor

The Lorenz strange attractor is defined by

$$\begin{aligned}\dot{r}_1 &= 10(r_2 - r_1) \\ \dot{r}_2 &= 28r_1 - r_2 - r_1r_3 \\ \dot{r}_3 &= r_1r_2 - 8r_3/3\end{aligned}\tag{8}$$

(See ☞ Fig. 14.) It is a member of a family of dynamical systems that displays a range of kinds of dynamics, some with strange attractor behavior, some without.

Sensitive dependence on initial conditions is popularly known as *the butterfly effect*. Lorenz suggests (Lorenz 1993, p. 14) that the name may have arisen from the title of a talk he gave in 1972, “Does the Flap of a Butterfly’s Wings in Brazil Set Off a Tornado in Texas?,” coupled with the butterfly-like shape of Lorenz attractor seen from some directions (☞ Fig. 14).

Reconstructing the Attractor

Given a physical continuous dynamical system with a high-dimensional state space (state vector \mathbf{r}_t), one can determine properties of its dynamics, given only scalar discrete time series observations (time series data $r_\tau, r_{2\tau}, \dots, r_{n\tau}, \dots$, where r_t is some scalar projection of the state vector \mathbf{r}_t). In particular, one can distinguish chaos (motion on a strange attractor) from noise.

The process of reconstructing the attractor from this data involves constructing a d -dimensional state vector $\hat{\mathbf{r}}_t$ from a sequence of time-lagged observations:

$$\hat{\mathbf{r}}_{nt} = (r_{nt}, r_{(n+k)\tau}, r_{(n+2k)\tau}, \dots, r_{(n+(d-1)k)\tau})\tag{9}$$

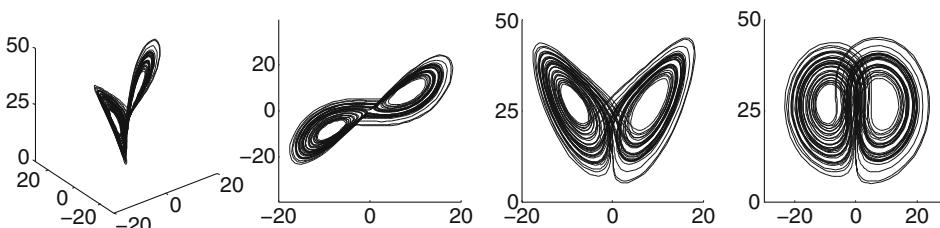

d should be $> 2d_a$, where d_a is the dimension of the system’s attractor; d should also be as small as possible, to avoid fitting noise; k should be large enough that the attractor is sufficiently sampled, but not so large that the correlations are lost. Taken’s *embedding theorem* then relates the invariants of motion, including attractor structure, of $\hat{\mathbf{r}}$ to those of \mathbf{r} . For more on this process, and other techniques for analyzing chaotic systems, see Ott et al. (1994).

Relationship to Discrete State Space Attractors

Wolfram (1984b) draws a rough analogy between his class 1, 2, and 3 CAs (see ☞ Sect. 2.1.5) and point, limit cycle, and strange attractors, respectively. He mentions that the class 4 CAs (the ones conjectured universal) “behave in a more complicated manner.” This might be thought to imply that there is no continuous analog of the discrete class 4 systems, and hence

Fig. 14

Lorenz strange attractor.

no universal computational properties in continuous matter. This is not so, as we see below (Sects. 2.3.4 and 2.3.5).

Kauffman (1990) calls RBNs whose attractor cycle length increases exponentially with n , “chaotic.” He emphasizes that this does not mean that flow on the attractor is divergent (it cannot be, in a discrete deterministic system); the state cycle is the analog of a 1D limit cycle. However, there is an analogy: Exponentially long cycles cover a lot of the state space before repeating (chaotic strange attractors never repeat), and “nearby” states (1 bit different) potentially *do* diverge (even possibly onto another attractor). However, in the discrete system, there is no direct analog of “nearby states diverging exponentially, but staying on the same attractor,” since there is usually no concept of distance between states in discrete dynamical systems, and if there were, successive hops through state space can be of any size: there is no simple “continuity” from which to diverge.

2.3.2 Computation in Terms of Attractors

We can interpret computation as finding which attractor basin the system is in, by following its trajectory to the relevant attractor. The output could be (some projection of) the computed attractor, including a subspace of the state space. Most instances of analog computing fall in this domain.

The programming problem is in finding the relevant dynamics, now restricted to natural (albeit engineered) material system properties, which are not arbitrary. The aim is to minimize the engineering required to implement the desired dynamics, by exploiting the natural dynamics.

Continuous systems computing in this way can exhibit *robustness*. A small perturbation to the system might shift it a small distance from its attractor, but its subsequent trajectory will converge back to the attractor. There can be a degree of continuity in the attractor basins, such that a small perturbation tends to remain in the same basin, unlike the discrete case.

It is not necessary for a dynamical system to have a complex (chaotic, strange) dynamics in order to be interesting or useful. Kelso (1995, p. 53) makes this point eloquently:

- ▶ Some people say that point attractors are boring and nonbiological; others say that the only biological systems that contain point attractors are dead ones. That is sheer nonsense from a theoretic modeling point of view, as it ignores the crucial issue of what fixed points refer to. When I talk about fixed points here it will be in the context of collective variable dynamics of some biological system, not some analogy to mechanical springs or pendula.

That is, the dynamics, including the underlying attractor structure, is part of the specific model, in particular, what state variables are used to capture the real-world system. State variables can capture more sophisticated concepts than simple particle positions and momenta.

2.3.3 Continuous Time Logistic Equation

The logistic growth equation is one of the simplest biologically based nonlinear ODEs. It is a simple model of population growth where there is exponential growth for small populations,

but an upper limit, or *carrying capacity*, that prevents unbounded growth. The equation was suggested by Verhulst in 1836 (see, e.g., Murray 1993, p. 2):

$$\dot{r} = \rho r(1 - r/\kappa) \quad (10)$$

It is rare among nonlinear ODEs in that it has an analytic solution

$$r(t) = \frac{\kappa r_0 e^{\rho t}}{\kappa + r_0(e^{\rho t} - 1)} \quad (11)$$

It has a single point attractor at $r_\infty = \kappa$: whatever the initial population r_0 , it always converges to the carrying capacity κ .

Contrast this smooth behavior with the very different complex periodic and chaotic behavior of its discrete time analog: the logistic map, [Sect. 2.2.2](#). This is a general feature: The discrete time analog of simple ODEs can exhibit similarly complex behavior as the logistic map. This does *not* mean, however, that ODEs themselves are unable to display computationally interesting dynamics.

2.3.4 Infinite Dimensions: PDEs

Consider the reaction–diffusion (RD) equation, which models chemical species reacting (nonlinearly) locally with each other, and diffusing (linearly) through space. The relevant state variables are the concentrations of the reacting diffusing chemicals, and are functions of time, and also of space: $r_i(t, \mathbf{x})$. For a two-chemical species, the RD equation is

$$\begin{aligned} \frac{\partial r_1}{\partial t} &= f_1(r_1, r_2) + k_1 \nabla^2 r_1 \\ \frac{\partial r_2}{\partial t} &= f_2(r_1, r_2) + k_2 \nabla^2 r_2 \end{aligned} \quad (12)$$

Each r_i , since it is a function of continuous space \mathbf{x} , can be thought of as an (uncountably) infinite-dimensional state variable. Rather than having a state vector with a finite number of indices r_i , we can consider an infinite-dimensional state vector indexed by position, $r(\mathbf{x})$. The state variable at each position can itself have multiple components (such as the two chemical concentrations, above), leading to $\mathbf{r}(\mathbf{x})$. The space derivative is used to define the dynamics in terms of a local (infinitesimal) neighborhood.

There is a natural link between partial differential equation (PDE) systems and cellular automata. CAs are one natural way to simulate PDEs in a discrete domain (Adamatzky et al. 2005; Wolfram 1985, prob. 9). Care is needed in this process to ensure that the CA models the correct PDE dynamics, and does not introduce artefacts due to its own discrete dynamics (Weimar and Boon 1994; Wolfram 1986a). Despite this caveat, there are some exact correspondences: *ultradiscretization* (Tokihiro et al. 1996) can be used to derive CA-like rules that preserve the properties of a given continuous system, for a class of integrable PDEs; *inverse ultradiscretization* (Kunishima et al. 2004) transforms a CA into a PDE, preserving its properties. A different approach represents CA configurations using continuous *bump functions* (Omohundro 1984), and derives a PDE that evolves the bumps to follow the given CA rule.

The dynamical theory of these infinite-dimensional spaces is not as well developed as in the finite case. Much of the work concentrates on PDEs whose dynamics can be rigorously reduced to a finite subspace, so that the existing dynamical systems theory is applicable. See, for example, Robinson (2001) and Teman (1997).

2.3.5 Reaction-Diffusion Computers

Reaction-diffusion computers (Adamatzky et al. 2005) use chemical dynamics. The relevant state variables are the concentrations of the reacting diffusing chemicals, which are functions of time and space: $r_i(t, \mathbf{x})$. For a two-chemical species, the relevant RD equation is given by [Eq. 12](#).

Reaction-diffusion systems have a rich set of behaviors, exhibiting spatial-temporal patterns including oscillations and propagating waves. The computation is performed by the interacting wave fronts; the output can be measured from the concentrations of the reagents. RD systems have been used to tackle a wide variety of computation problems (e.g., image processing (Kuhnert et al. 1989), robot navigation (Adamatzky et al. 2004)); here we look at two that demonstrate computation exploiting the natural dynamics, and one that demonstrates the potential for universal computation.

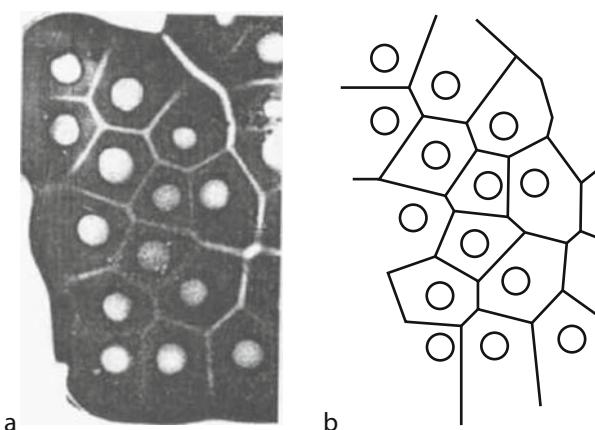

Voronoi Diagrams

An RD computer can solve a 2D Voronoi problem: given a set S of points in the plane, divide the plane into $|S|$ regions R such that every point in a given region $R_i(s_i)$ is closer to s_i than to any other $s_j \in S$.

This problem can be solved directly by a 2D RD computer (Tolmachiev and Adamatzky 1996) ([Fig. 15](#)). One reagent forms a substrate; the second reagent marks the position of the data set of points S . The data-reagent diffuses and reacts with the substrate-reagent, forming waves propagating from each data point, and leaving a colored precipitate. Waves meet at the borders of the Voronoi regions, since their constant speed of propagation implies that they have traveled equal distances from their starting points. When waves meet, they interact and form no precipitate. So the lack of precipitate indicates the computed boundaries of the Voronoi regions.

 Fig. 15

A reaction-diffusion (RD) computer solving a Voronoi problem. (Figure from Tolmachiev and Adamatzky 1996, [Fig. 3](#).)

Shortest Path Searching

A propagating wave technique can be used to find the shortest path through a maze or around obstacles (Steinbock et al. 1995; Agladze et al. 1997; Ito et al. 2004). The maze can be encoded in the chemical substrate, or by using a light mask. A wave is initiated at the start of the maze, and a series of time lapse pictures are taken as the wave propagates at a uniform speed, which provide a series of equidistant locations from the starting point; these are used in a post-processing phase to construct the shortest path (☞ [Fig. 16](#)).

Logic Gates

Propagating waves can be confined to channels (“wires”) and interact at junctions (“gates”) so arranged such that the interactions perform logical operations. See, for example, Motoike and Adamatzky (2004), Sielewiesiuk and Gorecki (2001), and Toth and Showalter (1995). Hence the continuous RD system dynamics can be arranged by careful choice of initial conditions to simulate a digital circuit.

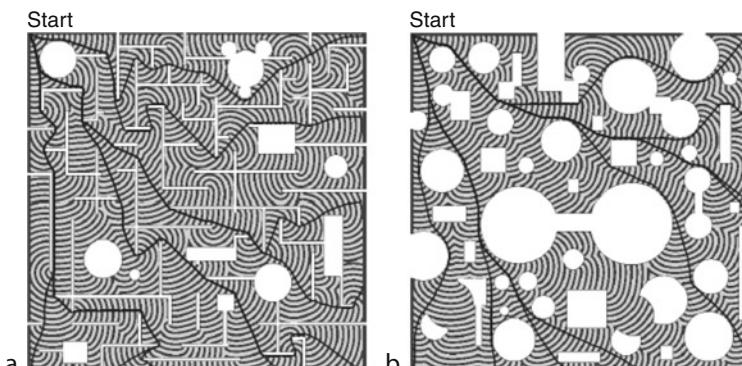

2.3.6 Generic Analog Computers

In general, analog computers gain their efficiency by directly exploiting the physical dynamics of the implementation medium. There is a wide range of problem-specific analog computers, such as the reaction–diffusion computers described above, but there are also general purpose analog computers.

For example, Mills has built implementations of Rubel’s general purpose extended analog computer (Rubel 1993). The computational substrate is simply a conductive sheet (Mills 2008a; Mills et al. 2006), which directly solves differential equations; the system is “programmed” by applying specific potentials and logic functions at particular points in the sheet. Mills has developed a computational metaphor to aid programming by analogy (Mills 2008b), and is currently developing a compiler to enable straightforward solution of given differential equations (Mills 2008, personal communication).

☞ **Fig. 16**

Computer simulation of a shortest path computation in mazes with obstacles. (From Ito et al. 2004.)

2.4 Hybrid Dynamical Systems

So far, all the systems considered have homogeneous dimensions, for example, all \mathcal{S} or all \mathcal{R} . More complicated dynamical systems have heterogeneous dimensions. For example, coupling a classical finite state machine with a continuous system would yield a hybrid system with a dimensionality like $\mathcal{S}^M \times \mathcal{R}^N$.

It is likely that the topology of such a hybrid system would consist of relatively weakly coupled sub-components (► Fig. 11b), which should help in their analysis from a dynamical systems point of view.

2.5 Summary

The classes of autonomous dynamical systems that have been discussed are summarized in ► *Table 3*.

From a computational perspective, one important classification dimension is the implementation: whether the computational dynamics is implemented “naturally,” that is, directly by the physical dynamics of the underlying medium, or whether it is implemented in terms of a virtual machine (VM) itself implemented on that underlying dynamics.

Discrete systems tend to be implemented in terms of VMs. This has the advantage that the computational dynamics is essentially independent of the underlying medium (witness the diversity of systems that implement Boolean logic, for example), and so can be analyzed in isolation. It has the disadvantage of the computational overhead imposed by the VM layer.

One goal of continuous dynamical systems is to provide a computational dynamics closely matched to the physical dynamics, with corresponding gains in efficiency. The downside is that such systems are more likely to be constrained by their physical dynamics, and so are less likely to be Turing-universal computational systems.

3 Open Dynamical Systems

3.1 Openness as Environmental Inputs

The systems described so far are *autonomous* or *closed*. They have an *initial condition* (identifying one state x_0 from the \mathcal{X}^N possible), and then the fixed (non-time-dependent) dynamics

► **Table 3**

Classification of the different kinds of autonomous dynamical systems, in terms of their state space and time evolution

	Discrete: $t \in \mathcal{N}$	Continuous: $t \in \mathcal{R}$
$s \in \mathcal{S}^N$	Finite CAs ; RBNs	
$s \in \mathcal{S}^\infty$	Infinite CAs ; TMs	
$r \in \mathcal{R}$	Iterated maps	
$r \in \mathcal{R}^N$	CMLs	ODEs
$r \in \mathcal{R}^\infty$		PDEs
$x \in \mathcal{S}^M \times \mathcal{R}^N$	Hybrid	

proceeds with no input or interference from the outside world. They move to an attractor, the result of the computation, or they may not discover an attractor, in which case the computation has no result. This is the classical, “ballistic” style of computation exemplified by the Turing machine, or a closed dissipative system relaxing to equilibrium.

Open, or nonautonomous, systems, on the other hand, have dynamics that are governed by parameters that change over time. These parameters are inputs from the environment.

Consider an open dynamical system with N degrees of freedom: its state can be defined by an ND state vector $\mathbf{x}(t) \in \mathcal{X}^N$. The state space is \mathcal{X}^N . Now there is also an input space \mathcal{P} , and an output space \mathcal{Q} . The dynamics f maps the current state and input to the next state and output; $f : \mathcal{X}^N \times \mathcal{P} \rightarrow \mathcal{X}^N \times \mathcal{Q}$.

There is a similarity here to a parameterized *family* of dynamics (⌚ Sect. 2.2.1). But here the parameter p is a function of t , and is considered an *input* to the dynamics, a way of modulating or controlling the dynamics, for example, moving it between periodic and chaotic attractor behaviors.

3.1.1 Timescales

Understanding open systems is significantly more challenging than understanding closed systems, and depends in part on the relationship between the timescale on which the input is changing and the timescale on which the dynamics is acting. Dynamical systems have a “natural” timescale: the time needed to discover the attractor. As Beer (1995) says

- ▶ Because ... the flow is a function of the parameters, in a nonautonomous dynamical system the system state is governed by a flow which is changing in time (perhaps drastically if the parameter values cross bifurcation points in parameter space). Nonautonomous systems are much more difficult to characterize than autonomous ones unless the input has a particularly simple (e.g., periodic) structure. In the nonautonomous case, most of the concepts that we have described above (e.g., attractors, basins of attraction, etc.) apply only on timescales small relative to the timescale of the parameter variations. However, one can sometimes piece together a qualitative understanding of the behaviour of a nonautonomous system from an understanding of its autonomous dynamics at constant inputs and the way in which its input varies in time.

That is, an input changes the dynamics of the system, by changing to a different member of the parameterized family. This new member might have moved attractors, or be on the other side of a bifurcation point with different kinds of attractors. A system immediately after an input will be in the same position in its state space, but the underlying attractor structure of that space may have changed.

So, if the input is changing slowly with respect to the dynamics, the system is able to complete any transient behavior and reach the changed attractor before the input changes the dynamics yet again, even if it has passed through a discontinuous, catastrophic bifurcation point. On these timescales, the system is able to “track” the changing dynamics, and so its behavior can be analyzed piecewise, as a sequence of essentially unchanging systems. Even so, such systems can exhibit *hysteresis*: Restoring a parameter to a previous value may not necessarily restore the system to its corresponding previous state, if this path through parameter space crosses catastrophic bifurcation points.

If the input is changing quickly with respect to the dynamics, then the system is unable to respond to changed dynamics before it has changed again. It will mostly be exhibiting transient behavior.

Most interesting and complex is the case where the input is changing on a timescale similar to that of the dynamics: then the system is influenced by its dynamics, but it may never quite, or only just, reach any attractor before the next change occurs.

The situation can get even more complicated, when the input parameter p is a function of space as well as time, $p(x, t)$. For example, it might be a temperature gradient, or magnetic field gradient, which can also drive the system.

3.1.2 Computation in Terms of Trajectories

Since such open systems need not reach a “halting state” of being on an attractor, the computational perspective is necessarily broader. The computation being performed can be viewed as the *trajectory* the system takes through the changing attractor space: which attractor basins are visited, in which order.

The discussion of timescales implies that, for useful computation, the dynamical timescale of the system should not be significantly slower than the input timescales.

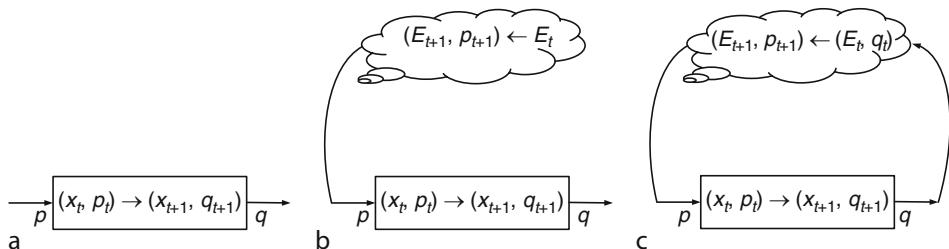

3.1.3 Environmental Constraints

In the simplest open case, it is assumed that the system can be provided with any input, regardless of what it is doing, or has done (Fig. 17a). The input may as well be considered random. This is not particularly interesting, except in the cases where the system can somehow exploit noise, for example, using some kind of informational analog of a ratchet mechanism (e.g., Dasmahapatra et al. (2006)).

This case is formally equivalent to a closed system, as the sequence of arbitrary inputs could conceptually be provided at the start, embedded in an (expanded) state $\mathcal{X}^N \times \text{seq } \mathcal{P}$ as part of the initial condition, along with some pointer to the “current time” value, and the dynamics updated to allow access only to the current value (e.g., see Cooper et al. (2002),

Fig. 17

Inputs. (a) arbitrary input stream; (b) constrained inputs from a structured environment; (c) constrained inputs from an interacting environment in a feedback loop.

where such an approach is taken to embed inputs into the initial state of the model of a formal language). So there is no new computational capability, except as provided by the (potentially, much) larger state space.

Type B: Environmentally Constrained Input Stream

More interesting is the case where the inputs come from an environment that has some rich dynamical structure that the system can couple to and exploit (☞ Fig. 17b). Here, the environment is an autonomous dynamical system, unaffected by any inputs of its own.

Since the environment is autonomous, its sequence of inputs could again conceptually be provided at the start. However, this case is qualitatively different from the previous one. We are now assuming that there is some *structure* in the environment, and hence in the sequence of inputs. This implies that there are regions of the system state space that are never explored, parts of its underlying dynamics that are never exercised. As before when talking of virtual machines (☞ Sect. 2.1.3), the computation is restricted to a subspace: the subspace and its trajectories here correspond to the computation in the context of the structured environment; that is, the inputs provide *information* that the system need not itself compute. And since the environment may be unboundedly large, the sequence of inputs may represent an unboundedly large amount of computation provided to the system.

Type C: Feedback Constrained Input Stream

Most interesting is the case where the environment and system are both open dynamical systems in a rich feedback loop. Then outputs from the system will alter the environment, and affect its subsequent inputs (☞ Fig. 17c). So the actual sequence of inputs cannot even conceptually be provided at the start.

Again, the environment's inputs will be constrained to a region of state space, but here this region is (partly) determined by the system: the environment and systems are coupled, the dynamics of each perturbing the trajectory of the other, in a feedback loop.

Such an environment may well contain other open systems similar to the system being considered. And again, since the environment may be unboundedly large, it may represent an unboundedly large amount of computation provided to the system, but here, the specific computation provided is affected by what the system does, because of the feedback coupling. This opens up the possibility for a system to offload some of its computational burden onto the environment (see ☞ Sect. 3.4.4).

Beer (1995) points out that such a coupled environment and system together form a higher-dimensional autonomous dynamical system, with its own attractors, and, because of its larger state space, that this combined system can “generate a richer range of dynamical behavior than either system could do individually.”

3.2 Open Discrete Space, Discrete Time Dynamical Systems

The autonomous discrete systems have an *initial condition* (identifying one state s_0 from the $|\mathcal{S}|^N$ possible). In the finite case, they always “halt” on an attractor cycle, this halting state (cycle) being the result of the computation; in the infinite case, they either halt on such a cycle, or they may not discover an attractor, in which case the computation has no result.

In the open discrete space, discrete time case, where $\mathcal{X} = \mathcal{S}$, the time evolution of the state, and the output function, are given by $(s_{t+1}, q_{t+1}) = f(s_t, p_t)$.

3.2.1 Modulating the Dynamics

The input can provide a “kick” or perturbation, changing (a few bits of) the state at a particular timestep. This may move the system into a different attractor basin.

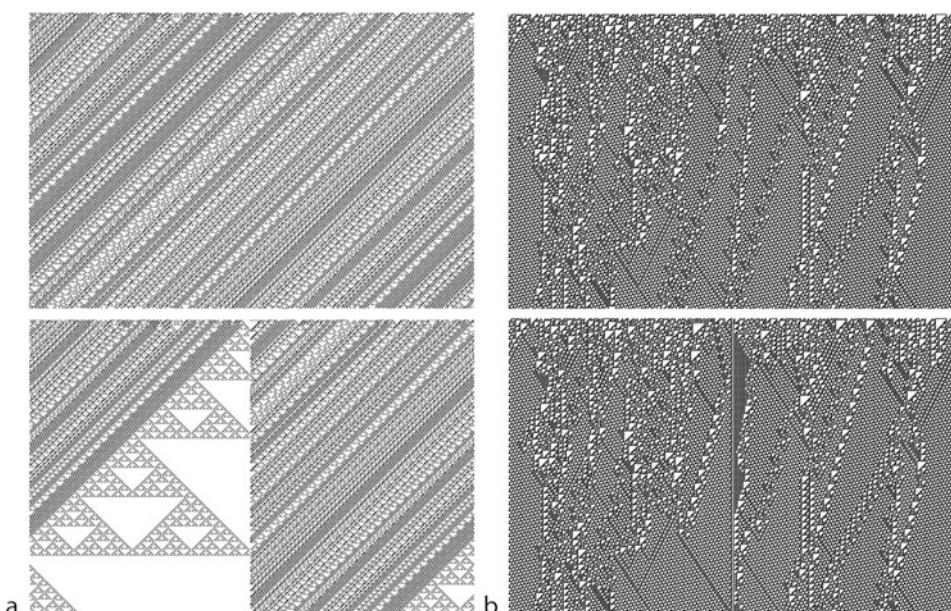

The input might also “clamp” the system into a particular substate (by fixing the value of some bits for many timesteps). This not only perturbs the system at the point where the bits are clamped, but can also change the global dynamics (if the natural dynamics would change the value of the clamped bits, for example), producing new attractors, and changing or removing existing attractors. For example, clamping some bits in a CA can result in “walls” across which information cannot flow, isolating regions, and hence changing the dynamical structure of the system. (See [Fig. 18](#).) Such a simple partitioning is harder to achieve in a more irregularly connected structure such as an RBN.

3.2.2 Perturbing Random Boolean Network State

Kauffman (1990) defines a *minimal perturbation* to the state of an RBN to be flipping the state of a single node at one timestep. Flipping the state of node i at time t is equivalent to changing its update rule at time $t-1$ to be $c_{i,t} = \neg\phi_i(\chi_{i,t-1})$. Such a perturbation leaves the underlying dynamics, and hence the attractor basin structure, the same; it merely moves the current state to a different position in the state space, from where it continues to evolve under the original dynamics: it is a transient perturbation to the state.

■ Fig. 18

Dependence of CA dynamics on a “clamped” bit. The upper plot shows ordinary periodic boundary conditions; the lower plot shows the same initial conditions, but with the central bit “clamped” to 0. (a) ECA rule 26; (b) ECA rule 110.

Kauffman (1990) describes the *stability* of RBN attractors to minimal perturbations: If the system is on an attractor and suffers a minimal perturbation, does it return to the same attractor, or move to a different one? Is the system *homeostatic*? (Homeostasis is the tendency to maintain a constant state, and to restore its state if perturbed.)

Kauffman (1993) describes the *reachability* of other attractors after a minimal perturbation: If the system moves to a different attractor, is it likely to move to any other attractor, or just a subset of them? If the current attractor is considered the analog of “cell type,” how many other types can it *differentiate* into under minimal perturbation?

Kauffman’s results are summarized in [Table 4](#), which picks out the $k=2$ networks as having “interesting” (non-chaotic) dynamics (a small number of attractors, with small cycle lengths) and interesting behavior under minimal perturbation (high stability so a perturbation usually has no effect; low reachability so when a perturbation moves the system to another attractor, it moves it to one of only a small subset of possible attractors).

3.2.3 Perturbing Random Boolean Network Connectivity

Kauffman (1990) also defines a *structural perturbation* to an RBN as being a permanent mutation in the connectivity or in the Boolean function. So a structural perturbation at time t_0 could change the update rule of cell i at all time $t > t_0$ to be $\phi'_i(\chi_{i,t})$ or change the neighborhood of cell i at all time $t > t_0$ to be $\chi'_{i,t}$. Since the dynamics is defined by all the ϕ_i and χ_i , such a perturbation changes the underlying dynamics, and hence the attractor basin structure: It is a permanent perturbation to the dynamics, yielding a new RBN.

Such a perturbation could have several consequences: a state previously on an attractor cycle might become a transient state; a state previously on a cycle might move to a cycle of different length, comprising different states; a state might move from an attractor with a small basin of attraction to one with a large basin; a state might move from a stable (homeostatic) attractor to an unstable attractor; and so on.

Kauffman (1993) relates structural perturbation to the *mutation* of a cell; if there is only a small change to the dynamics, this represents mutation to a “similar” kind of cell.

3.3 Open Continuous Space, Discrete Time Dynamical Systems

In the open continuous space, discrete time case, where $\mathfrak{X} = \mathcal{R}$, the time evolution of the state, and the output function, are given by $(\mathbf{r}_{t+1}, q_{t+1}) = f(\mathbf{r}_t, p_t)$.

Table 4

Dynamics of RBNs for different k (adapted from Kauffman (1993, Table 5.1))

k	Stability	Reachability
1	Low	High
2	High	Low
> 5	Low	High

3.3.1 Open Coupled Map Lattices, and Chaos Computing

Sinha and Ditto (1998, 1999) investigate the computational properties of coupled chaotic logistic maps (ϕ_0 =the logistic map with $\lambda=4$, see Sect. 2.2.3) with open boundaries. The coupling function ϕ_c is a threshold function: $\phi_c=\text{if } r < \theta \text{ then } 0 \text{ else } r - \theta$, and is unidirectional. This unidirectional relaxation propagates along the lattice until all elements have a value below threshold (all the $r_i \leq \theta$), at which point the next timestep iteration of the logistic dynamics occurs (so the timescale of the relaxation is much shorter than the timescale of the logistic dynamics). The boundary of the lattice is open, so the final element can relax below threshold by removing its excess value from the system. Depending on the particular threshold value, and the current state of the system, this process can result in nonlinear avalanches of relaxation along the lattice. Transients are short (typically one dynamical timestep), and the system displays a variety of attractor dynamics, stable to small amounts of noise, and determined by the input threshold parameter.

Sinha and Ditto (1998, 1999) discuss how to use this system to perform computation. A single lattice element with two inputs (either external, or from the coupled output of other lattice elements) and appropriate input value of its threshold can implement a universal NOR logic gate in a single iteration of the logistic dynamics, where the amount of output encodes the result. Hence, networks of such elements can be coupled together to implement more complicated logic circuits. Sinha and Ditto (1999) note that it is the chaotic properties in general, not the logistic map in particular, that give these coupled systems their computational abilities, and suggest a possible implementation based on nonlinear lasers forming a coupled chaotic Lorenz system. They dub their approach *chaos computing*.

Additionally, Sinha and Ditto (1998, 1999) discuss how to implement other functions, such as addition, multiplication, and least common multiple, by suitable choice of numerical encoding, coupling, and input thresholds. These choices program the underlying chaotic dynamics to perform computation directly, rather than emulating a virtual machine of compositions of logic gates (Sinha and Ditto 1999):

- ▶ dynamics can perform computation not just by emulating logic gates or simple arithmetic operations, but by performing more sophisticated operations through self-organization rather than composites of simpler operations.

Despite this observation, their subsequent work (Ditto et al. 2008; Sinha and Ditto 2006) concentrates on using more complicated (but realizable) chaotic dynamics to implement robust logic circuits, that can be readily reconfigured merely by altering thresholds. They emphasize the openness of their approach (Sinha and Ditto 2006):

- ▶ it can yield a gate architecture that can dynamically switch between different gates, without rewiring the circuit. Such configuration changes can be implemented either by a predetermined schedule or by the outcome of computation. Therefore, the flexibility of obtaining different logic operations using varying thresholds on the same physical element may lead to new dynamic architecture concepts

3.4 Open Continuous Space, Continuous Time Dynamical Systems

In the open continuous space, continuous time case, $\mathfrak{X} = \mathfrak{R}$, the time evolution of the state, and the sequence of outputs, are given by $(\dot{\mathbf{r}}, q(t)) = f(\mathbf{r}, p(t))$.

Note again the similarity to a parameterized *family* of dynamics (☞ Sect. 2.2.1), with the (input) parameter p being a function of t . Examples of such input parameters might include the temperature T of the system, or the value of an externally imposed magnetic field \mathbf{B} permeating the system.

3.4.1 Ott, Grebogi, Yorke (OGY) Control Laws

There are unstable periodic orbits in strange attractors. Small perturbations in the control parameter can be used to keep the system in one of these; the required perturbations are calculated using the OGY control laws (Ott et al. 1990). (It is not necessary to know the underlying dynamics to do this; application of the control laws involves calculating the required parameter from observations of the system.) There can be long transient behavior before the system gets “close” to the desired periodic orbit, and noise can result in bursts of chaotic behavior. The approach can also be used to switch between different periodic orbits with different characteristics (with some transient chaotic behavior).

Ott et al. (1990) note that a chaotic system is potentially more flexible, because this approach can be used to hold it in a variety of different periodic orbits, whereas this range of behaviors would require a range of separate systems with non-chaotic dynamics. Sinha and Ditto (☞ Sect. 3.3.1) make similar observations about their coupled nonlinear maps, although there they claim a lower computational burden (the thresholds can be simply calculated, and stored in a lookup table) and shorter (essentially zero) transient behaviors.

3.4.2 Liquid Crystal Systems

Liquid crystals are a form of matter that lies on the boundary between solids and liquids (sometimes called “the fourth phase of matter”). A liquid crystal has both complex dynamics (the molecules can flow and rotate) and complex structure (the molecules are ordered on length scales much bigger than their individual sizes).

Such materials can perform computation. Harding and Miller (Harding and Miller 2004, 2005; Harding et al. 2006) have demonstrated that a liquid crystal chip can be programmed to act as a tone discriminator (a simple arbitrary input system, where the inputs are tones of two different frequencies that are to be discriminated) and as a robot controller (a constrained feedback system, where the inputs from the environment depend on the robot’s position, and the robot’s outputs change its position).

It is currently unclear how the liquid crystal performs its computations: In the referenced cases, the material was programmed using an evolutionary algorithm. It would be interesting to analyze these results from a dynamical systems perspective.

3.4.3 NMR Logic Gates

Nuclear magnetic resonance (NMR) uses radio frequency pulses to manipulate nuclear spins in a magnetic field. Depending on the particular values chosen from a rich potential set of parameters (frequency, phase, duration, delay, and more), pulses can be combined in various ways to produce different outputs. These pulses and the outputs can be interpreted as encoding binary values. Under these interpretations, the system can be used to implement a single

universal logic gate, a circuit of these gates combined in parallel and in sequence that implement other logic gates, and a half-adder circuit (Roselló-Merino et al. 2010).

Under these interpretations, this is a Type A open system: Any arbitrary set of Boolean inputs is permitted, and the system implements the corresponding logic gate computation on these inputs. Under the wider view of the full parameter space, this is a Type B open system, with the inputs being restricted by the environment (the experimenter) to values that can be interpreted as binary bits. Hence, we see how setup corresponds to a logic gate virtual machine (► Sect. 2.1.3) implemented on the underlying dynamics of the nuclear spin system.

3.4.4 Embodiment

Beer (1995) takes a dynamical systems approach to adaptive agents in a changing environment. For example, a robot agent adapts its walking behavior depending on the kind of terrain it is moving across. So an agent receives sensory input from a structured environment (it sees its current surroundings), which affects its internal dynamics (its state changes), which affects its outputs (its leg movements), which in turn affects the environment (at a very minimum, the agent moves to a new location in the environment, and hence sees new surroundings). So “a significant fraction of behavior must be seen as emerging from the ongoing interaction between an agent and its environment.” Beer is talking here of Type C open dynamical systems (► Sect. 3.1.3), coupled to their environment in a feedback loop.

Beer’s aim is to use the language and concepts of dynamical systems theory to develop a theoretical framework for designing adaptive agents. Certain computational tasks, such as planning, can be greatly simplified by exploiting input from the structured environment (e.g., the agent seeing where it is). This relates to Brooks’ design principle: “use the world as its own model” (Brooks 1991).

Beer emphasizes that, because of the coupling with the environment, “an agent’s behavior properly resides only in the dynamics of the coupled system,” and hence cannot be understood or analyzed in isolation. Indeed, an agent is adapted to some environments and not others. Beer analyzes this idea of adaptive fit, and determines that it requires that an agent maintains its trajectory within a certain volume of its state space (which volume may change with time) under perturbations from the environment. This is related to an *autopoietic* (Maturana and Varela 1980) (self-creating and self-maintaining) view of adaptive fitness, and helps define what is needed for *homeostasis*.

This area also links with a whole burgeoning subdiscipline of using dynamical systems theory to model the brain and its cognitive processes. However, that is deemed to be outside the scope of this particular discussion. The interested reader is referred to Kelso (1995).

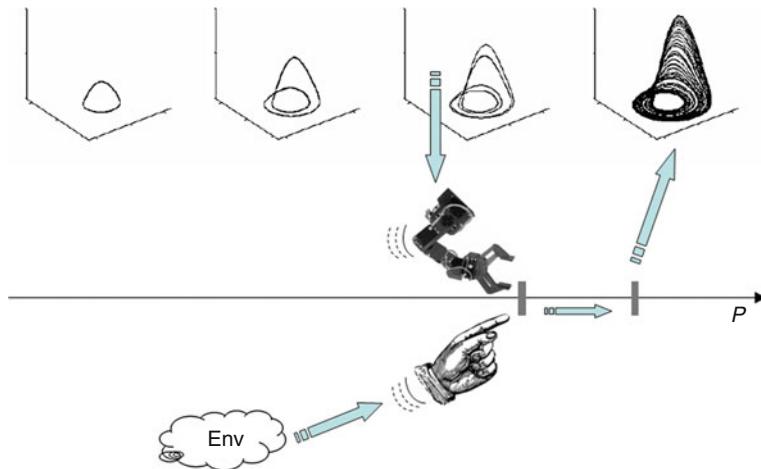

3.5 External Control Versus Internal Dynamics

Here we have considered the parameter $p(t)$ to be an externally provided input, moving a dynamical system between members of its parameterized family. Alternatively, we could have a case where the parameter p was another degree of freedom, or dimension, of the dynamical system, where the dynamics of the system itself affects the value of p (► Fig. 19).

This potentially gives a model of a *self-organizing* system. For example, Melby et al. (2000) describe a logistic map (► Sect. 2.2.2) where the value of the dynamical variable r_t is fed through a low-pass filter to (slowly) affect the parameter λ : The system self-adjusts to values

Fig. 19

Two sources of parameter variation: external control versus internal dynamics.

of λ at the edge of chaos, and does so even when subject to an external force attempting to drive it back into the chaotic region (Melby et al. 2002). The situation is a little more complicated in the presence of noise: The system still self-adjusts to suppress chaos, but a power-law distribution of chaotic outbreaks occurs (Melby et al. 2005).

An alternative view is of a hierarchy of coupled dynamical systems, where the outputs at one level couple to the control parameter(s) at another level. Abraham and Shaw (Abraham 1987; Abraham and Shaw 1987) explore this idea in more detail.

4 Constructive Dynamical Systems

So far, we have considered predetermined fixed state spaces of a given dimensionality. However, this is not the case even for classical computational systems. Their data structures define their abstract state space: every time new memory is allocated in the course of the computation, the state space grows in dimension; memory deallocation shrinks the state space. A dynamical systems perspective on computation needs to consider cases where the state space itself dynamically changes dimensionality, $\mathcal{X}^{N(t)}$.

In such cases, the dynamics *constructs* the state space, and the state space constrains the dynamics. Closed autonomous systems can exhibit such growth, classical computation being one such example. In open systems, this process can be thought of as the flow of information, matter, energy being recruited to construct new dimensions of the system: the system inputs “food” (constructs dimensions), and excretes “waste” (collapses dimensions). This process of modifying its own dimensionality affects the possible dynamics (recall, e.g., that strange attractors require at least a 3D continuous space [\(Sect. 2.3.1\)](#)).

This is an aspect of dynamical systems theory that has received very little attention: the current theory assumes a predefined, fixed state space. Because of the paucity of theory in this area, this section is intended to illustrate the kinds of processes that need to be incorporated in such a theory.

Metadynamics

One approach to incorporating growth might be to model the system with an infinite number of dimensions, confining the dynamics to the finite-dimensional subspace corresponding to the current state space. As new dimensions are needed, the dynamics expands into the preexisting dimensions. However, this approach appears to be a mathematical “trick” that hides the essential properties of the underlying system: precisely what confines the dynamics to a subspace, what causes it to grow into new dimensions, and what determines the topology (the way the information flows between dimensions)? (This approach also has a small technical issue: how to distinguish a system that is not using a particular dimension, from one that is using it, but is currently confined to the zero value of that dimension: how to distinguish “absence” from the “presence of nothing.” This can in turn be solved by a further mathematical trick, of introducing some special value, \perp , to make this distinction. But the tricks are piling up.)

A different approach might be to have these new dimensions start in some small “curled up” form; a dimension could “uncurl” or “unfold” sufficiently to support the current state value along that dimension, and curl back up when no longer needed. Alternatively, the dimensions might be fractal in nature, with the fractal dimension of the state space increasing, gradually “fattening up” the new dimension.

This suggests that the state space itself might have a *metadynamics*. The metadynamics (the high-level dynamics of the state space) can be studied in isolation from the low-level dynamics (trajectories of the system through the state space).

Another form of metadynamics is to allow the topology (see [Sect. 2.2.4](#)) to change dynamically, even if the dimensionality is constant. Such “network dynamics” allows the neighborhood function ([Sect. 2.1.5](#)) to be a function of time, $v(t)$.

Baguelin et al. (Baguelin et al. 2003; Moulay and Baguelin 2005) consider a metadynamical transition rule, which changes the state space (and the corresponding dynamical state transition rule) on a slower timescale than the system’s dynamics: the system spends most of its time evolving under its dynamics, punctuated by relatively few metadynamical state space changes. The overall system dynamics is defined by “concatenating” the various lower-level dynamical behaviors at the metadynamical change points. Baguelin et al. (Baguelin et al. 2003; Moulay and Baguelin 2005) apply this approach to interacting populations of bacteria and phages (the dynamics) that are also evolving (a slower timescale metadynamics).

Whatever approach is used, it needs to be able to cope with different types of dimensions, as the dynamics results in new types of state variables being constructed (e.g., in evolution, new species can be considered to occupy new types of dimensions). If such types cannot be statically predetermined, but computed only by the unfolding dynamics, it is harder to see how to incorporate this into an analysis based on a known, preexisting set of state spaces.

Timescales

Important timescales in a constructive dynamical system are the speed at which the state space grows compared to dynamics on that space. Where growth timescales are much less than the dynamical timescales (a change in the number of dimensions tends to happen after the system has relaxed to an attractor), piecewise approximations may be made in a way similar to slow open systems ([Sect. 3.1.1](#)), as in the metadynamics approach outlined above. But in faster-changing systems (e.g., L-Systems [Sect. 4.1.2](#), where the dimensionality can change every iteration timestep) this is not possible, and new analysis techniques must be sought.

Computation in Terms of Construction

In an autonomous (closed) constructive system, the result of the computation (if the computation halts) could still be considered as the attractor (final macrostate), and additionally include the structure (dimensionality and topology) of the final grown state space.

In an open, non-halting constructive system, the result of the computation could still be considered as the trajectory through a growing state space, and additionally include the structure (dimensionality and topology) of the state space along that trajectory.

4.1 Constructive Discrete Dynamical Systems

4.1.1 Classical Computation

Turing Machine

A Turing machine can be thought of as a growing system: The tape is of finite but unbounded length, and can be considered to grow (lazily) whenever a new tape position is required. It can also be considered to shrink if the last symbol on the tape is erased.

So the question of growth can be linked to undecidability: Whether the dimensionality of the state space stays bounded (if the computation halts or loops), or grows without limit, is formally undecidable.

Object Orientation

Object orientation systems are particularly constructive in this sense: new objects are created, increasing the dimensionality of the state space; when they go out of scope, the state space shrinks again.

Such systems are usually designed on the software engineering principle of ensuring “weak coupling” by small interfaces, which keeps components separate and modular by restricting the information flow. That is, the topology of the dynamics is deliberately restricted.

Contrast the connectivity of RBNs, which have a “small-world” topology, and require a large number of connections to be cut to partition the graph (❷ Fig. 11). This enables rapid information flow, potentially enabling different classes of dynamics. The consequences of these design decisions are rarely addressed from a dynamical systems perspective.

Closed or Open

These classical computational systems can be closed (e.g., the TM model), or open (interactive systems). The open systems are usually analyzed as Type A (❷ Sect. 3.1.3), where the external environment can potentially provide any input.

4.1.2 Rewriting Systems

Imagine trying to “grow” an RBN where, if it got to a certain state, a new node would appear, or an existing node would disappear (with consequent rewiring). The appearance or disappearance of a node would change the dimensionality of the state space (to $N \pm 1$), and also the underlying attractor structure, and hence change the computation being performed.

Similarly, imagine trying to “grow” a 1D CA. One could add a new cell, growing the dimensionality of the state space from \mathcal{S}^N to \mathcal{S}^{N+1} . Where should the cell be added in the line? The CA dynamics is symmetric under renumbering shifts, and so it should be possible to add the cell anywhere with equal ease. But unless it is added at special position $i=N$, subsequent cells have to be renumbered. This illustrates the tyranny of a global coordinate system: “The introduction of numbers as coordinates . . . is an act of violence” (Weyl 1949). Instead we would like a coordinate-free, or purely topological, approach to growth.

L-Systems

Lindenmayer’s L-Systems (Prusinkiewicz and Lindenmayer 1990) are such a coordinate-free approach to growth: They are generative grammars that define how symbols in a string are rewritten (“grow”) depending on their local context (their topology, their neighborhood symbols), not on any global coordinate system.

The simplest D0L-Systems (deterministic, context free) can be described in the notation of this chapter as follows. The state s is a string of elements (symbols) drawn from the finite alphabet \mathcal{S} , so $s \in \mathcal{S}^*$. The local dynamics ϕ (rewriting rules, or productions) is given by $\phi : \mathcal{S} \rightarrow \mathcal{S}^*$. At each timestep, each element in the state string is updated (rewritten) in parallel: $s_{i,t+1} = \phi(s_{i,t})$, and the resulting substrings concatenated to form the new state string. (Note here that indices are used merely to identify the string elements in order to help define the local dynamics. They are not a fundamental part of the string data type, which supports operations such as insertion and deletion, unlike the fundamentally indexed array data type.)

In conventional use, one starts from some initial state (axiom) $s_0 \in \mathcal{S}^+$, and follows the dynamics for several iterations to reveal the “grown” structure. However, the dynamics does not necessarily result in a different number of dimensions (a changed length string). For example, Danks et al. (2007, 2008) use L-Systems to model protein folding: there the rewriting models the change in conformation of the (rendered) string, and does not result in any change in the length of the string itself.

In Parametric L-Systems (Prusinkiewicz and Lindenmayer 1990), each symbol has associated parameters, and so the state space is $(\mathcal{S} \times \mathcal{P})^*$.

In the context-free case, there is no information flow between the dimensions: Each individual dimension grows into new dimensions in a manner based on its own substate alone. Context-sensitive L-Systems (Prusinkiewicz and Lindenmayer 1990) couple the dimensions together, and define a tree-structured topology on the growing space. In standard L-Systems, the topology is explicitly encoded in the state string, by use of reserved symbols to define branching.

L-Systems also include a *rendering* step, where the symbols in the string are interpreted as commands in some language, typically a turtle graphics language, to construct a representation of the string (Prusinkiewicz and Lindenmayer 1990). In standard L-Systems this rendering produces a geometrical structure that follows the tree-structured topology of the state space, typically to produce rendered images of plants. However, other renderings are possible, and can produce non-geometric outputs and outputs with different topologies. For example, Hornby and Pollack (2001) interpret the symbols as instructions for generating topological descriptions of neural networks.

These simplest L-Systems are autonomous dynamical systems, and any computation performed in the rendering step is separate from the dynamics of the growth process.

Parametric L-Systems, where the values of (some) parameters are inputs, are Type A or Type B open dynamical systems (● Sect. 3.1.3). In typical L-System applications, they are used

as Type B, because the input is assumed to be coming from some constrained environmental source (e.g., day length, or other weather conditions).

Environmentally sensitive L-Systems (Prusinkiewicz et al. 1994) are also Type B open dynamical systems (⌚ Sect. 3.1.3) of a different form. The dynamics again takes into account external inputs (e.g., the amount and direction of sunlight, or collision with static obstacles, when modeling plant growth), but here the particular rendering process is coupled into the dynamics, as the input is a function of the specific geometry of the rendered result (rendered leaves shading other leaves, etc.), not just the topology of the abstract state.

Open L-Systems (Měch and Prusinkiewicz 1996) are Type C open dynamical systems (⌚ Sect. 3.1.3). They include a feedback process, so the environment is affected by the L-System (e.g., the environment might be the water supply, and the L-System the growing roots that are affecting the amount of water). Again, this approach couples the particular rendering process into the dynamics.

P-Systems

Păun's P-systems (Păun 2000), and other membrane computing formalisms, are another form of rewriting systems with an underlying tree-structured topology. Here the tree structure models not the branching of a plant, but the nesting of membranes, or containers. Membranes contain symbols, and rules that act on the symbols, and on membranes (creating, connecting, and dissolving them). The computational model successively applies the rules until no more are applicable; the computation has halted, and the symbols in a given membrane are the result of the computation. Much theoretical effort is expended on determining the computational power of different classes of membrane systems: Turing-complete systems exist. So this prototypical system has a rather classical view of computation, but there is a plethora of variants with different computational models.

Topological Approach

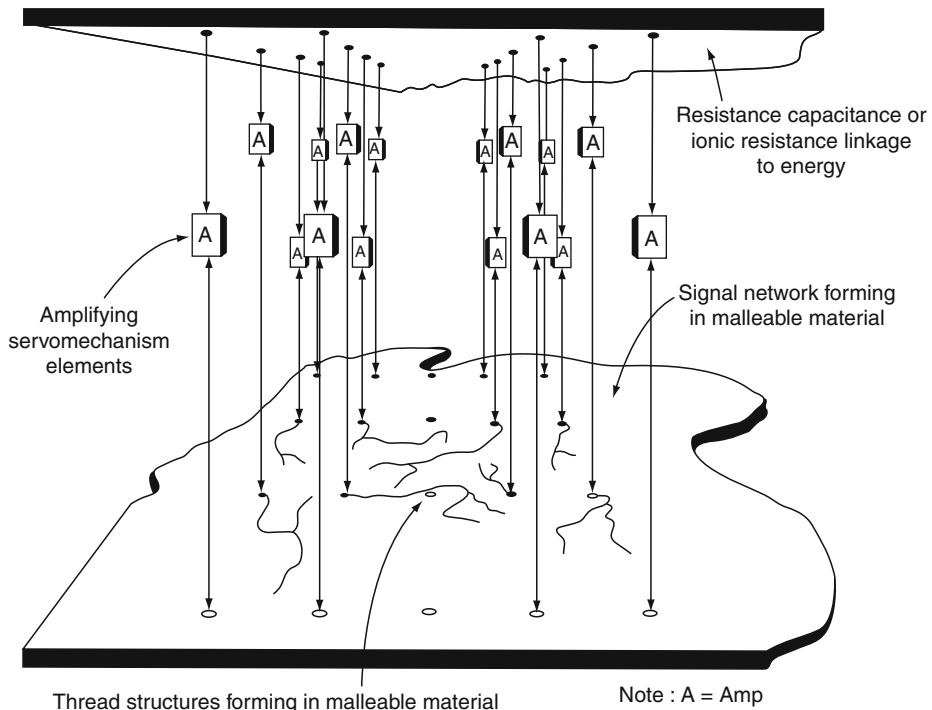

Michel and coworkers (Giavitto and Michel 2002) contrast the “absolute space” coordinate-based philosophy of Newton, with the relative space, coordinate-free philosophy of Leibniz, from a computational perspective. Their approach to (discrete) “dynamical systems with a dynamical structure (DS)²” is topological, focussing on the neighborhood relation and induced subcollections (essentially a set of related elements in a neighborhood). The neighborhood relation can specify structures ranging from the regular spatial neighborhood of a CA to the logical neighborhood of a data structure such as a list, graph, or array (Giavitto et al. 2005). The approach then specifies global dynamics in terms of parallel application of local transformations that rewrite subcollections (Spicher et al. 2004; Giavitto et al. 2005). This approach subsumes dynamic rewriting systems such as L-Systems and P-systems, as well as more static-structured CA-like rewritings (Giavitto et al. 2005).

4.2 Constructive Continuous Dynamical Systems

Gordon Pask was a member of the Cybernetics movement. In the 1950s, he built a system that could “grow” into an “ear” (a sensor capable of detecting sound waves, or magnetic fields) by adaptively laying down suitable conducting filaments (⌚ Fig. 20) in response to environmental inputs and a structured “reward” input.

Fig. 20

Pask's schematic indicating the relationship between the electrode array and the ferrous sulfate medium (adapted from Pask (1960), as cited by Cariani (1993, Fig. 1)).

Cariani (1993) provides an excellent review of this work, and some implication in terms of “organizationally closed” (i.e., able to construct their own input filters), “informationally open” systems. In an open, adaptive, self-constructing system

- ▶ the dimensionality of the signal space can increase over time as new informational channels evolve. Hill-climbing is thus accomplished not only by following gradients upwards, but also by changing the dimensionality of the problem landscape when one can go no further using those dimensions already available.

4.3 Constructive Hybrid Dynamical Systems

Winfree and coworkers (Winfree 2003; Rothemund et al. 2004) are implementing “algorithmic self assembly.” They use carefully designed DNA fragments to implement nanoscale “sticky tiles,” which self-assemble into crystalline structures. The self-assembly can be interpreted as a computation: Which computation is performed depends on the tiles’ design that determines which tiles they will stick to. Their running example is the implementation of a rule 90 ECA (which from a single “on” state grows a Sierpinski gasket). Other tile designs can implement other CAs, or even a representation of the tape of a TM.

The model of this system is a hybrid system. There is an abstract tile assembly model that captures the discrete dynamics of tiles (the particular CA or TM behavior). This is augmented with a kinetic tile assembly model, which captures continuous properties that account for errors in the assembly process.

They speculate that a similar process could be used to construct molecular electronic circuits and other nanoscale devices. That is, design a constructive dynamics to grow a structure that then has an autonomous computational dynamics.

5 Discussion and Conclusions

Classical computational systems can be analyzed in terms of autonomous discrete dynamical systems. The dynamical systems approach can be extended to continuous systems, to give a computational perspective on embodied computational devices. It can be extended again, to include open dynamical systems coupled to a structured dynamical environment, and again to include constructive, or growing systems. The dynamical systems theory is, however, less well developed in these latter cases.

In addition to the straightforward computational perspective, this dynamical systems viewpoint gives insight into important properties of complex computational systems: robustness and emergence.

5.1 Robustness

Homeostasis

Robustness is the ability to maintain function in the presence of perturbations, stresses, or errors. The system exhibits *homeostasis*. Classical computation, on the other hand, is notoriously *fragile*: A single bit change can completely alter the behavior of the system.

From a dynamical systems computational point of view, robustness is the ability to find the attractor even when perturbed from the current trajectory. A system will find the attractor from anywhere within its basin of attraction: If a perturbation nevertheless maintains the basin, the system will be robust to that perturbation.

Here we see the source of classical computation's fragility: extremely small basins of attraction, such that any perturbation is likely to move the system to a different basin, hence to a different attractor, resulting in a different computation.

Compare this situation to the dynamical structure of $k=2$ RBNs (☞ Sect. 2.1.6). There a perturbation is likely to leave the system in the same basin. “Small attractors located inside a volume of states constituting their basins of attraction are the natural image of stable systems exhibiting homeostasis.” (Kauffman 1993, p. 467) So robustness requires large basins of attraction, which implies relatively few macrostates compared to the number of microstates.

Continuous systems have greater potential for robustness. They have a notion of locality: A small perturbation moves the system a small distance in its state space, and is therefore likely to be in the same basin. (Although it is true that as well as fractal strange attractors, there can be fractal-structured basins; in such cases, a small perturbation might end up in one of many other basins.) Alternatively, the small perturbation could be a small change to a parameter. Provided the parameter does not cross a bifurcation point, this will result in only a small change to the dynamics.

Kitano (2004) explicitly casts a discussion of various kinds of biological robustness in terms of dynamical systems attractors.

Precision

Robustness comes at the price of precision, however. Many microstates per macrostate means a loss of precision: we no longer distinguish these microstates. Also, real-valued output from a continuous system cannot be measured with arbitrary precision. Similar to the case when considering the timescales, the precision of the computation and output should be matched to the precision of the environment and inputs.

Homeorhesis

Waddington (1957) notes that homeostasis is too restrictive a term when considering growing systems, since they do not have a “steady” state to which to return: They are embarked on some trajectory through their ever-changing state space. He introduces the term *homeorhesis* (Waddington 1957, p. 32], meaning “constant flow,” in that systems actually maintain a constant trajectory through developmental space. He deprecates the alternative term, *canalization*, because it may (Waddington 1957, p. 43–44]

- ▶ suggest too concrete an image to be suitable as a name for the abstract quality to which it refers; but this seems a less important failing than those involved in the alternative term homeostasis.

Note that this implies that the developmental trajectory is in some sense an attractor of the growth process: A perturbation away from the growth trajectory is attracted back to that *trajectory*, not merely to some final attractor state. In biological terms, this is robust morphodynamics.

5.2 Emergence

The attractors and their basins, and the bifurcation points of parameterized systems, are *emergent properties* of their dynamics (Stepney et al. 2006).

Although the microstates are changing on an attractor cycle, this can lead to a stable macrostate if observed on a timescale longer than the attractor period. In the dynamical systems view, everything is process (motion on an attractor), but when it is viewed on a suitable timescale, it can behave like a thing.

- ▶ An attractor functions as a symbol when it is viewed . . . by a *slow observer*. If the dynamic along the attractor is too fast to be recorded by the slow-reading observer, he then may recognize the attractor only by its averaged attributes . . . , but fail to recognize the trajectory along the attractor as a deterministic system. (Abraham 1987)

The slow observer does not see the intricate dynamics on the attractor, just some averaged behavior, and this dynamics becomes an atomic component in its own right. What is lost is the microstructure; what remains is a stable pattern that becomes an entity in its own right. This connects directly with the concepts of relative timescales, where there is a sufficient difference between a fast timescale (of the underlying dynamics of the system), and a slower timescale (of the inputs perturbing the system (Sect. 3.1.1; of the metadynamic timescales of state space change (Sect. 4; of the slow observer of these processes).

These new high-level emergent entities can have their own state space and (meta)dynamics, particularly when coupled to other dynamical systems such as the environment, or in some

hierarchical structure. So their (higher level) dynamics will exhibit attractors; motion on these attractors will appear as emergent entities to (even slower) observers; and so on.

5.3 The Future

These discussions imply that we need a dynamical systems theory of open, constructive computational systems, where new dimensions of state space, and new types of dimensions, are constructed by the computation as it progresses. This will provide one of the tools we need to enable us to study, understand, design, and reason about robust emergent computational systems, covering the range from classically discrete, to nonclassical embodied systems.

Acknowledgments

My thanks to Ed Powley for providing [Figs. 1](#), [3](#), [4](#), and [18](#), and for drawing attention to the work on exact correspondences between CAs and PDEs in [Sect. 2.3.4](#). My thanks also to Andy Adamatzky, Leo Caves, Ed Clark, Simon Hickinbotham, Mic Lones, Adam Nellis, Ed Powley, and Jon Timmis for comments on a previous draft.
